The *Domain Name System* (DNS) of the Internet is a modern-day miracle that has proved to be exceptionally prodigious. This technology effectively supported the operation of the Internet from a scale of a few hundred thousand users to today's system of some 3 billion users and an estimated 8 to 10 billion devices. Not only has it supported that level of growth, it has done so without any obvious cracks within the basic protocol. But that point should not imply that nothing has changed in the DNS protocol over the past 30 years. While the basic architecture of the DNS as a simple query/response protocol has remained consistent over this period, we have adorned the base query/response protocol with various optional “bells and whistles” that are intended to improve its robustness, and we have constantly updated the platform infrastructure of the DNS to cope with ever-increasing query loads as the Internet expands. In this article we look at one aspect of this effort: the current considerations of how to scale the root of the DNS.

An Introduction to the DNS

The DNS is a hierarchically distributed naming system. The inherent utility of a name system in a digital network lies in an efficient and consistent mapping function between *names* and *IP addresses*. With the progenitor of the DNS, this mapping function took the form of a single file (**HOSTS.TXT**) that listed all the active host names and the corresponding IP address for each address that resided on each host. The problem with this approach was the coordination of entries in this hosts file so that all hosts had a consistent view of the name space of the network. As the network grew, the administrative burden of coordinating this burgeoning name space became unworkable. The DNS replaced this replicated file with a dynamic query system that allowed hosts to query a distributed name data base and retrieve the current value of the mapped IP address.

To achieve this goal, the name system uses a hierarchical structure. A name in the DNS is a sequence of labels that scan from left to right. This sequence of labels can be viewed in a pairwise fashion, where the label to the left is the “child” of the “parent” label to the right. The apex of this hierarchical name structure is the root, which is notionally defined as the trailing “.” at the rightmost part of a *Fully Qualified Domain Name* (FQDN).

As a name-resolution system, the DNS is constructed as a collection of agents that ask questions and receive answers, so called *Resolvers*, and a set of servers that can provide the authoritative answer for a certain set of questions, *Authoritative Name Servers*. A set of name servers that are configured as being authoritative for a given *zone* should provide identical answers in response to queries for names that lie within this zone.

The task of a resolver is to ask questions of servers. But if each server is able to provide answers for only specific zones, the question then becomes: which server to ask?

For example, to resolve the name `www.example.com.`, a resolver needs to find the authoritative name servers for the zone `example.com.` This information (the set of authoritative name servers for a zone) is stored as part of a zone delegation record that is loaded into the parent zone. In our example, to resolve `www.example.com.`, a resolver needs to query any of the servers for the `example.com.` zone. These servers can be found by querying any of the authoritative name servers for the `com.` zone. But to do that a resolver needs to know who are the authoritative name servers for the `com.` zone. This information is held in the Root Zone, and can be retrieved by sending a query to any of the *Root Zone Servers*.

The way this process is implemented in the DNS is that when an authoritative name server is queried for a name that lies within the scope of a delegated child of the zone of the server, the server will respond to the query not with the desired answer, but with the set of authoritative name servers for the immediate child zone that encompasses the name of the query.

Therefore, when a recursive resolver is passed a query relating to a name about which it has no knowledge, it will first send the query for this name to a root server. The response is not the desired information, but the name servers that are authoritative for the top-level domain name being queried. The recursive resolver will then query one of these name servers for the same name, and will receive in response the name servers that are authoritative for the next level of domain name, and so on. For example, a resolver with no a priori knowledge of the DNS other than a list of servers for the root zone, when attempting to resolve the name `www.example.com.`, will first query one of the root servers for this name. The response of the root server should be the set of authoritative name servers for the `.com` zone. The resolver will next query one of these servers with the same query. The response will be the set of servers for the `example.com.` zone. When one of these servers is queried, it should respond with the desired *Resource Record* (such as the mapped IP address of the name).

To make the DNS work efficiently, resolvers typically remember these responses in a local cache, and will not re-query for the same information unless the cached entry has timed out in the local cache. For example, a subsequent query for `ftp.example.com.` would use the local cache of the resolver to select the set of authoritative name servers for `example.com` and pose this query directly to one of these servers.

So resolvers can dynamically discover and cache all aspects of the DNS, with one critical exception. The root zone of the DNS cannot be dynamically discovered in this manner, because it has no parent. To get around this problem, DNS resolvers are configured with a *root hints* file, which contains a list of IP addresses of those name servers that are authoritative for the root zone. When a resolver starts up, it sends a *root priming query* to one of the servers listed in the hints file, requesting the current set of root name servers. In this way the resolver then is primed with the current set of root name servers.

What are root servers used for?

As explained previously, one intended role of the root servers is to respond to root priming queries. Secondly, as previously explained, the root servers respond to queries relating to labels that are defined in the root zone, and also respond negatively to queries relating to labels that are not defined in the root zone. Resolvers establish the identity of name servers for those names that are at the *top level* of the DNS name hierarchy by directing a query to a root server.

Obviously, if every name-resolution attempt involved a resolver making a query to the root name servers, then the DNS root servers would have melted under the consequent load years ago! Resolvers reduce this load by caching the answers they receive, so that the profile of queries set to the root are dominated by queries for “new” names that resolvers have not previously seen (and cached). Typically, the response from the root name server is one that indicates that the name does not exist in the root zone. Given that the overwhelming role of the root servers is to reply with a “no such name” response, then it would seem that the role of the root server is somewhat inconsequential. However, resolvers do not keep a permanent copy of the responses they receive from their queries for names that exist in the root zone. They use a timed local cache, and from time to time the resolver needs to repeat the query in order to refresh the cache entry. If the root servers disappeared, these refresh queries would fail and the resolver would be unable to answer further queries about this zone. So while the predominate load on the root servers is to respond to junk queries, their continuing availability is of paramount importance to the Internet. And if the resolvers of a network were isolated from the root server constellation, then the network would, over a short period of time, cease to have a working name system.

This situation would lead us to the thought that if root servers are so critical, then a single host serving the root zone for the entire Internet would be a poor design choice. Perhaps every network should run a root server. This thought touches on numerous considerations, not the least of which includes considerations of the underlying query and response protocol that the DNS uses.

DNS Protocol Considerations

The DNS is a simple query/response protocol. In order to allow a query agent to recognize the appropriate response, the response is a copy of the original query, with additional fields included.

The two mainstream IP transport protocols are the *User Datagram Protocol* (UDP) and the *Transmission Control Protocol* (TCP). TCP is ill-suited to simple query/response transactions, given that each TCP connection requires an initial packet exchange to open a connection, and a closing exchange, and while the transaction is open the server needs to maintain TCP session context. UDP eschews this overhead, and each query can be loaded into a single UDP packet, as can the corresponding response. Although TCP is a permitted transport protocol for DNS, the overwhelming operational preference is to use UDP. It's fast, efficient, and works well. But that's not quite the entire story. We need to go down one level of the protocol stack and look at the IP protocol.

The *IPv4 Host Requirements Specification*^[1] mandates that all compliant IP host systems be able to accept and process an IP packet that is at least 576 octets. Individual IP fragments may be smaller than this number, but the host must be able to reassemble the original IP packet if it is 576 bytes or less. The consequence of this requirement is that compliant hosts need not necessarily accept an IP packet larger than 576 octets, but they will all accept packets of this size or smaller.

Allowing for 20 octets of the IP header and a maximum of 40 octets of IP header options, 516 octets of payload remain. UDP headers are 8 octets, so we would expect that if we were to define a protocol that used UDP as its transport protocol, then a UDP payload of a maximum of 508 octets of payload would be assured to reach any IPv4-compliant host. However, the DNS specification is subtly mismatched, and the *DNS Specification*^[2] specifies a DNS payload size of 512 octets or less.

So how many distinct root name servers can be listed in a priming response if we want to keep the response size to 512 octets or less? The adoption of 13 distinct root servers is a compromise between these two pressures. The exact number was the outcome of the number of distinct root server labels, and their IPv4 addresses, that can be loaded into an unsigned IPv4 UDP response to a root server priming query that is less than 512 octets. An example of a root priming response is shown in Figure 1 on page 6. (The DNS is a binary protocol that uses field compression where possible. The *dig* utility^[3] generates specific DNS queries and produces a text representation of the response.)

This response is 503 octets, which will also just fit into the 512-byte limit as defined by the *Applications Requirements Specification*^[4].

Evolutionary Pressures

These days it's rare to see a host impose a maximum IP datagram size of 576 octets. A more common size of IP datagrams is 1,500 octets, as defined by the payload size of Ethernet frames. In theory, an IPv4 datagram can be up to 65,535 octets, and in IPv6 the jumbo payload option allows for an IPv6 datagram of some 4 billion octets, but both of these upper bounds are very much theoretical limits.

More practical limits can be found in the unstandardized work to support large packets in 802.3 networks, where the value of 9,000 octets for *Maximum Transmission Unit* (MTU) sizes is sometimes found on vendors' IEEE 802.3 equipment for Gigabit Ethernet^[11]. However, there are two problems with this 9,000 octet packet size. Not all networks support the transmission of 9,000 octet packets without resorting to packet fragmentation, and there are classes of security middleware that reject all packet fragments on the basis of their assumed security risk. So a 1,500-octet value appears to be a practical assumption for the maximum size of an unfragmented IP datagram that has a reasonable probability of being passed through IP networks. This is a useful assumption for the root priming response, as it is now larger than 508 (or even 512) octets by default.

IPv6

The transition of the Internet to use IPv6 implies a protracted period of support for both IP protocols, and the root server priming response is no exception to this implication. When we add the IPv6 addresses of the 13 root name servers to the packet, the size of the response expands to 755 octets, as shown in Figure 2 on page 8. (As is shown in the response, the E root server does not have an IPv6 address.)

DNSSEC

The next change has been in the adoption of *Domain Name System Security Extensions* (DNSSEC), used to sign the root zone^[5]. The priming response now needs to contain the digital signature of the *Name Server* (NS) records, which expands the root priming response by a further 158 octets (Figure 3 on page 9).

When the 576-octet boundary is crossed, it seems that any response up to 1,432 octets would have an equal probability to be supported by all DNS resolvers, so there is a case to be made that the 13 root name servers could be expanded to a slightly larger set of 14 or 15 servers and have the root priming response sit within 1,432 octets. But perhaps that is not quite the case, because the root priming response may yet need to grow further. The consideration here is the question of how to perform a rollover of the keys used to sign the root zone, and it would be prudent to leave some additional space in the response to allow for the use of a second digital signature. It would also be prudent to allow for a slightly larger key size, given the overall shift to longer keys over the past couple of decades of cryptography. The consequence is that it's unlikely that a further one or two root name servers would really be feasible.

Even Larger Responses?

Why not go over this limit and allow the response to be fragmented? After all, *Extension Mechanisms for DNS* (EDNS0)^[6] allows for a resolver to inform the server of the maximum-size DNS payload that it can reassemble. The EDNS0 specification suggests a size of 4,096 as a “good compromise,” and it appears that many resolvers have followed this advice.

However, as we've already noted, the problem is that when a datagram exceeds 1,500 octets, it usually has to be fragmented within the network. In IPv4, fragmentation is not uncommon, but at the same time many security firewalls regard the admission of fragments as a security risk, and the silent discarding of fragments has been observed. In IPv6 the handling of UDP fragmentation is quite different. The gateway has to send an *Internet Control Message Protocol Version 6* (ICMPv6) message back to the packet originator, and the host will then inscribe an entry in its own IP forwarding table with the revised MTU size. Subsequent UDP responses to this destination address will then use this revised MTU size, but the original response is irretrievably lost. Many aspects of this behavior are prone to error, including the use of IPv6 privacy addresses, the filtering of incoming ICMPv6 messages, the finite size of the IPv6 forwarding table, and the vulnerability of the server to spoofed ICMPv6 messages.

So while responses larger than 1,500 octets are feasible, operationally it would be prudent to limit the size of the root zone priming response to be less than 1,432 octets in IPv4. Playing it cautiously with response to packet fragmentation in IPv6 would further reduce this upper bound to 1,232 octets, because the IPv6 specification defines 1,280 as the minimum packet size that will assuredly be passed through an IPv6 network without fragmentation.

More Root Servers?

Operating just 13 root name servers is not enough for the Internet, and it has not been for many years. Adding a further 1 or 2 new root server instances was never going to change that situation, given that the demand is for many thousands of new root server instances, even if the information for these additional servers could be packed into an unfragmented root priming response.

However, one aspect of the DNS service architecture can be usefully exploited. While every resolver has to reach at least one root name server at all times, no resolver has to reach every instance of the set of root name servers at all times.

What this reality implies is that the demands of scaling the root service in the face of an expanding network can be addressed through the adoption of *anycast* clouds for many of the root name servers.

What Is “Anycast?”

Normally it is considered to be a configuration error for two or more distinct hosts to share a common IP address. However, there are times when this feature can be usefully exploited to support a highly robust service with potentially high performance. The essential prerequisite is that every instance of an anycast constellation will respond in precisely the same manner to a given input. This way it does not matter which instance of a set of host servers receives the query; the response will be the same. In an anycast scenario, the routing system essentially segments the network so that all end points that are “close” to one instance of a host within the anycast service set will have their packets directed to one host, while other end points will be directed by the routing system to use other hosts.

Anycast is most effective when using a stateless simple query/response protocol, such as DNS over UDP. However, anycast can be supported when using a TCP transport protocol, although care should be taken to ensure that the TCP sessions are relatively short in duration and that routing instability is minimized, because the redirection of packets in the middle of a TCP session to a different host in the anycast set will cause the TCP session to fail. Some operational considerations of anycast services are documented in *Operation of Anycast Services*^[7].

The anycast structure has numerous major attributes that help the root server system. The first is that the multiple instances of the root server instance split up the query load against the IP address of that server into the localities served by each anycast instance. This scenario allows the root service instance to distribute its load, improving its service. Equally, it allows the root server instance to appear to be “close” to many disparate parts of the client base simultaneously, also contributing to an improvement in its service profile. This technique also allows the root server to cope with various forms of denial-of-service attacks. Wide-scale distributed attacks are spread across multiple server instances, implying that a greater server capacity is deployed to absorb the attack.

Point attacks from a small set of sources are pinned against a single server instance, minimizing the collateral damage from such an attack to a single instance of the anycast server set.

Although anycast has considerable capability and has enjoyed operational success in recent years, there are still some problems with its operational behavior. The major problem is that this environment is still “controlled,” and each anycast instance is, in effect, operated by the anycast service root name server operator. You can’t just spin up your own instance of a root server and expect that it will engender the same level of trust in the integrity of its operation as a duly controlled and managed instance of a root service.

But why not?

Why can’t we arbitrarily expand the root service in the Internet to a level well beyond these 13 root service operators? Can we admit the concept of an “uncontrolled” root zone where anyone can offer a root zone resolution service?

Scaling the Root

There have been a couple of recent Internet Drafts on potential ways to further scale the service of the root zone that does not require the explicit permission of an existing root zone operator.

The first of these drafts is a proposal to operate a root slave service on the local loopback interface^[8] of a resolver. This approach is not an architectural change to the DNS (or at least not intentionally). For recursive resolvers that implement this approach, this approach is a form of change in query behavior because a recursive resolver so configured will no longer query the root servers, but instead direct these queries to a local instance of a slave server that is listening on the recursive resolver loopback address. This slave server is serving a locally held instance of the root zone, and the recursive resolver would perform DNSSEC validation of responses from this local slave to ensure the integrity of responses received in this manner. For users of this recursive resolver, there is no apparent change to the DNS or to their local configurations.

The motivation behind this proposal is that a population of recursive resolvers is still too far away from all of the root servers, and this situation causes delays in the DNS resolution function. The caching properties of recursive DNS resolvers is such that the overall majority of queries directed to the root servers are for nonexistent top-level domains, so a pragmatic restatement of the problem space is that there are recursive resolvers that take too long to generate a *Non-existent Domain Name* (NXDOMAIN) response, and this approach would reduce this time delay.

However, given this particular formulation of the problem space, then the larger and more comprehensive the anycast constellations of the root servers, the less the demand for this particular approach.

Locales where there are adequately close DNS root services from the anycast root servers would find no particular advantage in operating a local slave DNS root server because the marginal speed differential may not be an adequate offset for the added complexity of configuration and operation of the local slave server.

The linking of the root zone information to the loopback is a point of fragility in the setup. Setting up a slave DNS server that is authoritative for the root zone would require using multiple root servers to ensure that it has access to a root zone from at least one of the anycast server constellations at any time. If at any time it cannot retrieve a master copy of the root zone, it should respond with a SERVFAIL (server failure) code, and the local recursive resolver should interpret this response as a signal to revert to conventional queries against the root servers.

This proposal provides integrity in the local root server through the mechanism of having the recursive resolver perform DNSSEC validation against the responses received from the local root slave. If the recursive resolver is configured as a DNSSEC-validating resolver, then it is configurable on current implementations of DNS recursive resolvers. However, if it is desired to limit DNSSEC validation to just the responses received from the local slave root server, then this configuration is not within the current capabilities of the more widely used DNS resolver implementations today.

The advantages of this approach is that the decision to set up a local slave root server is one that is entirely local to the recursive resolver, and the impacts of this decision affect only the clients of this recursive resolver. No coordination with the root server operators is required, nor is any explicit notification. The local slave server is only indirectly visible to the clients of this recursive resolver and no other.

A second proposal is slightly more conventional in that it proposes adding a new anycast root server constellation to the DNS root, but instead of adding a new entry to the existing root server set, it proposes a second root server hints file.^[9]

One possible motivation behind this proposal lies in the observation that before the root was DNSSEC-signed, we placed much reliance in the concept that the root zone was served from only a small number of IP addresses, but when the root zone is DNSSEC-signed, then the integrity of the responses generated from a root zone is based on the ability of the receiver of the response to validate the signed responses using its local copy of the root keys. Who serves the zone in a DNSSEC context is largely irrelevant.

This approach uses the same root zone signing key to sign a second root zone, where the root zone is served by an exclusively assigned anycast address set. This second set of addresses would not be exclusively assigned to any root server operators, but allowed to be used by any party, in a form of uncontrolled anycast.

In some ways this proposal is similar to the existing AS112 work^[10], where anyone can set up a server to respond to common queries for nonexistent top-level domains (such as `.local`) with NXDOMAIN responses. The implication is that if there is a perception that a locale is poorly served by the existing root server anycast constellations, then a local instance of this particular anycast root server can be set up. Because the address is specifically dedicated for unowned anycast, there is no need to coordinate with either the existing root server operators or with other operators of root zone servers on the same anycast address. A prospective operator of one of these root servers simply serves the unowned anycast root zone from one of the small pool (two address couplets, each linking an IPv4 and an IPv6 address) of reserved anycast addresses. Recursive resolvers would query this server by using a distinct unowned anycast root hints file.

Why would any recursive resolver trust the veracity of responses received from one of these unowned anycast root servers? We could well ask the same of recursive resolvers who query into any of the 13 anycast constellations for the root zone, and to some extent the risks of being led astray are similar. The one mitigation of the latter case is that hijacking an existing anycast constellation prefix requires the coercive corruption of the routing system to inject a false instance of an “owned” address, although there is no such concept as hijacking of the unowned anycast prefix. However, in both cases some skepticism on the part of the recursive resolver is to be encouraged, and recursive resolvers should be motivated to validate all such responses using DNSSEC, using the local copy of the DNS trust anchor material. This practice is still a part of “good housekeeping” recommended operational practice for recursive resolvers using the existing root servers, but is a more strongly worded requirement for resolvers using this unowned anycast service.

Although it could be regarded as a byproduct of a single hierarchical name space, the centralization of root zone information in the DNS is operationally problematical and does not cleanly fit within a distributed and decentralized peer model of a network architecture. The adoption of root server anycast constellations is an attempt to respond to this situation, to an extent, by overprovisioning of this critical service. A similar picture is emerging in the area of content provisioning, where cloud-based content is essentially an exercise in overprovisioning, where single points of distribution are replaced by a larger scale of multiple delivery points in order to improve the quality of the delivered service.

However, end users don’t enjoy the same level of control, and are dependent on external conditions that are effectively out of their direct control. Not only does this dependence result in highly variable service experiences, but it also leaves the user highly exposed to various forms of online surveillance. The distributing computing world has created external dependencies for users where access to local service is reliant on external availabilities.

The DNS is a good example of this scenario, in so far as resolution of a DNS name that is not already contained in local caches requires priming queries to external servers. Obviously these dependencies on external services highlight fragility where local services cannot be reliably provided using only local infrastructure.

Both of these proposals are incremental in nature, and propose a form of augmentation to the existing structure of recursive resolvers and the root name server, rather than any fundamental change to the existing structure. In so doing, there is a distinct possibility that this form of uncoordinated piecemeal expansion at a local level could prove to be more effective across the Internet, and the critical role of the existing 13 root server operators would diminish over time if it were.

Neither of these proposed approaches is entirely without some form of change. All these uncoordinated root server operators would mean that push notification of root zone changes via the NOTIFY message would not be not feasible, so it would be back to periodic zone transfers and timers in the root zone headers. There is no longer a quick mistake-correction capability in the root zone if served in this way, although it could be argued that the massive level of caching of DNS information actually implied that any changes in the root zone were subject to cache flushing in any case, irrespective of the speed of zone change at the level of the root server anycast constellations.

What is perhaps more worrisome is that the unowned anycast proposal is in effect a proposal to fork the root zone, and recursive resolvers are forced to position themselves within one regime or the other. The only common glue left in this environment is the root key, because the only way that a client of either regime can detect that it is receiving genuine answers is to perform response validation using the root key. This type of validation is placing a massive amount of invested trust in a security artifact that is used today by only a very small subset of recursive resolvers.

It also needs to be noted that our experience to date with unowned anycast has been very poor. At one stage the IPv6 transition experimented with a form of unowned anycast in the form of 6to4 tunnel servers, and the results were hardly reassuring. Anycast clouds follow routing, not geography, and diagnosing operational failures that occur within an uncoordinated anycast structure can range from the merely challenging to highly cryptic and insoluble. The relationship between a recursive resolver and the actual root server it is querying is then occluded, and instances of structural failure in DNS name resolution are far harder to diagnose and correct. Considering that the name translation function is an essential foundation for the Internet, adding operational opacity to the root zone query function is not a step that should be taken lightly.

But that reality does not imply that the other proposal is free from operational concerns, either. The complexity of the local slave resolver, with two concurrent DNS resolvers operating within the same host, should also be questioned. Although there is a current convention in DNS resolver and server deployment to avoid the model of a “mixed” mode resolver that is both an authoritative (or slave) server for some domains and a recursive resolver for all other domains, this avoidance is perhaps nothing more than a convention, and it seems overkill for a resolver to phrase a root query and reach through the loopback interface to ask a co-resident DNS resolver the queries that are being posed to the root.

Why not just operate the local resolver in mixed mode and allow the root query to simply become a memory lookup within a single DNS resolver instance? Perhaps the only justification in this case is the issue of root zone integrity. In the mixed mode of a single resolver instance, the question that arises is a reasonable one: How can the local resolver validate the contents of the transferred root zone? In the loopback model, the local resolver performs DNSSEC validation of the root zone responses and therefore does not necessarily need to separately validate the contents of the transferred root zone. In theory a mixed-mode resolver could DNSSEC-validate the responses retrieved from its local instance of a slave zone server before passing them to the recursive resolver function, but it’s not clear that any existing DNS resolver implementations perform this form of DNSSEC validation of internal queries in a mixed mode of operation. Alternate approaches of including a zone signature to ensure integrity are also a possibility to ensure that the recursive resolver is not placed into a position of inadvertently serving corrupt root zone data.

Why not take this thought a further step, and allow any recursive resolver to be a slave server for the root zone? If the zone transfer function included an integrity check across the entire transferred zone (such as a hash of the transferred zone, signed by the root zone signing key), then the recursive resolver could be assured that it was then serving an authentic copy of the root zone.

However, such an integrity check on the transferred zone only assists the local recursive resolver in assuring itself that it has obtained an authentic and current copy of the zone. Clients of that recursive resolver should be as skeptical as ever and ask for DNSSEC signatures, and perform DNSSEC validation over all signed responses that are received from the recursive resolver. The advantage of this approach is that it permits essentially an unlimited number of root name servers, where every recursive server that wants to can serve its own validated copy of the root zone. The disadvantage is that, like all large distributed systems, there is some introduced inertia into the system and updates take time to propagate. However, in a space that is already highly cached, the difference between what happens today and what would happen in such a scenario may well be very hard to see.

There are other ways that a recursive resolver can authoritatively serve responses from the root zone that avoids an explicit root zone transfer, yet still primes the recursive resolver with authoritative information about the contents of the root zone. The response to a query for a nonexistent domain provides NSEC responses that allow a resolver to construct a local cache of the entire root zone (Figure 4).

In the example shown in Figure 4, the response from the root server for the top-level name **nosuchdomain.** indicates in the signed NSEC record that was returned that all names that lie between **no.** and **np.** can be correctly interpreted to be nonexistent domains. As long as the resolver can successfully validate the digital signatures contained in this response, the resolver can cache this negative result and serve NX domain responses for all names in this range for the lifetime of the cache.

Figure 4: Example of an NSEC Response

Conclusions

DNSSEC is indeed an extremely valuable asset for the DNS, and we can move forward with a larger and more robust system if we can count on various efforts to subvert the operation DNS being thwarted by all forms of clients of the DNS, even to the level of applications insisting that they are exposed to the DNS responses and their signatures, and performing their own validation on the received data.

There is a more general observation about scaling in the Internet. We are finding it increasingly challenging to react to inexorable pressures of scaling the infrastructure of the Internet while still maintaining basic backward compatibility with systems that conform only to technical standards of the 1980s. We need to move on. We have moved beyond the 512-octet packet limit, and these days it's reasonable to assume that useful resolvers can support EDNS0 options in DNS queries. Resolvers should perform DNSSEC validation. Wondering why there are 13 available slots for root name server operators, and wondering about how we could alter their composition, or change the interaction with the DNS root to support one or two additional root servers, are unproductive lines of investigation at so many levels. It may well be time to contemplate a different DNS that does not involve these arbitrary constraints over the number and composition of players that serve the signed root zone. Instead we should rely on using DNSSEC validation to ensure that the responses received from queries to the root zone are authentic.

The attraction of unconstrained systems is that local actors can respond to local needs, and respond by using local resources, without having to coordinate or cross-subsidize the activities of others. Much of the momentum of the Internet is directed by this loosely constrained model of interaction. If we can use the possibilities opened up by securing the DNS payload, where the question of who passed the DNS information to you is irrelevant but the question of whether the information is locally verifiable is critically important, then and only then can we contemplate what it would take to operate an unconstrained DNS system for serving the root zone.

Gigabit Ethernet: From 1 to 100 Gbps and Beyond

by William Stallings

Since its first introduction in the early 1980s, Ethernet has been the dominant technology for implementing *Local-Area Networks* (LANs) in office environments. Over the years, the data-rate demands placed on LANs have grown at a rapid pace. Fortunately, Ethernet technology has adapted to provide ever-higher capacity to meet these needs. We are now in the era of the Gigabit Ethernet.

Ethernet began as an experimental bus-based 2.94-Mbps system^[1] using coaxial cable. In a shared bus system, all stations attach to a common cable, with only one station able to successfully transmit at a time. A *Medium Access Control* (MAC) protocol based on collision detection arbitrates the use of the bus. In essence, each station is free to transmit MAC frames on the bus. If a station detects a collision during transmission, it backs off a certain amount of time and tries again.

The first commercially available Ethernet products were bus-based systems operating at 10 Mbps^[2]. This introduction coincided with the standardization of Ethernet by the IEEE 802.3 committee. With no change to the MAC protocol or MAC frame format, Ethernet could also be configured in a star topology, with traffic going through a central hub, again with transmission limited to a single station at a time through the hub. To enable an increase in the data rate, a switch replaces the hub, allowing full-duplex operation. With the switch, the same MAC format and protocol are used, although collision detection is no longer needed. As the demand has evolved and the data rate requirement increased, some enhancements to the MAC layer have been added, such as provision for larger frame sizes.

Currently, Ethernet systems are available at speeds up to 100 Gbps. Table 1 summarizes the successive generations of IEEE 802.3 standardization.

Table 1: IEEE 802.3 Physical Layer Standards

Year Introduced	1983	1995	1998	2003	2010
Maximum data transfer speed	10 Mbps	100 Mbps	1 Gbps	10 Gbps	40 Gbps, 100 Gbps
Transmission media	Coax cable, unshielded twisted pair, optical fiber	Unshielded twisted pair, shielded twisted pair, optical fiber	Unshielded twisted pair, optical fiber, shielded twisted pair	Optical fiber	Optical fiber, backplane

Ethernet quickly achieved widespread acceptance and soon became the dominant technology for LANs. Its dominance has since spread to *Metropolitan-Area Networks* (MANs) and a wide range of applications and environments.

The huge success of Ethernet is due to its extraordinary adaptability. The same MAC protocol and frame format are used at all data rates. The differences are at the physical layer, in the definition of signaling technique and transmission medium.

In the remainder of this article, we look at characteristics of Ethernet in the gigabit range.

1-Gbps Ethernet

For many years the initial standard of Ethernet, at 10 Mbps, was adequate for most office environments. By the early 1990s, it was clear that higher data rates were needed to support the growing traffic load on the typical LAN. Key drivers in this evolution include:

- *Centralized Server Farms*: In many multimedia applications, there is a need for the client system to be able to draw huge amounts of data from multiple, centralized servers, called *Server Farms*. As the performance of the servers has increased, the network has become the bottleneck.
- *Power Workgroups*: These groups typically consist of a small number of cooperating users who need to exchange massive data files across the network. Example applications are software development and computer-aided design.
- *High-speed Local Backbone*: As processing demand grows, enterprises develop a configuration of multiple LANs interconnected with a high-speed backbone network.

To meet such needs, the IEEE 802.3 committee developed a set of specifications for Ethernet at 100 Mbps, followed a few years later by a 1-Gbps family of standards. In each case, the new specifications defined transmission media and transmission encoding schemes built on the basic Ethernet framework, making the transition easier than if a completely new specification were issued.

The 1-Gbps standard includes a variety of transmission medium options^[3, 4] (Figure 1):

- *+1000BASE-SX*: This short-wavelength option supports duplex links of up to 275 m using 62.5- μ m multimode or up to 550 m using 50- μ m multimode fiber. Wavelengths are in the range of 770 to 860 nm.
- *1000BASE-LX*: This long-wavelength option supports duplex links of up to 550 m of 62.5- μ m or 50- μ m multimode fiber or 5 km of 10- μ m single-mode fiber. Wavelengths are in the range of 1270 to 1355 nm.

- **1000BASE-CX:** This option supports 1-Gbps links among devices located within a single room or equipment rack, using copper jumpers (specialized shielded twisted-pair cable that spans no more than 25 m). Each link is composed of a separate shielded twisted pair running in each direction.
- **1000BASE-T:** This option uses four pairs of Category 5 unshielded twisted pair to support devices over a range of up to 100 m, transmitting and receiving on all four pairs at the same time, with echo cancellation circuitry.

Figure 1: 1-Gbps Ethernet Medium Options (log scale)

The signal encoding scheme used for the first three Gigabit Ethernet options just listed is 8B/10B. With 8B/10B, each 8 bits of data is converted into 10 bits for transmission^[3]. The extra bits serve two purposes. First, the resulting signal stream has more transitions between logical 1 and 0 than an uncoded stream; it avoids the possibility of long strings of 1s or 0s that make synchronization between transmitter and receiver more difficult. Second, the code is designed in such a way as to provide a useful error-detection capability.

The signal-encoding scheme used for 1000BASE-T is 4D-PAM5, a complex scheme whose description is beyond our scope.

In a typical application of Gigabit Ethernet, a 1-Gbps LAN switch provides backbone connectivity for central servers and high-speed workgroup Ethernet switches. Each workgroup LAN switch supports both 1-Gbps links, to connect to the backbone LAN switch and to support high-performance workgroup servers, and 100-Mbps links, to support high-performance workstations, servers, and 100-Mbps LAN switches.

10-Gbps Ethernet

Even as the ink was drying on the 1-Gbps specification, the continuing increase in local traffic made this specification inadequate for needs in the short-term future. Accordingly, the IEEE 802.3 committee soon issued a standard for 10-Gbps Ethernet. The principal requirement for 10-Gbps Ethernet was the increase in intranet (local interconnected networks) and Internet traffic. Numerous factors contribute to the explosive growth in both Internet and intranet traffic:

- An increase in the number of network connections
- An increase in the connection speed of each end station (for example, 10-Mbps users moving to 100 Mbps, and analog 56k users moving to DSL and cable modems)
- An increase in the deployment of bandwidth-intensive applications such as high-quality video
- An increase in Web hosting and application hosting traffic

Initially, network managers used 10-Gbps Ethernet to provide high-speed, local backbone interconnection between large-capacity switches. As the demand for bandwidth increased, 10-Gbps Ethernet began to be deployed throughout the entire network, to include server farm, backbone, and campus-wide connectivity. This technology enables *Internet Service Providers* (ISPs) and *Network Service Providers* (NSPs) to create very-high-speed links at a very low cost, between co-located, carrier-class switches, and routers^[5].

The technology also allows the construction of MANs and *Wide-Area Networks* (WANs) that connect geographically dispersed LANs between campuses or *Points of Presence* (PoPs). Thus, Ethernet begins to compete with *Asynchronous Transfer Mode* (ATM) and other wide-area transmission and networking technologies. In most cases where the customer requirement is data and TCP/IP transport, 10-Gbps Ethernet provides substantial value over ATM transport for both network end users and service providers:

- No expensive, bandwidth-consuming conversion between Ethernet packets and ATM cells is required; the network is Ethernet, end to end.
- The combination of IP and Ethernet offers *Quality of Service* (QoS) and traffic policing capabilities that approach those provided by ATM, so that advanced traffic-engineering technologies are available to users and providers.
- A wide variety of standard optical interfaces (wavelengths and link distances) have been specified for 10 Gigabit Ethernet, optimizing its operation and cost for LAN, MAN, or WAN applications.

The goal for maximum link distances cover a range of applications is from 300 m to 40 km. The links operate in full-duplex mode only, using a variety of optical fiber physical media.

Figure 2: 10-Gbps Ethernet Distance Options (log scale)

Four physical layer options are defined for 10-Gbps Ethernet (Figure 2). The first three have two suboptions: an “R” suboption and a “W” suboption. The R designation refers to a family of physical layer implementations that use a signal encoding technique known as 64B/66B. With 64B/66B, each 64 bits of data is converted into 66 bits for transmission, resulting in substantially less overhead than 8B/10B but providing the same types of benefits. The R implementations are designed for use over *dark fiber* meaning a fiber-optic cable that is not in use and that is not connected to any other equipment. The W designation refers to a family of physical layer implementations that also use 64B/66B signaling but are then encapsulated to connect to SONET equipment.

The four physical layer options are as follows:

- **10GBASE-S (*short*):** Designed for 850-nm transmission on multimode fiber. This medium can achieve distances up to 300 m. There are 10GBASE-SR and 10GBASE-SW versions.
- **10GBASE-L (*long*):** Designed for 1310-nm transmission on single-mode fiber. This medium can achieve distances up to 10 km. There are 10GBASE-LR and 10GBASE-LW versions.
- **10GBASE-E (*extended*):** Designed for 1550-nm transmission on single-mode fiber. This medium can achieve distances up to 40 km. There are 10GBASE-ER and 10GBASE-EW versions.
- **10GBASE-LX4:** Designed for 1310-nm transmission on single-mode or multimode fiber. This medium can achieve distances up to 10 km. This medium uses *Wavelength-Division Multiplexing* (WDM) to multiplex the bit stream across four light waves.

40-/100-Gbps Ethernet

Ethernet is widely deployed and is the preferred technology for wired local-area networking. Ethernet dominates enterprise LANs, broadband access, and data center networking, and it has also become popular for communication across MANs and even WANs. Further, it is now the preferred carrier wire-line vehicle for bridging wireless technologies, such as Wi-Fi and WiMAX, into local Ethernet networks.

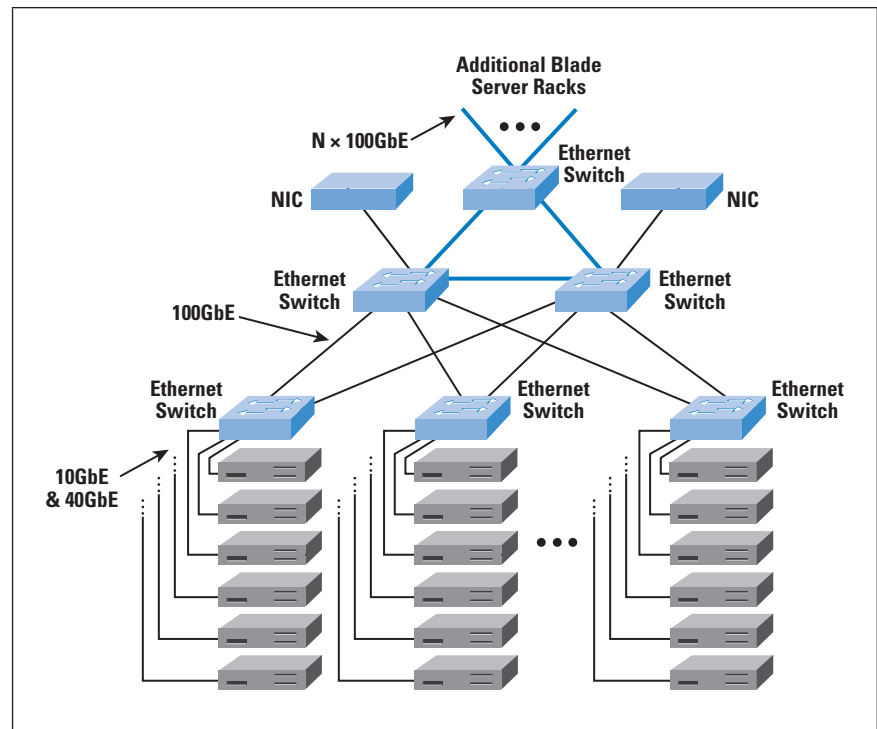

This popularity of Ethernet technology is due to the availability of cost-effective, reliable, and interoperable networking products from a variety of vendors. The development of converged and unified communications, the evolution of massive server farms, and the continuing expansion of *Voice over IP* (VoIP), *Television over IP* (TVoIP), and Web 2.0 applications have accelerated the need for ever-faster Ethernet switches. The following are market drivers for 100-Gbps Ethernet:

- *Data center/Internet Media Providers*: To support the growth of Internet multimedia content and Web applications, content providers have been expanding data centers, pushing 10-Gbps Ethernet to its limits. These providers are likely to be high-volume early adopters of 100-Gbps Ethernet.
- *Metro-Video/Service Providers*: Video on demand has been leading a new generation of 10-Gbps Ethernet metropolitan/core network build-outs. These providers are likely to be high-volume adopters in the medium term.
- *Enterprise LANs*: Continuing growth in convergence of voice/video/data and in unified communications is accelerating network switch demands. However, most enterprises still rely on 1-Gbps or a mix of 1-Gbps and 10-Gbps Ethernet, and adoption of 100-Gbps Ethernet is likely to be slow.
- *Internet exchanges/ISP Core Routing*: With the massive amount of traffic flowing through these nodes, these installations are likely to be early adopters of 100-Gbps Ethernet.

In 2007, the IEEE 802.3 working group authorized the *IEEE P802.3ba 40-Gbps and 100-Gbps Ethernet Task Force*. The 802.3ba project authorization request cited numerous examples of applications that require greater data-rate capacity than 10-Gbps Ethernet offers, including Internet exchanges, high-performance computing, and video-on-demand delivery. The authorization request justified the need for two different data rates in the new standard (40 Gbps and 100 Gbps) by recognizing that aggregate network requirements and end-station requirements are increasing at different rates.

An example of the application of 100-Gbps Ethernet is shown in Figure 3. The trend at large data centers, with substantial banks of blade servers, is the deployment of 10-Gbps ports on individual servers to handle the massive multimedia traffic provided by these servers. Typically, a single blade-server rack will contain multiple servers and one or two 10-Gbps Ethernet switches to interconnect all the servers and provide connectivity to the rest of the facility. The switches are often mounted in the rack and referred to as *Top-of-Rack* (ToR) switches. The term ToR has become synonymous with a server access switch, even if it is not located “top of rack.” For very large data centers, such as cloud providers, the interconnection of multiple blade-server racks with additional 10-Gbps switches is increasingly inadequate. To handle the increased traffic load, switches operating at greater than 10 Gbps are needed to support the interconnection of server racks and to provide adequate capacity for connecting off-site through *Network Interface Controllers* (NICs).

Figure 3: Example 100-Gbps Ethernet Configuration for Massive Blade-Server Cloud Site

The first products in this category appeared in 2009, and the IEEE 802.3ba standard was finalized in 2010. Initially, many enterprises are deploying 40-Gbps switches, but both 40- and 100-Gbps switches are projected to enjoy increased market penetration in the next few years^[6, 7, 8].

IEEE 802.3ba specifies three types of transmission media as shown in Table 2: copper backplane, twin axial (a type of cable similar to coaxial cable), and optical fiber. For copper media, four separate physical lanes are specified. For optical fiber, either 4 or 10 wavelengths are specified, depending on data rate and distance^[9, 10, 11].

Table 2: Media Options for 40- and 100-Gbps Ethernet

	40 Gbps	100 Gbps
1-m backplane	40GBASE-KR4	
10-m copper	40GBASE-CR4	100GBASE-CR10
100-m multimode fiber	40GBASE-SR4	100GBASE-SR10
10-km single-mode fiber	40GBASE-LR4	100GBASE-LR4
40-km single-mode fiber		100GBASE-ER4

Naming nomenclature:

Copper: K = Backplane; C = Cable assembly

Optical: S = Short reach (100 m); L - Long reach (10 km);

E = Extended long reach (40 km)

Coding scheme: R = 64B/66B block coding

Final number: Number of lanes (copper wires or fiber wavelengths)

Multilane Distribution

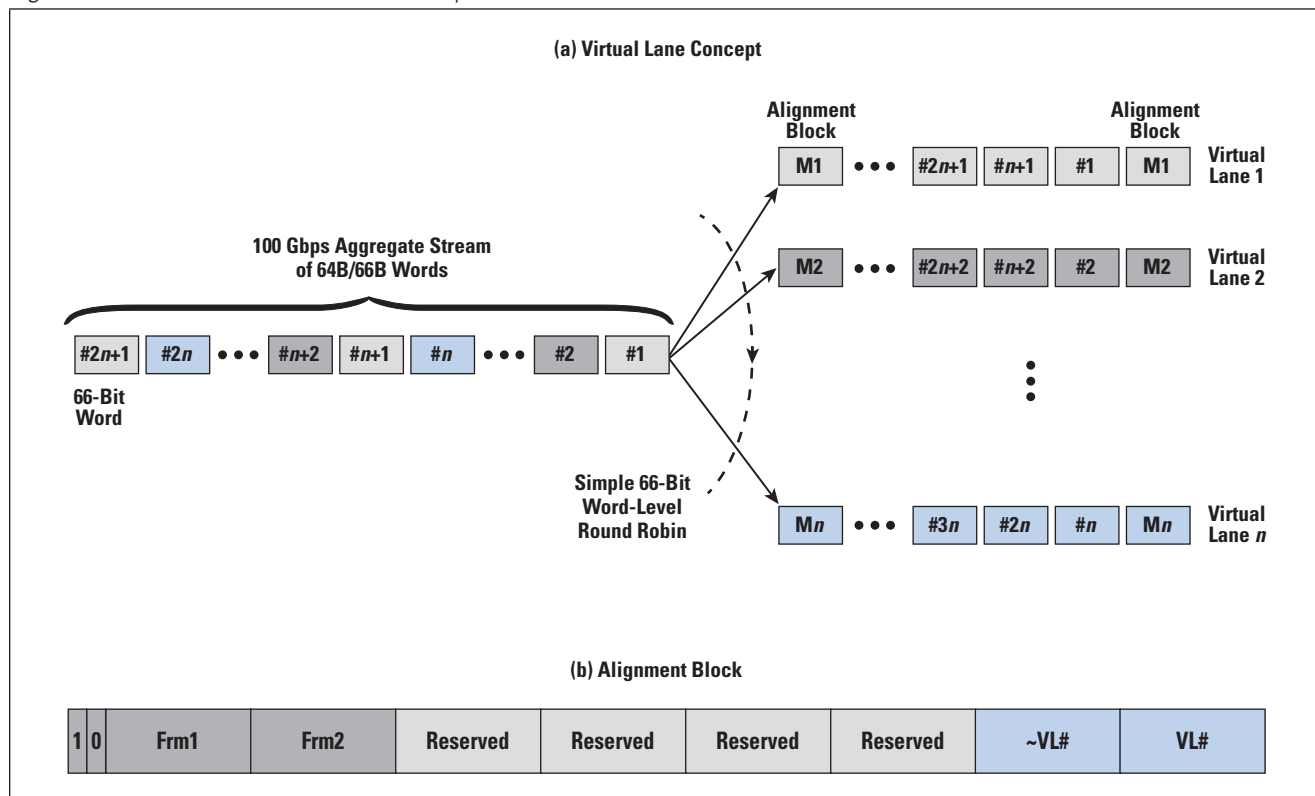

The 802.3ba standard uses a technique known as multilane distribution to achieve the required data rates. Two separate concepts need to be addressed: multilane distribution and virtual lanes.

The general idea of *multilane distribution* is that, in order to accommodate the very high data rates of 40 and 100 Gbps, the physical link between an end station and an Ethernet switch or the physical link between two switches may be implemented as multiple parallel channels. These parallel channels could be separate physical wires, such as four parallel twisted-pair links between nodes. Alternatively, the parallel channels could be separate frequency channels, such as provided by WDM over a single optical fiber link.

For simplicity and manufacturing ease, we would like to specify a specific multiple-lane structure in the electrical physical sublayer of the device, known as the *Physical Medium Attachment* (PMA) sublayer. The lanes produced are referred to as *virtual lanes*. If a different number of lanes are actually in use in the electrical or optical link, then the virtual lanes are distributed into the appropriate number of physical lanes in the *Physical Medium Dependent* (PMD) sublayer. This is a form of inverse multiplexing.

Figure 4a shows the virtual lane scheme at the transmitter. The user data stream is encoded using the 64B/66B, which is also used in 10-Gbps Ethernet. Data is distributed to the virtual lanes one 66-bit word at a time using a simple round robin scheme (first word to first lane, second word to second lane, etc.). A unique 66-bit alignment block is added to each virtual lane periodically. The alignment blocks are used to identify and reorder the virtual lanes and thus reconstruct the aggregate data stream.

Figure 4: Multilane Distribution for 100-Gbps Ethernet

The virtual lanes are then transmitted over physical lanes. If the number of physical lanes is smaller than the number of virtual lanes, then bit-level multiplexing is used to transmit the virtual lane traffic. The number of virtual lanes must be an integer multiple (1 or more) of the number of physical lanes.

Figure 4b shows the format of the alignment block. The block consists of 8 single-byte fields preceded by the 2-bit synchronization field, which has the value 10. The Frm fields contain a fixed framing pattern common to all virtual lanes and used by the receiver to locate the alignment blocks. The VL# fields contain a pattern unique to the virtual lane: one of the fields is the binary inverse of the other.

25-/50-Gbps Ethernet

One of the options for implementing 100 Gbps is as four 25-Gbps physical lanes. Thus, it would be relatively easy to develop standards for 25- and 50-Gbps Ethernet, using one or two lanes, respectively. Having these two lower-speed alternatives, based on the 100-Gbps technology, would give users more flexibility in meeting existing and near-term demands with a solution that would scale easily to higher data rates.

Such considerations have led to the formation of the *25 Gigabit Ethernet Consortium* by numerous leading cloud networking providers, including Google and Microsoft. The objective of the consortium is to support an industry-standard, interoperable Ethernet specification that boosts the performance and slashes the interconnect cost per Gbps between the NIC and ToR switch. The specification adopted by the consortium prescribes a single-lane 25-Gbps Ethernet and dual-lane 50-Gbps Ethernet link protocol, enabling up to 2.5 times higher performance per physical lane on twinax copper wire between the rack endpoint and switch compared to current 10- and 40-Gbps Ethernet links. The IEEE 802.3 committee is presently developing the needed standards for 25 Gbps, and it may include 50 Gbps^[12, 13].

It is too early to say how these various options (25, 40, 50, and 100 Gbps) will play out in the marketplace. In the intermediate term, the 100-Gbps switch is likely to predominate at large sites, but the availability of these slower and cheaper alternatives gives enterprises numerous paths for scaling up to meet increasing demand.

400-Gbps Ethernet

The growth in demand never lets up. IEEE 802.3 is currently exploring technology options for producing a 400-Gbps Ethernet standard, although no timetable is yet in place^[14, 15, 16, 17]. Looking beyond that milestone, there is widespread acknowledgment that a 1-Tbps (terabit per second, trillion bits per second) standard will eventually be produced^[18].

2.5-/5-Gbps Ethernet

As a testament to the versatility and ubiquity of Ethernet, and at the same time the fact that ever-higher data rates are being standardized, consensus is developing to standardize two lower rates: 2.5 and 5 Gbps^[19, 20]. These relatively low speeds are also known as *Multirate Gigabit BASE-T* (MGBASE-T). Currently, the *MGBASE-T Alliance* is overseeing the development of these standards outside of IEEE. It is likely that the IEEE 802.3 committee will ultimately issue standards based on these industry efforts.

These new data rates are intended mainly to support IEEE 802.11ac wireless traffic into a wired network. IEEE 802.11ac is a 3.2-Gbps Wi-Fi standard that is gaining acceptance where more than 1 Gbps of throughput is needed, such as to support mobile users in the office environment^[21]. This new wireless standard overruns 1-Gbps Ethernet link support but may not require the next step up, which is 10 Gbps. Assuming that 2.5 and 5 Gbps can be made to work over the same cable that supports 1 Gbps, then this standard would provide a much-needed uplink speed improvement for access points supporting 802.11ac radios with their high-bandwidth capabilities.

Conclusion

Ethernet is widely deployed and is the preferred technology for wired local-area networking. Ethernet dominates enterprise LANs, broadband access, and data center networking, and it has also become popular for communication across MANs and even WANs. Further, it is now the preferred carrier wire-line vehicle for bridging wireless technologies, such as Wi-Fi and WiMAX, into local Ethernet networks. Further, the Ethernet marketplace is now large enough to accelerate the development of speeds for specific use cases, such as 25/50 Gbps for data center ToR designs and 2.5/5 Gbps for wireless infrastructure backhaul. The availability of a wide variety of standardized Ethernet data rates allows the network manager to customize a solution to optimize performance, cost, and energy consumption goals^[22].

This popularity of Ethernet technology is due to the availability of cost-effective, reliable, and interoperable networking products from a variety of vendors. The development of converged and unified communications, the evolution of massive server farms, and the continuing expansion of VoIP, TVoIP, and Web 2.0 applications have accelerated the need for ever-faster Ethernet switches.

The success of Gigabit Ethernet and 10-Gbps Ethernet highlights the importance of network-management concerns in choosing a network technology. The 40- and 100-Gbps Ethernet specifications offer compatibility with existing installed LANs, network-management software, and applications. This compatibility has accounted for the survival of 30-year-old technology in today's fast-evolving network environment.

ARPANET History

Bolt Beranek and Newman Report 4799 entitled “A History of the ARPANET: The First Decade,” is a fascinating document for anyone interested in early Internet History. First published in 1981, a scanned PDF version can be downloaded from the following link:

www.darpa.mil/WorkArea/DownloadAsset.aspx?id=2677

IANA Transition

Since the United States *National Telecommunications and Information Administration* (NTIA) announced its intent to “...transition Key Internet Domain Name Functions to the global multistakeholder community” last March, a flurry of activity has been taking place within the Internet technical and policy communities. The following website provides further information and links to the relevant working groups and documents: <https://www.icann.org/stewardship>

Upcoming Events

The *North American Network Operators’ Group* (NANOG) will meet in San Francisco, California, June 1–3, 2015 and in Montreal, Quebec, Canada, October 5–7, 2015. See: <http://nanog.org>

The *Internet Corporation for Assigned Names and Numbers* (ICANN) will meet in Buenos Aires, Argentina, June 21–25, 2015, and in Dublin, Ireland, October 18–22, 2015. See: <http://icann.org/>

The *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT) will meet in Auckland, New Zealand, February 16–26, 2016. See: <http://www.apricot.net>

The *Internet Engineering Task Force* (IETF) will meet in Prague, Czech Republic, July 19–24, 2015, and in Yokohama, Japan, November 1–6, 2015. See: <http://www.ietf.org/meeting/>

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

FROM THE EDITOR

The *Transmission Control Protocol* (TCP) is one of the core protocols used in today's Internet. This issue of IPJ is almost entirely devoted to discussions about TCP. Anyone who has studied TCP/IP will have marveled at the "ASCII Art" state diagram for TCP on page 23 of RFC 793, published in 1981. This diagram is a good illustration of both the power and the limitations of using only text characters to draw a "picture." I am happy to report that efforts to define a new format for the RFC series of documents are nearing completion. We will report further on this new RFC format in a future issue.

Your mobile device contains several interfaces, such as USB, WiFi, Cellular Data, and Bluetooth. Most, if not all, of these interfaces can be used for Internet communications, specifically to carry TCP/IP datagrams. In our first article, Geoff Huston looks at an emerging standard, *Multipath TCP* (MPTCP), which allows TCP to operate several simultaneous connections using *different* interfaces.

Although TCP has not fundamentally changed since its introduction in 1981, much work has gone into improving TCP performance in the presence of network congestion and variations in network throughput. Our second article, entitled "TCP Protocol Wars," recalls a term from the late 1980s that referred to the battle between TCP/IP and the ISO/OSI Protocol Suite. This time, the term is used more humorously to compare the many special implementations and refinements to TCP.

If you received a printed copy of this journal in the mail, you should also have received a subscription activation e-mail with information about how to update and renew your subscription. If you didn't receive such a message, it may be because we do not have your correct e-mail address on file. To update and renew your subscription, just send a message to ipj@protocoljournal.org and include your subscription ID. Your subscription ID and expiration date are printed on the back of your journal.

Let me once again remind you that IPJ relies on the support of numerous individuals and organizations. If you or your company would like to sponsor IPJ, please contact us for further details. IP Multi-Addressing and Multipath TCP

by Geoff Huston, APNIC

The *Transmission Control Protocol* (TCP) is a core protocol of the Internet networking protocol suite. This protocol transforms the underlying unreliable datagram delivery service provided by the *Internet Protocol* (IP) into a reliable data stream protocol. For me this protocol was the single greatest transformative moment in the evolution of computer networks.

Prior to TCP, computer network protocols assumed that computers wanted a lossless reliable service from the network, and worked hard to provide it. The *Digital Data Communications Message Protocol* (DDCMP) in Digital Equipment Corporation's *DECnet* was a lossless data link control protocol. X.25 in the telecommunications world provided reliable stream services to the attached computers. Indeed, I recall that Ethernet was criticized when it was introduced to the world because of its lack of a reliable acknowledgement mechanism. TCP changed all of that. TCP pushed all of the critical functionality supporting reliable data transmission right out of the network and into the shared state of the computers at each end of the TCP conversation. TCP embodies the *End-to-End Principle* of the Internet architecture, where there is no benefit in replicating within the network functionality that can be provided by the end points of a conversation. What TCP required of the network was a far simpler service where packets were allowed to be delivered out of order, but packets could be dropped and TCP would detect and repair the problem and deliver to the far-end application precisely the same bit stream that was passed into the TCP socket in the first place.

The TCP protocol is now some 40 years old, but that doesn't mean that it has been frozen over all these years.

TCP is not only a reliable data stream protocol, but also a protocol that uses *Adaptive Rate Control*. TCP can operate in a mode that allows the protocol to push as much data through the network as it can. A common mode of operation is for an individual TCP session to constantly probe into the network to see what the highest sustainable data rate is, interpreting packet loss as the signal to drop the sending rate and resume the probing. This aspect of TCP has been a constant field of study, and much work has been done in the area of flow control. We now have many variants of TCP that attempt to optimize the flow rates across various forms of networks.

Other work has looked at the TCP data acknowledgement process, attempting to improve the efficiency of the algorithm under a broad diversity of conditions. *Selective Acknowledgments* (SACK) allowed a receiver to send back more information to the sender in response to missing data. *Forward Acknowledgment* (FACK) addresses data-loss issues during TCP *Slow Start*.

One approach to trying to improve the relative outcome of a data transfer, as compared to other simultaneously open TCP sessions, is to split the data into multiple parts and send each part in its own TCP session. This splitting effectively opens up numerous parallel TCP sessions. A variant of TCP, *MulTCP*, emulates the behavior of multiple parallel TCP sessions in a single TCP session. These behaviors assume the same endpoints for the parallel TCP sessions and assume the same end-to-end path through the network. An evolution of TCP that uses multiple parallel sessions but tries to spread these sessions across multiple *paths* through the network is *Multipath TCP* (MPTCP).

Multipath TCP had a brief moment of prominence when it was revealed that Apple's release of iOS 7 contained an implementation of Multipath TCP for the company's *Siri* application, but it has the potential to play a bigger role in the mobile Internet. In this article, I will explore this TCP option in a little more detail, and see how it works and how it may prove to be useful in today's mobile networks.

Multi-Addressing in IP

First we need to return to one of the basic concepts of networking, that of addressing and addresses. Addresses in the Internet Protocol were subtly different from many other computer communications protocols that were commonly used in the 1970s and 1980s. While many other protocols used the communications protocol-level address as the address of the host computer, the Internet Protocol was careful to associate an IP address with the *interface* to a network. This distinction was a relatively unimportant one in most cases because computers usually had only a single network attachment interface. But it was a critical distinction when the computer had two or more interfaces to two or more networks. An IP host with two network interfaces has two IP addresses—one for each interface. In IP it is the interface between the device and the network that is the addressed endpoint in a communication. An IP host accepts an IP packet as being addressed to itself if the IP address in the packet matches the IP addresses of the network interface that received the packet, and when sending a packet, the source address in the outgoing packet is the IP address of the network interface that was used to pass the packet from the host into the network.

As simple as this model of network addressing may be, it does present some operational problems. One implication of this form of addressing is that when a host has multiple interfaces, the application-level conversations using TCP are “sticky.” If, for example, a TCP session was opened on one network interface, the network stack in the host cannot quietly migrate this active session to another interface while maintaining the common session state. An attempt by one “end” of a TCP conversation to change the IP address for an active session would not normally be recognized at the other end of the conversation as being part of the original session. So having multiple interfaces and multiple addresses does not create additional resiliency of TCP connections.

The simplicity of giving each network interface a unique IP address does not suit every possible use case, and it was not all that long before the concept of *secondary addresses* came into use. The use of secondary addresses was a way of using multiple addresses to refer to a host by allowing a network interface to be configured with multiple IP addresses. In this scenario, an interface receives packets addressed to any of the IP addresses associated with the interface. Outgoing packet handling allows the transport layer to specify the source IP address, and this action overrides the default action of using the primary address of the interface on outgoing packets. Secondary addresses have their uses, particularly when you are trying to achieve the appearance of multiple application-level “personas” on a single common platform, but in IPv4 they were perhaps more of a specialized solution to a particular family of requirements, rather than a commonly used approach. Applications using TCP were still “sticky” with IP addresses that were used in the initial TCP handshake and could not switch the session between secondary IP addresses on the same interface.

IPv6 addressing is somewhat different. The protocol allows from the outset for an individual interface to be assigned multiple IPv6 unicast addresses without the notion of “primary” and “secondary” addresses. The IPv6 protocol introduces the concept of an address *scope*, so an address may be assuredly unique in the context of the local link-layer network, or it may have a global scope, for example. Privacy considerations have also introduced the concept of permanent and temporary addresses, and the efforts to support a certain form of mobility have introduced the concepts of *home addresses* and *care-of addresses*.

However, to some extent these IPv6 changes are cosmetic modifications to the original IPv4 address model. If an IPv6 host has multiple interfaces, each of these interfaces has its own set of IPv6 addresses, and when a TCP session is started using one address pair TCP does not admit the ability to shift to a different address pair in the life of the TCP session. A TCP conversation that started over one network interface is stuck with that network interface for the life of the conversation, whether it’s IPv4 or IPv6.

The Internet has changed significantly with the introduction of the mobile Internet, and the topic of multi-addresses is central to many of the problems with mobility. Mobile devices are adorned with many IP addresses. The cellular radio interface has its collection of IP addresses. Most of these “smart” devices also have a WiFi interface that also has its set of IPv4 and possibly IPv6 addresses. And there may be a Bluetooth network interface with IP addresses, and perhaps some USB network interface as well. When active, each of these network interfaces requires its own local IP address. We now are in an Internet where devices with multiple active interfaces and multiple usable IP addresses are relatively commonplace. But how can we use these multiple addresses?

For many scenarios there is little value in being able to use multiple addresses. The conventional behavior is where each new session is directed to a particular interface, and the session is given an outbound address as determined by local policies. However, when we start to consider applications in which the binding of location and identity is more fluid, network connections are transient, and the cost and capacity of connections differ (as is often the case in today's mobile cellular radio services and in WiFi roaming services), then having a session that has a certain amount of agility to switch across networks can be a significant factor.

If individual end-to-end sessions could use multiple addresses, and by inference could use multiple interfaces, then an application could perform a seamless handoff between cellular data and WiFi, or even use both at the same time. Given that the TCP interface to IPv4 and IPv6 is identical, it is even quite feasible to contemplate a seamless handoff between the two IP protocols. The decision as to which carriage service to use at any time would no longer be a decision of the mobile carrier or that of the WiFi carrier, or that of the device, or that of its host operating system. If applications could use multiple addresses, multiple protocols, and multiple interfaces, then the decision could be left to the application itself to determine how best to meet its needs as connections options become available or as they shut down. At the same time as the debate between traditional mobile operators in the licensed spectrum space and the WiFi operators in the unlicensed spectrum space heats up over access to the unlicensed spectrum, the very nature of how devices and applications implement "WiFi handoff" is changing. Who is in control of this handoff function is changing as a result. Multi-Addressing and Multipath TCP is an interesting response to this situation; it allows individual applications to determine how they want to operate in a multi-connected environment.

SHIM6

One of the first attempts to use multiple addresses in IP was the *Site Multihoming by IPv6 Intermediation* (SHIM6) effort in IPv6.

In this case the motivation was end-site resilience in an environment of multiple external connections, and the constraint was to avoid the use of an independently routed IPv6 address prefix for the site. So SHIM6 was an effort to support site multi-homing without routing fragmentation. To understand the SHIM6 model, we need to start with an end site that does not have its own provider-independent IPv6 address prefix, yet is connected to two or more upstream transit providers that each provide addresses to the end site. In IPv4 it's common to see this scenario approached with *Network Address Translators* (NATs). In IPv4 the site is internally addressed using a private address prefix, and the interface to each upstream provider is provisioned with a NAT. Outbound packets have their source address rewritten to use an address that is part of the provider's prefix as it transits the NAT.

Which provider is used is a case of internal routing policies toward each of the NATs. Although it is possible to configure a similar setup in IPv6 using an IPv6 *Unique Local Address* (ULA) prefix as the internal address and NAT IPv6-to-IPv6 devices connected to each upstream service provider, one of the concepts behind IPv6 and its massive increase in address space was the elimination of NATs. So how can an IPv6 end site be homed into multiple upstream service providers without needing to advertise a more specific routing entry in the interdomain routing tables and avoiding the use of any form of network address translation?

The conventional IPv6 architecture has the site receiving an end-site prefix delegation from each of its upstream service providers, and the interface routers each advertising its end-site prefix into the site. Hosts within the site see both router advertisements, and they configure their interface with multiple IPv6 addresses, one for each site prefix. Presumably, the end site chooses to multi-home in order to benefit from the additional resiliency that such a configuration should offer. When the link to one provider is down, there is a good chance that the other link will remain up, particularly if the site has been careful to engineer the multi-homed configuration using discrete components at every level. It would be even better if even when the link to the upstream provider is up and that provider can't reach a specific destination, another of the site's upstream providers could continue to support all active end-to-end conversations without interruption, in exactly the same manner as when this functionality is implemented in the routing system.

What SHIM6 attempted was a host-based approach to use the additional local IPv6 addresses in the host as indicators of potential backup paths to a destination. If a communication with a remote counterpart were to fail (that is, the flow of incoming packets from the remote host stopped), then the IP-level shim in the local host would switch to use a different source/destination address pair. To prevent the upper-level transport protocol from being fatally confused by these address changes in the middle of one or more active sessions, the local SHIM module also included a network address translation function. This function helped ensure that although the address pair on the wire may have changed, the address pair presented to the upper layer by the shim would remain constant, and the path change would not be directly visible at the transport layer of the protocol stack.

This approach essentially folds the NAT function into the host IP protocol stack. In terms of design it avoided altering either TCP or *User Datagram Protocol* (UDP), and endeavoured to preserve the IP addresses used by active transport sessions. What this approach implied was that if you wanted to change the routing path but not change the IP addresses used by transport, then address translation was an inevitable consequence.

Network-based NATs was the response in IPv4, and to avoid this problem in IPv6 the SHIM6 effort attempted to push the NAT functionality further “back,” implementing a NAT in each host.

SHIM6 was an approach that was less than entirely satisfactory.

Network operators expressed deep distrust of pushing decision-making functionality back into individual hosts (a distrust that network operators continue to hold when the same issue arises with WiFi handoff). The network operators wanted to control the connectivity structure for the hosts in their network, in precisely the same manner as the routing system provided network-level control over traffic flows. So although these network operators had some sympathy with the SHIM6 objective of avoiding further bloat in the routing table, which reduced the “independence” of attached end sites by using IPv6 address prefixes drawn from the upstream address block, they were unsupportive of an approach that pushed connectivity choice and control back to individual end host systems.

Outside of this issue of control over the end host was another multi-homing problem that SHIM6 did not address. Although the provision of backup paths in the case of failure of the primary path is useful, what is even more useful is the ability to use the backup paths in some form of load-sharing configuration. However, at this point the SHIM6 approach runs into problems. Because SHIM6 operates at the IP layer, it is not directly aware of packet sequencing. When a SHIM unit at one end of a conversation splays a sequence of packets across multiple paths, the corresponding SHIM unit at the remote end passes the packets into the upper transport layer in the order of their arrival, not in the original order. This out-of-order delivery can be a significant problem for TCP if SHIM6 leaves multiple paths open. The best SHIM6 can provide is a primary/backup model for individual sessions, where at any time all data traffic for a session is passed along the primary path.

Inexorably, we are drawn to the conclusion that the most effective place to insert functionality that allows a data flow to use multiple potential paths across the network is in the transport layer itself, and we need to jack ourselves further up the protocol stack from the IP level approach of SHIM6 and re-examine the space from the perspective of TCP.

Multipath TCP

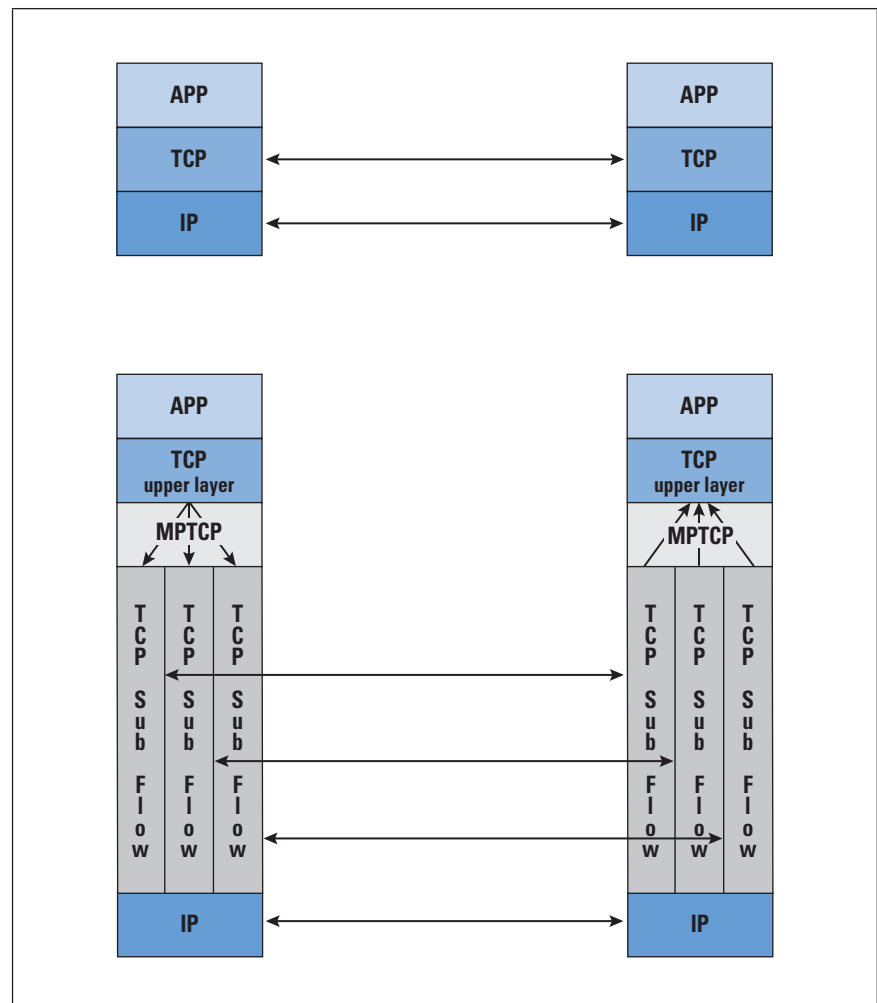

The approach of incorporating multiple IP addresses in the transport protocol is comparable to the efforts of SHIM6 one level further down in the protocol stack, in so far as this approach is an end-to-end mechanism with a shared multiplex state maintained in the two end hosts, and no state whatsoever in the network.

The basic mechanisms for MPTCP are also similar to that of SHIM6, with an initial capability exchange to confirm that both parties support the mechanism, allowing the parties to then open up additional paths, or channels. But at this point the functionality diverges. In SHIM6 these alternate paths are provisioned as backup paths if the primary path fails, whereas in the case of MPTCP these additional paths can be used immediately to spread the load of the communication across these paths, if the application so desires.

One of the most critical assumptions of MPTCP was drawn from SHIM6, in that the existence of multiple addresses in a host is sufficient to indicate the existence of multiple diverse paths within the network. Whether or not this assumption is, in fact, the case is perhaps not that critical, in that even in the case where the addresses are on the same path from end to end, the result is roughly equivalent to running multiple parallel sessions of TCP.

The basic approach to MPTCP is the division of the single outbound flow of the application into multiple *subflows*, each operating its own end-to-end TCP session, and the rejoining of multiple input subflows into a single flow to present to the remote counterpart application. This approach is shown in Figure 1.

Figure 1: Comparison of Standard TCP and MPTCP Protocol Stacks

This solution is essentially a “shim” inserted in the TCP module. To the upper-level application, MPTCP can operate in a manner that is entirely consistent with TCP, so that the opening up of subflows and the manner in which data is assigned to particular subflows is intentionally opaque to the upper-level application. The envisaged *Application Programming Interface* (API) allows the application to add and remove addresses from the local multipath pool, but the remainder of the operation of the MPTCP shim is not envisaged to be managed directly by the application. MPTCP also leaves the lower-level components of TCP essentially untouched, in so far as each MPTCP subflow is a conventional TCP flow. On the data sender’s side, the MPTCP shim essentially splits the received stream from the application into blocks and directs individual blocks into separate TCP subflows. On the receiver’s side, the MPTCP shim assembles the blocks from each TCP subflow and reassembles the original data stream to pass to the local application.

Operation of MPTCP

TCP has the ability to include 40 bytes of TCP *options* in the TCP header, indicated by the *Data Offset* value. If the Data Offset value is greater than 5, then the space between the final 32-bit word of the TCP header (*Checksum* and *Urgent Pointer*) and the first octet of the data can be used for options. MPTCP uses the *Option Kind* value of 30 to denote MPTCP options. All MPTCP signalling is contained in this TCP header options field.

The MPTCP operation starts when the initiating host passes a MP_CAPABLE capability message in the MPTCP options field to the remote host as part of the initial TCP SYN message when opening the TCP session. The SYN+ACK response contains a MP_CAPABLE flag in its MPTCP options field of the SYN+ACK response if the other end is also MPTCP-capable. The combined TCP and MPTCP handshake concludes with the ACK and MP_CAPABLE flag, confirming that both ends now have each other’s MPTCP session data. This capability negotiation exchanges 64-bit keys for the session, and each party generates a 32-bit hash of the session keys, which are subsequently used as a shared secret between the two hosts for this particular session to identify subsequent subjoin connection attempts.

Further TCP subflows can be added to the MPTCP session by a conventional TCP SYN exchange with the MPTCP option included. In this case the exchange contains the MP_JOIN values in the MPTCP options field. The values in the MP_JOIN exchange include the hash of the original receiver’s session key and the token value from the initial session, so that both ends can associate the new TCP session with the existing session, as well as a random value intended to prevent replay attacks.

The MP_JOIN option also includes the sender's address index value to allow both ends of the conversation to reference a particular address even when NATs on the path perform address transforms. MPTCP allows these MP_JOINS to be established on any port number, and by either end of the connection. Therefore, although a MPTCP web session may start using a port 80 service on the server, subsequent subflows may be established on any port pair, and it is not necessary for the server to have a LISTEN open on the new port. The MPTCP session token allows the 5-tuple of the new subflow (protocol number, source and destination addresses, and source and destination port numbers) to be associated with the originally established MPTCP flow. Two hosts can also inform each other of new local addresses without opening a new session by sending ADD_ADDR messages, and remove them with the complementary REMOVE_ADDR message.

Individual subflows use conventional TCP signalling. However, MPTCP adds a *Data Sequence Signal* (DSS) to the connection that describes the overall state of the data flow across the aggregate of all of the TCP subflows that are part of this MPTCP session. The sender sequence numbers include the overall data sequence number and the subflow sequence number that is used for the mapping of this data segment into a particular subflow. The DSS Data ACK sequence number is the aggregate acknowledgement of the highest in-order data that the receiver receives. MPTCP does not use SACK, because this acknowledgement is left to the individual subflows.

To prevent data loss that causes blockage on an individual subflow, a sender can retransmit data on additional subflows. Each subflow uses a conventional TCP sequencing algorithm, so an unreliable connection will cause that subflow to stall. In this case MPTCP can use a different subflow to resend the data, and if the stalled condition is persistent it can reset the stalled subflow with a TCP RST within the context of the subflow.

Individual subflows are stopped by a conventional TCP exchange of FIN messages, or through the TCP RST message. The shutting down of the MPTCP session is indicated by a data FIN message that is part of the data sequencing signalling within the MPTCP option space.

Congestion control appears still to be an open issue for MPTCP. An experimental approach is to couple the congestion windows of each of the subflows, increasing the sum of the total window sizes at a linear rate per *Round-Trip Time* (RTT) interval, and applying the greatest increase to the subflows with the largest existing window. In this way the aggregate flow is no worse than a single TCP session on the best available path, and the individual subflows take up a fair share of each of the paths they use. Other approaches are being considered that may reduce the level of coupling of the individual subflows.

MPTCP and Middleware

Today's Internet is not the Internet of old. It is replete with various forms of middleware that include NATs, load balancers, traffic shapers, proxies, filters, and firewalls. The implication of this reality is that any deviation from the most basic forms of the use of IP will run into various issues with various forms of middleware.

For MPTCP, the most obvious problem is that of middleware that strips out unknown TCP options.

However, more insidious issues come with the ADD_ADDR messages and NATs on the path. Sending IP addresses within the data payload of a NATed connection is always a failure-prone option, and MPTCP is no exception here. MPTCP contains no inbuilt NAT detection functions, and there is no way to determine the direction of the NAT. A host can communicate to the remote end its own IP address or additional available addresses, but if there is a NAT translating the local-host outbound connections, then the actual address will be unavailable for use until the host actually starts a TCP session using this local address as the source.

A simple approach that is effective where NATs are in place is to leave the role of initiation of new subflows to the host that started the connection in the first place. In a client-server environment this solution would imply that the role of setting up new subflows is best left to the client in such cases. However, no such constraints exist when there are no NATs, and in that case either end can initiate new subflows, and the ADD_ADDR messages can keep the other end informed about potential new parallel paths between the two hosts. Logically it makes little sense for MPTCP itself to define a NAT-sensing probe behavior, but it makes a lot of sense for the application using MPTCP to undertake such a test.

The Implications of MPTCP

MPTCP admits considerable flexibility in the way an application can operate when many connection options are available.

All TCP subflows carry the MPTCP option, so that the MPTCP shared state is shared across all active TCP subflows. No single subflow is the "master" in the MCTCP sense. Subflows can be created when interfaces come up, and removed when they go down. Subflows are also IP protocol agnostic: they can use a collection of IPv4 and IPv6 connections simultaneously. Subflows can be used to load-share across multiple network paths, or operate in a primary/backup configuration depending on the application and the flexibility offered in the API in particular implementations of MPTCP.

When applied to mobile devices, this behavior can lead to unexpected results. I always assumed that my device was incapable of “active handoff.” Any connections that were initiated across the cellular radio interface had to stay on that interface, and any connections established over the WiFi interface would also stay on that WiFi network. I always understood that active sessions could not be handed off to a different network. Although it was never an explicitly documented feature (or if it was I have never seen it), I had also assumed that when my mobile device was in an area with an active WiFi connection, then the WiFi would take precedence over its *fourth-generation* (4G) connection for all new connections. This assumption matched the factor of typical data tariffs, where the marginal cost of data over 4G is typically somewhere between 10 and 1,000 times higher than the marginal cost of the same data volume over the WiFi connection. But if applications use MPTCP instead of TCP, then how will they balance their network use across the various networks? The way MPTCP is defined it appears that applications simply open subflows on all available local interfaces, and then the fastest network, rather than the cheapest, will take on the greatest volume of traffic.

But, as usual, it can always get more complicated. What if the WiFi network is a corporate service, with NATs, split-horizon *Virtual Private Networks* (VPNs) and various secure servers? If my device starts to perform MPTCP in such contexts, then to what extent are the properties of my WiFi connection preserved in the cellular data connection? Have I exposed new vulnerabilities by doing this? How can a virtual interface, such as a VPN, inform an MPTCP-aware application that other interfaces are not in the same security domain as the VPN interface?

However, it does appear that MPTCP has a role to play in the area of seamless WiFi handoff. With MPTCP is it possible for a mobile handset to enter a WiFi-serviced area and include a WiFi subflow into the existing data transfer without stopping and restarting the data flow? The application may even shut down the cellular radio subflow when the WiFi subflow is active. This functionality is under the control of the application using MPTCP, rather than being under the control of the host operating system of the carrier.

Going Up the Stack

Of course it does not stop at the transport layer and with the use of MPTCP. Customized applications can perform handoffs themselves.

For example, the “mosh” application is an example of a serial form of address agility, where the session state is a shared secret, and the server will accept a reconnection from any client’s IP address, as long as the client can demonstrate its knowledge of the shared secret.

Extending the TCP data-transfer model to enlist multiple active TCP sessions at the application level in a load-balancing configuration is also possible, in a manner not all that different from MPTCP.

Of course one could take this further. Rather than use multiple TCP sessions between the same two endpoints, you could instead share the data from the same server across multiple endpoints, and use multiple TCP sessions to these multiple servers. At this point you have something that looks remarkably like the peer-to-peer data-distribution architecture.

Another approach is to format the data stream into “messages” and permit multiple messages to be sent across diverse paths between the two communicating systems. This approach, the *Stream Control Transmission Protocol* (SCTP), is similar to MPTCP in that it can take advantage of multiple addresses to support multiple paths. It combines the message transaction qualities of UDP with the reliable in-sequenced transport services of TCP. The problem of course in today’s network is that because it is neither TCP nor UDP, many forms of middleware, including NATs, are often hostile to SCTP and they drop SCTP packets. One additional cost of the escalation of middleware in today’s Internet. These days innovation in protocol models is limited by the rather narrow rules applied by network middleware, and the approximate general rule in today’s Internet is that it’s TCP, UDP, or middleware fodder!

It has been observed numerous times that the abstraction of a network protocol stack is somewhat arbitrary, and it’s possible to address exactly the same set of requirements at many different levels in the reference stack. In the work on multipath support in the Internet, we’ve seen approaches that exploit parallel data streams at the data link layer, at the IP layer, within routing, in the transport layer, and in the application layer. Each has its respective strengths and weaknesses. But what worries me is what happens if you inadvertently encounter a situation where you have all of these approaches active at the same time? Is the outcome one of amazing efficiency, or paralyzing complexity?

TCP Protocol Wars

by Geoff Huston, APNIC

There are two end-to-end transport protocols in common use in today's Internet: the *User Datagram Protocol* (UDP) and the *Transmission Control Protocol* (TCP).

UDP is an abstraction of the basic IP datagram, in that UDP is an unreliable medium. Packets sent using UDP may or may not go to their intended destination. UDP packets may be reordered, duplicated, or lost. UDP has no flow control or throttling. The packet quantization in UDP is explicit: if the sender splits data into two UDP packets, then the receiver will collect the data using two distinct read operations.

TCP is a reliable end-to-end flow-controlled stream protocol. A stream of data passed into a TCP socket at one end will be read as a stream of data at the other end. The packet quantization is hidden from the application, as are the mechanics of flow control, loss detection, and retransmission and session establishment and teardown. TCP will not preserve any inherent timing within the data stream, but will preserve the integrity of the stream.

Critically, the Internet assumes that most of the network resources are devoted to passing TCP traffic, and it also assumes that the flow-control algorithms used by these TCP sessions all behave in approximately similar ways. If the switching and transmission resources of the network are seen as a common resource, then the assumption about the uniform behavior of TCP sessions implies that these end-to-end transport sessions will behave similarly under contention. The result is that, to a reasonable level of approximation, a set of concurrent TCP sessions will self-equilibrate to give each TCP session an equal share of the common resource. In other words, the network itself does not have to impose "fairness" on the TCP flows that pass across it—as long as all the flows are controlled by a uniform flow-control algorithm, the flows will interact with each other in a manner that is likely to allocate an equal proportion of the network resources to each active TCP flow. At least that's the theory.

This theory raises numerous questions of whether these assumptions are true in today's Internet and what may be changing with these assumptions.

Other Protocols?

Is it still a choice between UDP and TCP? Despite many technical efforts to specify new end-to-end transport protocols, there is little chance that any new protocol will gain acceptance in today's Internet. The network contains large numbers of intercepting "middleware," and these units function as security firewalls by using rules that are very limited in the protocols that they admit.

The most common filters in middleware are configured to admit only IP protocols 6 and 17 (TCP and UDP, respectively), and drop all others. This setup has implied that more recent end-to-end transport protocols, such as the *Stream Control Transmission Protocol* (SCTP)^[10] or the *Datagram Congestion Control Protocol* (DCCP)^[11], for example, have very limited applicability in the public Internet, because they can be used only in environments where there is no such intercepting middleware.

TCP or UDP?

In this world where choice is limited to TCP or UDP, the conventional view was that the bulk of the traffic was carried in TCP, whereas UDP was used in limited contexts for *Domain Name System* (DNS) name resolution, running time, and network management. This view raises the question as to whether TCP still carries the bulk of the Internet traffic load.

It is not necessarily true that TCP still carries the bulk of the Internet traffic load, although reliable data sources that provide visibility into the actual traffic profile seen on end user-facing networks is not easily forthcoming. A recent study of traffic profiles between 2002 and 2009 by the *Center for Applied Internet Data Analysis* (CAIDA)^[1] points to a UDP/TCP ratio value of 0.11 when looking at the volume of data being transported by the two protocols. In other words, some 90% of the traffic was carried inside TCP sessions and 10% inside UDP sessions. For UDP this value is considerably higher than would be conventionally expected from the combination of only DNS and *Network Time Protocol* (NTP) payloads in UDP. The study points out: “A port-based analysis suggests that the recent increase in UDP flows on the traces analyzed stems mainly from *Peer-to-Peer* (P2P) applications using UDP for their overlay signalling traffic,” a result that corresponds to reports of the use of the *Low Extra Delay Background Transport* (LEDBAT) protocol for *BitTorrent*^[2]. More recently, video streaming applications have also turned to TCP, using local buffer management in the playback device to overcome TCP-induced signal jitter.

It is reasonable to assume that the overall majority of the Internet traffic load is carried in TCP, and therefore the behavior of the TCP flow-control algorithm is a matter of interest.

TCP Flow Control – TCP Reno

TCP does not have a single flow-control algorithm. Although the common TCP protocol specification defines how to establish and shut down a session, and defines the way in which received data is acknowledged back to the sender, the core protocol specification does not specify how the two ends negotiate the speed at which data is passed between them. This negotiation has been left to the various implementations of the TCP flow-control algorithm.

“Conventional” flow control in TCP is typified by the behavior of the TCP *Reno* algorithm (Figure 1).

Figure 1: Idealised TCP Reno Flow Control

There are two distinct phases of behavior: the *Slow Start* phase, where the sending rate is doubled every *Round-Trip Time* (RTT) interval, and a *Congestion Avoidance* phase, where the sending rate is increased by a fixed amount—one *Message Segment Size* (MSS)—in each RTT interval. When the sender is notified of packet loss—by receiving a duplicate *Acknowledgment* (ACK) message from the receiver—the actions of the sender vary according to its current phase. In *Slow Start* phase a duplicate ACK will shift the sender to *Congestion Avoidance* mode. In *Congestion Avoidance* mode a duplicate ACK will cause the sender to halve its sending rate and continue in this mode. Three duplicate ACKs in succession will cause the session to restart from scratch in *Slow Start* mode, because three duplicate ACKs signals a higher rate of congestion which means that the two ends of the TCP stream have lost their shared flow state assumption.

In steady state the TCP Reno flow-control algorithm increases the flow rate by a constant amount each round-trip time interval, and when a packet is dropped, because of buffer overflow in a switch, the algorithm halves the flow rate. The result is an *Additive Increase Multiplicative Decrease* (AIMD) algorithm, which tends to place high levels of pressure on the buffers in the network while there is still available buffer space, and react dramatically when the buffers eventually overfill and reach the packet drop point. Crudely, this process is a “boom and bust” form of feedback control.

Better than Reno

There have been strong motivations by application families to break out of this form of TCP flow-control behavior. One motivation is to use a more even packet flow across the network, and remove some of the “jerkiness” inherent in TCP Reno. There is also the motivation that a more sensitive flow-control application could achieve a superior outcome compared to TCP Reno. In other words, a different TCP flow-control algorithm could achieve better than its “fair share” when competing against a set of concurrent TCP Reno flows.

The first of these motivations is a simple change. In an attempt to double the pressure on other concurrent TCP sessions, the AIMD algorithm can be adjusted by increasing the sending speed a larger constant amount, and decreasing it by less following packet loss (*MulTCP* uses this model). For example, if the speed was increased by 2 MSS units each RTT interval and the sending rate was reduced by one-quarter rather than one-half upon receipt of a duplicate ACK, then the resultant behavior would, in an approximate sense, behave like two concurrent TCP sessions, and in a fair sharing scenario this form of flow control would attempt to secure double the network resources of an equivalent TCP Reno session.

Another variant of this approach is *Highspeed TCP* which increases its frequency of probing into potentially claimable capacity by increasing its sending rate by a larger volume while keeping its reduction rate at a constant value. This protocol probes for the packet-loss onset at a far higher frequency than either TCP Reno or *MulTCP*, and is capable of accelerating to much higher flow speeds in a much shorter time interval.

Binary Increase Congestion Control (BIC) and its variant CUBIC use a nonlinear increase function rather than a constant rate increase function (Figure 2). Instead of increasing the speed by a fixed amount each RTT in Congestion Avoidance mode, BIC remembers the sending rate at the onset of packet drop, and each RTT interval increases its speed by one-half of the difference between the current sending rate and the assumed bottleneck rate.

BIC quickly drives the session towards the bottleneck capacity, and then probes more cautiously when the sending speed is close to the bottleneck capacity. Again, compared to a Reno flow session, CUBIC should produce a superior outcome.

Other flow-control algorithms move away from using packet loss as the control indication and tend to oscillate more frequently around the point of the onset of queuing in the routers in the network path. This form of feedback control is sensitive to the relative time differences between sent packets and received ACKs.

An example is “packet-pair” flow-controlled TCP, where the sending rate is increased as long as the time interval between two packets being sent is equal to the time interval of the received ACKs. If the ACK interval becomes larger, then this increase is interpreted as the onset of queuing in the sending path, and the sending rate is decreased until the ACK timing interval once again equals the send timing interval.

Apple’s Macintosh systems use *New Reno*, a variant of the Reno flow-control algorithm that improves the Reno loss recovery procedure, but is otherwise the same AIMD control algorithm. Linux kernels have switched to use CUBIC, a variant of the BIC algorithm that uses a cubic function rather than an exponential function to govern window inflation.

Other approaches have headed further away from conventional TCP and change both the server and the client. One way to change both the server and the client is to avoid the use of the operating system-provided implementation of TCP completely, place a TCP-styled reliable flow-control streaming protocol into the application itself, and use the UDP interface of the operating system to pass packets to and from the network.

This approach has been used in the widely deployed *BitTorrent* application (LEDBAT), and more recently by Google in its experiments with *Quick UDP Internet Connections* (QUIC)^[8] and *SPDY* (pronounced “speedy”).

Google’s QUIC uses a TCP emulation in UDP that has a data encoding that includes *Forward Error Correcting Codes* (FEC) as a way of performing a limited amount of repair of the data stream in the face of packet loss without retransmission. QUIC performs bandwidth estimation as a means of rapidly reaching an efficient sending rate. SPDY further assists QUIC by multiplexing application sessions within a single end-to-end transport protocol session. This approach avoids the startup overhead of each TCP session, and leverages the observation that TCP takes some time to establish the bottleneck capacity of the network. The use of UDP also avoids intercepting middleware that performs deep packet inspection on TCP flows and modifies their advertised window size to perform external moderation on TCP flow rate.

There is, however, one issue with the use of UDP as a substitute for TCP, and although public reports from Google on this topic have not been published, it is a source of concern. The problem relates to the use of UDP through *Network Address Translators* (NATs)^[12] and the issue of address binding times within the NAT. In TCP a NAT takes its directions from TCP. When the NAT sees an opening TCP handshake packet from the “inside,” it creates a temporary address binding and sends the packet to its intended destination (with the translated source address of course). The reception of the response part of the handshake at the NAT causes the NAT to confirm its binding entry and apply it to subsequent packets in this TCP flow. The NAT holds state until it sees a closing exchange or a reset signal that closes the TCP session, or until an idle timer expires. For TCP the NAT is attempting to hold the binding for as long as the TCP session is active. For NATs, UDP is different. Unlike TCP, there is no flow-status information in UDP. So when the NAT creates a UDP binding, it has to hold it for a certain amount of time. There is no clear technical standard here, so implementations vary. Some NATs use very short timers and release the binding quickly, matching the expectation of the use of UDP as a simple query/response protocol. The use of UDP as an ersatz packet-framing protocol for user-level TCP implementation requires the NAT to hold the UDP address binding for longer intervals, corresponding to the hidden TCP session. Some NATs will do so, while others will destroy the binding even though there are still UDP packets active, thus disturbing the hidden TCP session.

This example illustrates the level of compromise in today’s environment between end-to-end protocols and network middleware. TCP sessions are being modified by active middleware that attempts to govern the TCP flow rate by active modification of window sizes within the TCP session, negating some of the efforts of the TCP session to optimize its flow speed.

TCP in UDP passes control of the TCP flow management to the application, and hides the TCP flow parameters from the network. However, UDP sessions are susceptible to interruption by NAT intervention, because some NATs assume that UDP is used only for micro-sessions, and long-held UDP sessions are some form of anomalous behavior that should be filtered by removing the UDP port binding in the NAT.

The Transport Protocol Ecosystem

The Internet is somewhat unique in so far as there is no intrinsic network-level functionality that can allocate a certain amount of network resources to each active flow being carried across the network. The network is not actively “managed.” Network resources are allocated to traffic flows in a manner similar to fluid-flow equilibrium. Each active flow exerts pressure on all other concurrent flows. The higher the relative imbalance, the more the largest flows are pressured to reduce their flow rate by the smaller flows. The system reaches a meta-equilibrium point when all concurrent flows receive approximately equal amounts of network resource.

The underlying assumption here is that a fair result is achieved if all the concurrent flows are operating in a similar manner. What is happening in the network today is a fragmentation of the TCP flow-control algorithm as operating systems, and even applications, prefer to use a customized flow-control algorithm that attempts to optimize their position by exerting slightly more pressure on other TCP sessions, causing them to drop their flow rates in response. These techniques do not create additional network transmission capacity, they bias the way in which network capacity is available to individual traffic flows in their favor. So if a TCP session is able to secure better than its “fair share” of a laden network, then other sessions are necessarily affected and receive less than their “fair share.”

There is some relationship between these protocol-level efforts and the *Net Neutrality* policy debates. The proponents of a Net Neutrality position argue that the network should be a largely passive entity, and that the interaction of the various traffic flows produces a fair and efficient outcome. The network resources will be fully allocated to carrying traffic with relatively small levels of retransmission (efficiency), and the concurrent flows will interact with each other to produce an outcome where each flow gathers approximately equal network resource (fair). With the increasing level of diversity in approaches to packet-flow management, and the options of whether to use the flow-control services provided by the operating system platform or go the path of using UDP as the transport protocol and passing the flow-control algorithm to the application, what is being witnessed is some amount of escalation in competitive pressure between applications to secure network resources.

IAB Statement on the Trade in Security Technologies

The *Internet Architecture Board* (IAB) published the following statement on June 15, 2015:

“The Internet Architecture Board is deeply sympathetic with the desire to enhance the security of Internet protocols, infrastructure, and Internet-connected systems. We believe, however, that efforts to enhance Internet security must proceed from a thorough knowledge of the threats against the network, its protocols, and the systems attached to it. Efforts to limit the export or transfer of Internet security technologies seem likely to limit that knowledge in ways that ultimately will frustrate the general goal of a secure and stable Internet.

The identification of vulnerabilities is a fundamental part of security practice. Restrictions on systems which perform that function will make it substantially more difficult for those performing that function to design and deploy secure systems.

Traffic analysis systems, though they may be used in other ways, are a similarly crucial part of the methods used to identify attacks and to analyze the success of remediations put in place. The Internet is a deeply interconnected set of networks that spans international borders, and attacks may occur in one part of the Internet that have extensive ramifications for the operation of the whole. Limiting traffic analysis technologies to specific territories seems likely to hinder efforts to detect and thwart both active threats and other network issues.

We note that in 1996 the IAB and *Internet Engineering Steering Group* (IESG) jointly published RFC 1984^[1], with the following comments on a similar matter, the export of encryption technology:

Export controls on encryption place companies in that country at a competitive disadvantage. Their competitors from countries without export restrictions can sell systems whose only design constraint is being secure, and easy to use.

Usage controls on encryption will also place companies in that country at a competitive disadvantage because these companies cannot securely and easily engage in electronic commerce.

Export controls and usage controls are slowing the deployment of security at the same time as the Internet is exponentially increasing in size and attackers are increasing in sophistication. This puts users in a dangerous position as they are forced to rely on insecure electronic communication.

We believe the same points to be fundamentally true for the export of traffic analysis, penetration testing, and similar security technologies.

While it may appear possible to narrowly circumscribe restrictions so that they target technologies that serve no possible purpose but attack, any modular system, including those intended solely for research, will like have some elements that, divorced from the system, would serve no other purpose. Efforts to target such systems will thus likely sweep up many other security technologies. We therefore recommend that export restrictions on security technologies be generally avoided.”

A Primer on IPv4 Scarcity

The April 2015 Issue of the ACM SIGCOMM *Computer Communication Review* contained an excellent summary of the rise and fall of the IPv4 address space^[1]. The authors have managed to be wonderfully concise, packing into just a little over 8 pages a history of the initial address allocation practices, the evolution of needs-based address provisioning through the *Regional Internet Registry* (RIR) framework, and the onset of depletion and exhaustion in the last five years. The paper also reviews the routed address space, and explains the differences between *occupied*, *routed*, and *allocated* address space. It also explains the concept of efficiency of utilization of addresses. The authors consider IPv4 addresses as a resource and the long standing debate over whether addresses can be considered as conventional “property,” as well as the tension between the policies of the various registries and the perspectives of the holders of address space. The paper outlines recent efforts to augment the registry functions with a form of certification allowing third parties to use a *Public Key Infrastructure* (PKI) to validate the authenticity of attestations about addresses and their use, particularly in the context of the Internet’s routing system. The paper details current efforts in coping with an environment where the traditional source of IPv4 addresses has been exhausted, considers address *markets*, and the interplay between efforts to increase the address utilization efficiency in IPv4 and incentives to adopt IPv6.

Corrections

While we are all looking forward to *Terabit* (1000G) Ethernet, the article in IPJ Volume 18, No.1 entitled “Gigabit Ethernet,” contained errors in the table on page 27. Thanks to reader Marcin Cieślak for pointing this out. Here is the corrected version:

Table 2: Media Options for 40- and 100-Gbps Ethernet

	40 Gbps	100 Gbps
1-m backplane	40GBASE-KR4	
10-m copper	40GBASE-CR4	100GBASE-CR10
100-m multimode fiber	40GBASE-SR4	100GBASE-SR10
10-km single-mode fiber	40GBASE-LR4	100GBASE-LR4
40-km single-mode fiber		100GBASE-ER4

Naming nomenclature:

Copper: K = Backplane; C = Cable assembly

Optical: S = Short reach (100 m); L - Long reach (10 km);

E = Extended long reach (40 km)

Coding scheme: R = 64B/66B block coding

Final number: Number of lanes (copper wires or fiber wavelengths)

Also in Volume 18, No. 1, we told you about Bolt Beranek and Newman Report 4799 entitled “A History of the ARPANET: The First Decade.” It appears that this document is no longer available from the link we gave, so we have placed a copy in the “Downloads” section of our website at protocoljournal.org.

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

FROM THE EDITOR

Just over a year ago we relaunched *The Internet Protocol Journal* (IPJ) under a new funding model. Since that time we have published 5 issues of IPJ, designed and implemented a new subscription system, built a website, established new relationships with authors and contractors, and, most importantly, rebuilt our subscriber base with both previous and new subscribers. With some 15,000 print subscribers and 6,600 e-mail subscribers, we are recreating that all-important *community* that makes this publication unique. We've already received many messages of support and appreciation as well as suggestions for topics and article submissions. Please keep them coming!

None of the work behind IPJ would be possible without the support of numerous individuals and organizations. If you or your company would like to sponsor IPJ, please contact us for further details. Our website at protocoljournal.org contains all back issues, subscription information, a list of current sponsors, and much more.

The general topic of *Internet of Things* (IoT) has received much attention in recent years. One way to explain IoT is to describe it as a large collection of Internet-aware *sensors*—such as the temperature sensor in a thermostat, and associated *actuators*—such as the electronic switch that turns your heating or air conditioning unit on or off. However, Internet-aware sensors can also be used to measure details about the Internet itself, and this is the idea behind the *RIPE Atlas* project, which is described in our main article in this issue.

Just as I was finishing writing this editorial, the *American Registry for Internet Numbers* (ARIN) issued the final IPv4 addresses in its free pool. If your organization has not yet deployed IPv6, now would be a good time to start the process. You will find many articles and pointers to further information about IPv6 in back issues of IPJ, all available from our website.

Another reminder that if you received a printed copy of this journal in the mail, you should also have received a subscription activation e-mail. If you didn't receive such a message, it may be because we do not have your correct e-mail address on file. To update or renew your subscription, just send a message to ipj@protocoljournal.org and include your subscription ID. Your subscription ID is printed on the back of your journal.

RIPE Atlas: A Global Internet Measurement Network

by RIPE NCC Staff

R IPE Atlas is a global Internet measurement network that provides an understanding of the state of the IP Layer in real time. Here we describe the functionality and design of RIPE Atlas, which collects information about Internet connectivity and reachability via thousands of measurement devices around the world. Then it makes this data available to everyone by measuring the *Internet Protocol* (IP) layer of the Internet with real packets, from anywhere, at any time, by everyone, and for the benefit of all.

- *Real packets:* RIPE Atlas measures the IP layer of the whole Internet—not just the last mile or the network of a single provider. It sends real packets and observes responses so it can directly measure the performance of the IP layer. RIPE Atlas does not focus on measuring applications, which run on top of the IP layer. RIPE Atlas is not an observer of metadata like *Border Gateway Protocol* (BGP) routing traffic; there is no need to make inferences from metadata. And it does not observe any user traffic, thus avoiding many ethical concerns. RIPE Atlas supports five different types of measurements: *ping*, *traceroute*, *Domain Name System* (DNS), *Secure Sockets Layer* (SSL), and the *Network Time Protocol* (NTP).
- *From anywhere:* As of July 2015, RIPE Atlas comprises more than 8,400 active vantage points globally. These vantage points are both small hardware devices called probes that volunteers connect to their home or business networks, and *anchors*, which are generally installed in data centres and act as both enhanced probes with more measurement capacity and regional measurement targets within the greater RIPE Atlas network. Currently, more than 8,300 probes and 133 anchors are deployed in 173 countries and in 11% of all IPv6 *Autonomous System Numbers* (ASNs) and 6% of all IPv4 ASNs. Although this coverage is still far from “everywhere,” it is quite an extensive network—and the architecture allows for scaling up by another order of magnitude.
- *At any time:* Measurements can be started at any time from a chosen subset of these devices and can be performed quickly, or they can be set up to run for weeks, months, or even years. This scenario allows for both quick glances for troubleshooting purposes and deeper analyses of long-term trends. In order to make results comparable, we carefully control the experimental conditions.
- *By everyone:* RIPE Atlas was conceived to collaboratively build and share a huge measurement infrastructure, rather than building individual small ones for exclusive use. Everyone can contribute to RIPE Atlas by hosting a probe or anchor, by building tools to run measurements or analyse results, by providing sponsorship funding, or by helping us distribute probes to difficult-to-reach locations. Everyone contributing to RIPE Atlas can use the network to run their own measurements from virtually all devices.

- *For all:* RIPE Atlas data is openly available, and everyone can benefit from the tools and analyses that others provide. By default, measurement specifications are open for inspection, and all results are accessible to everyone and can be accessed for many years. This continued accessibility means that anyone can reproduce experiments and analyses using RIPE Atlas data, and that is the only way to do real science; it fosters development and the sharing of tools. Having all data openly available also allows others to reuse existing results. RIPE Atlas data consists of a large number of results from a large number of vantage points to a large number of destinations. The topology of the IP layer is far from flat or fully interconnected; thus, by design, the data contains a lot of information about “core” parts of the IP layer. This information can be used to produce maps about the IP layer topology, and that is why we chose the name, *RIPE Atlas*.

In general, RIPE Atlas can be used to:

- Continuously monitor the reachability of a network or host from thousands of vantage points around the globe
- Investigate and troubleshoot reported network problems by conducting ad hoc connectivity checks
- Test IPv6 connectivity
- Check the responsiveness of DNS infrastructure, such as root name servers
- Execute measurements from a large number of vantage points for use in academic research

We describe specific use cases for RIPE Atlas data in more detail in the “Use Cases” section later in this article.

History and Funding

Before RIPE Atlas, the *Réseaux IP Européens Network Coordination Centre* (RIPE NCC) ran numerous other measurement platforms. RIPE Atlas replaced the older *Test Traffic Measurement Service* (TTM)^[1], an active measurement tool geared towards optimising the use of transmission resources that was developed at a time when transmission capacity was much scarcer than it is now. In contrast, RIPE Atlas was developed for an environment where a stable and well-optimised network layer is more critical to the quality of service in the IP layer than squeezing the most out of scarce transmission resources.

The RIPE NCC^[2] began developing RIPE Atlas in 2010 to complement its array of measurement and data-gathering tools^[3] with membership-supported funding. The RIPE NCC membership continues to fund the bulk of RIPE Atlas operations, expansion, and development. Many external sponsors also support RIPE Atlas financially.

Our focus on the IP layer of the entire Internet is very much in line with the needs of our members, mainly Internet Service Providers, who provide the bulk of the funding. In recent years, RIPE Atlas has been extended to measure numerous core services, such as the DNS, in addition to the IP layer. However, this added measurement does not affect our main focus. We are also committed to keeping all measurement data accessible for as long as possible so that this data can be used for future purposes and so that anything based on it can be independently verified at any time.

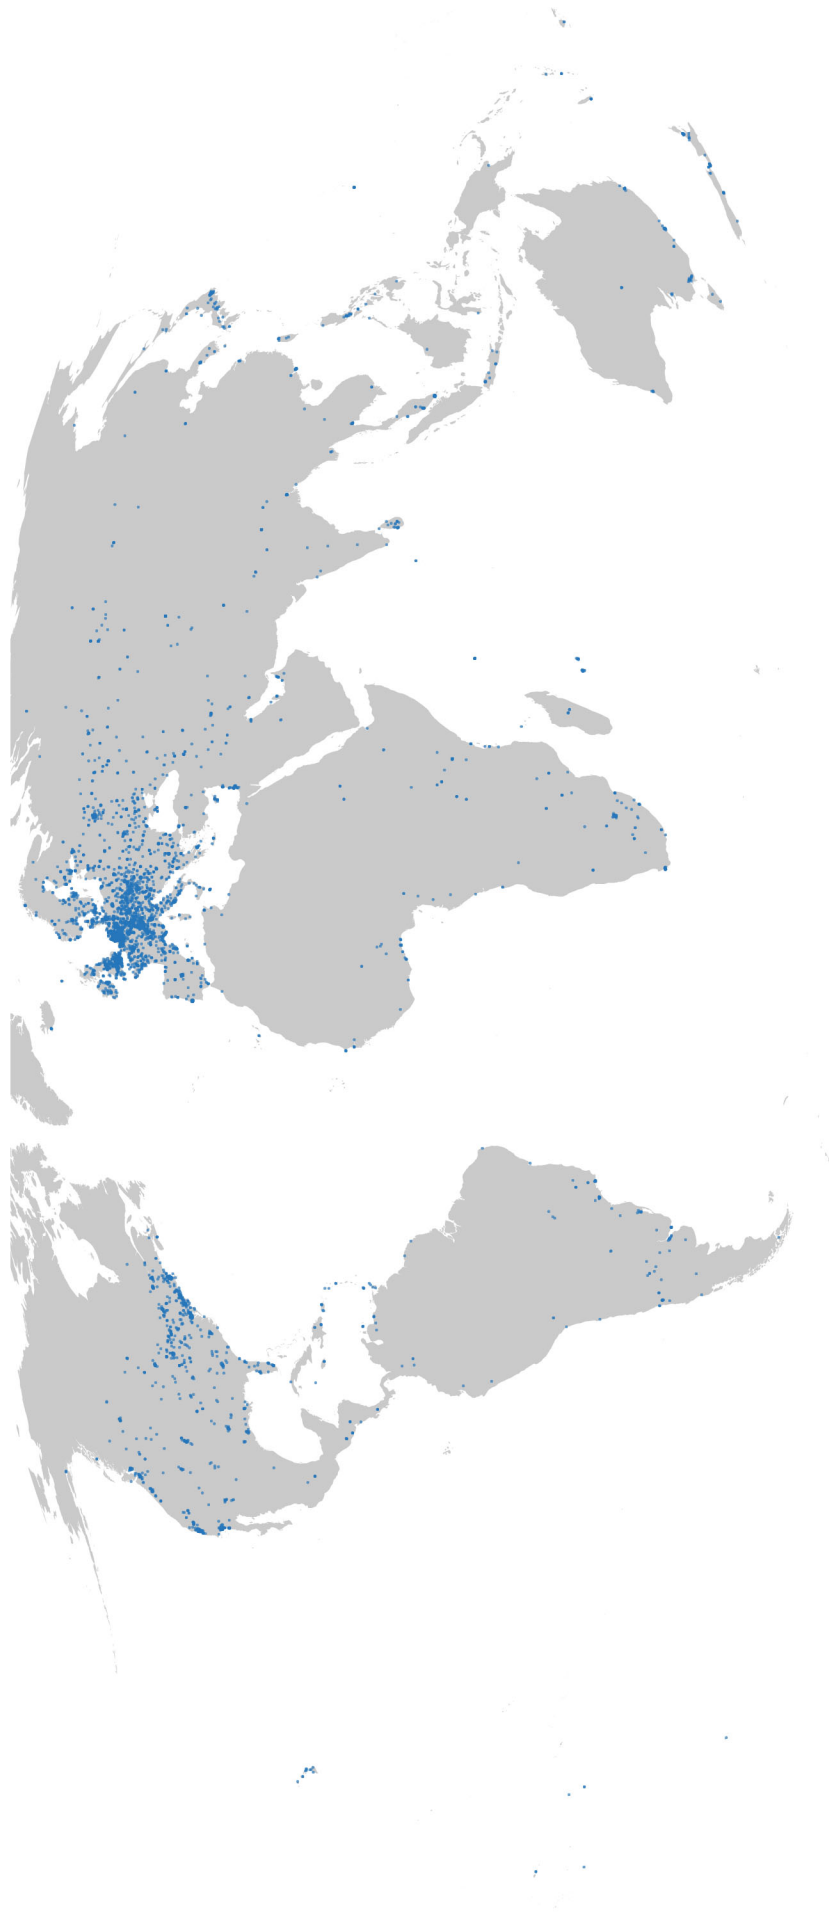

Use Cases

Since the beginning of RIPE Atlas, the network has produced interesting data that everyone can use, regardless of whether or not they host a probe or anchor themselves. Over the last few years especially, the increased reach of the network has meant that researchers, operators, and other RIPE Atlas users have used RIPE Atlas data to debug network problems, analyse network behaviour, and conduct their own interesting research. Many useful visualisations have also been developed based on RIPE Atlas data. Here we list just a few examples:

- A group of researchers from Africa measured inter-domain routing to determine the best possible locations to establish Internet exchange points in the region.^[4]
- A severe power outage and a variety of network outages were analysed and visualised, highlighting how the Internet routes around outages.^[5, 6]
- Engineers from the *Wikimedia Foundation* and the RIPE NCC collaborated on a project to measure the latency of Wikimedia sites and improve performance for users worldwide.^[7]
- Recently, the RIPE NCC developed a tool to analyse how much of a country's local traffic actually leaves the country, and the role that Internet exchange points play in keeping traffic local.^[8]
- A team of researchers investigated content-blocking incidents in Turkey and Russia, as well as outlining ethical considerations when using measurement networks that involve volunteers as hosts, and giving a comparative overview of RIPE Atlas and other measurement networks.^[9]

RIPE Atlas users also produce useful and stunning visualisations that make it easier to grasp the results of RIPE Atlas measurements. For example, one network operator visualised the measurements collected by the local RIPE Atlas anchor, and was able to analyse the quality of the local connectivity and topology changes and help debug network problems.^[10] *CartoDB* helped us visualise network outages and other interesting network behaviour based on RIPE Atlas.^[11] RIPE Atlas also helps make geolocation data of Internet infrastructure more accurate over time. We started a crowd-sourcing project in which operators can specify the geolocation of servers and other equipment based on RIPE Atlas *traceroute* data.^[12]

Figure 1: RIPE Atlas Probes Connected on 2015-07-20 at 05:42:26 UTC ^[23]

The first-ever *RIPE Atlas Hackathon*, held in March 2015, also produced a great variety of visualisations based on RIPE Atlas measurement data, including visualised *traceroute* consistencies over time, a display connecting large-scale probe disconnections to Twitter feeds and weather data, and a map of probe data by country.^[13]

Overall Design

We defined a few fundamental principles early on that influenced the system design: our choice to use dedicated hardware devices as vantage points, the ability to scale up, the distributed and collaborative nature of the deployment, and the related security considerations.

Hardware vs. Software Vantage Points

Even though it incurs measurable costs, we chose dedicated hardware devices as vantage points for many reasons.

The hardware devices are “install and forget,” and in this sense they are not prone to disappearing after an operating system upgrade or a home router replacement, for example. They are easy to deploy because they act as just another device on the network, and after installation they can run uninterrupted, 24/7. Hardware probes also provide a well-defined environment, so the results are much more comparable than widely varying platforms. All in all, these conditions support the goals of achieving datasets with long time series.

We also prefer to not assume responsibility for code that runs on host-provided systems. Any bug or vulnerability in a hardware probe does not affect or compromise another system. If necessary, a probe can easily be disabled by simply unplugging it.

The current generation of probes is well suited to support the functionality of the system. At the moment, the probes are much more constrained by bandwidth limitations, which the hosts can impose themselves, rather than their CPU, memory, or storage capabilities.

Scalability and Resilience

At the time of RIPE Atlas’ conception, about 35,000 *Autonomous Systems* (ASs), were active on the Internet. If we wanted to have vantage points in all of them, account for some of them not being active all the time, and aim for some additional redundancy, we needed to plan for three devices in each network—leading to a rough approximation of 100,000 probes. Of course it’s naïve to think we can install a device in every single AS, plus bigger and geographically more distributed networks would require even more probes. But this number is very useful as a potential upper limit, and it served as a good base for the infrastructure design.

Having this scalability goal does not mean that we immediately deployed enough infrastructure components to handle the full load. The system is in constant evolution in terms of supporting the hardware infrastructure, the redundancy and scalability of critical components, and the software components we use.

The scalability goal also pointed out early on the need for deploying controls on how the measurements and probes behave. Even with much lower deployed numbers, it's not reasonable to run all measurements on all probes all the time, so there is a need for controlling the amount, distribution, and scheduling of system resources. This need gave rise to numerous principles and components, like the credit system and the scheduler, which we describe in the next section.

The infrastructure is designed to operate in a distributed fashion. Most components have enough local knowledge to fulfill their role but don't necessarily know about the state of the whole system or even other components. This setup makes it possible to operate most functions even in the case of a network split. For example, probes keep on executing measurements even if they are not connected to the infrastructure, and all components (including probes) buffer results in case the "next hop" in the result processing chain is unavailable. The communication protocols are designed such that they can handle temporary disruptions. In this sense the system is self-healing; assuming that infrastructure problems can eventually be resolved, the probes and the associated processing pipeline will eventually converge on a stable state and all buffered data will be delivered. The probes are also "headless" (they don't have a console interface), and it's essential for the system to be able to support this kind of recovery.

Collaborative Approach and the Ecosystem

No global measurement network can grow beyond a trivial size without relying on collaborators and fostering an interested community around it.

Our approach is relatively simple: we ask network operators and users to help us reach new networks and deploy probes in them. By installing a probe in a network that previously didn't contain any, probe hosts increase the number of vantage points and allow RIPE Atlas to execute measurements from this new network. Beyond contributing to the larger network, probe hosts also enjoy tangible benefits:

- By keeping the probe active, the host accumulates "credits," a form of currency they can use to perform their own customised measurements using the RIPE Atlas network.
- As soon as a probe becomes active, it starts a set of "built-in" measurements that can point out potential local issues with the host's network.
- Probe hosts can use the credits they earn to execute measurements using any probe in the network, with numerous rules that regulate the use of these resources, as described later in this article.

The costs for measurements are determined such that they are proportional to the complexity of the measurement, the amount of traffic generated, and a few other factors that depend on the specific measurement type.

We also impose a daily limit on the number of credits that users can spend, the number of measurements each user can run, and the number of probes they can use in these measurements. The purpose of the credit system and these constraints is to prevent abuse and overload of the system itself or of popular measurement targets. However, a lack of credits should not prevent any reasonable use of RIPE Atlas. Credits can be transferred between users, and we provide additional credits for tool developers and specific measurement campaigns.

Security Considerations

Since the very idea of RIPE Atlas is to send and receive network traffic from vantage points across the globe, security and reliability have been very important from the beginning of the project.

In order to reduce the attack surface of the probes, we decided to make them as closed as possible. They don't offer any services that users or programs can connect to (in the TCP/IP sense). Instead, they make only outgoing connections, both towards the RIPE Atlas infrastructure and for measurements. They also don't share any authentication tokens among each other; each probe has its own key that it uses to authenticate itself to the infrastructure. Of course, since the probes are physically in the hands of hosts, it's virtually impossible to make them resilient to tampering or disassembly, but these actions should not affect other probes in the network.

All communication within the infrastructure (probes included) is done via encrypted, mutually authenticated channels. In the case of the probes, this communication is through a *Secure Shell* (SSH) protocol connection that is also used to channel control traffic and result traffic back and forth, whereas we use *Transport Layer Security* (TLS) for communication between the control components.

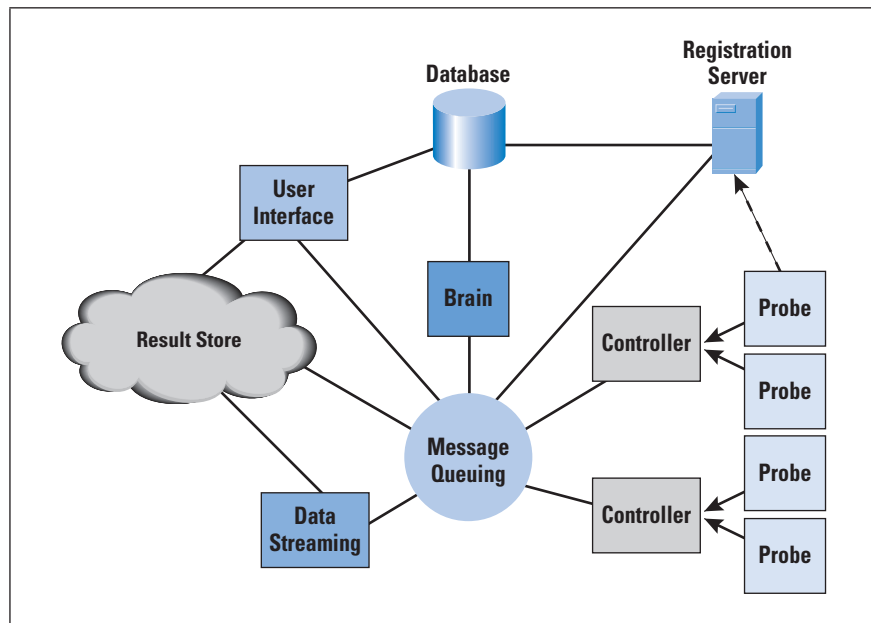

The software running on the probes is field-upgradeable, with the probes being able to verify the authenticity of new firmware via cryptographic signatures. This setup allows us to deploy new functionality as well as security enhancements, so the risk of having a security vulnerability that we are unable to fix is very low.

Of course, no system is 100% resilient against attacks. We run a custom firmware, which may have its flaws, on baseline operating systems (*CentOS*, *OpenWrt*, and *uClinux*). We believe the current security mechanisms provide adequate protection against casual attackers, and the potential for more serious disruptions to the network is limited to sufficiently resourceful attackers, making it quite low.

Architecture and Infrastructure

The RIPE Atlas architecture is designed with the previously mentioned key principles in mind: scalability, resilience, and so on. The general structure is shown in Figure 2.

Figure 2: The Overall System Structure

A central *Structured Query Language* (SQL) system database contains a lot of the key information: almost all of the information about the probes and their various properties; metadata about measurements; users; credits; etc.

A cluster of *message queue servers* acts as the central nervous system for the architecture. It provides connectivity between the various components, and ensures a one-time, guaranteed message delivery with very small delays. It also eliminates the need for each component to maintain knowledge about which other components are present, whether they are connected, etc. This cluster has enough capacity to both deal with control messages and pass on result data, though at a later point we may split these two tasks or change to a more direct data-reporting channel.

Whenever a probe starts up, it first connects to one of many pre-configured *registration servers*. These servers allow only connections from known probes using their specific public keys. When a probe connects, the servers determine which controller the probe should be directed to based on the location of the probe, the availability of controllers, and other factors. The servers then redirect the probe to the chosen controller and notify this controller about the probe. During this process, they inform the probe and the controller about each other's public keys.

The *controllers* accept probe connections from the list of probes they get from the registration servers; they do not have full knowledge of all probes. Once a probe connects, they keep the channel open to receive results and to notify the probes about measurement tasks. Although theoretically each controller can handle a large number of probes, we're trying not to overuse this capability in order to avoid too much fate-sharing between probes when individual controllers or data centres become disconnected.

The *brains* execute higher-level functions in the system, notably the measurement scheduling. This activity happens based on the requests received via the *User Interface* (UI) and *Application Program Interface* (API), and involves an elaborate set of steps about probe preselection, negotiations with the controllers about probe availability, etc. Brains also act as an interface and filtering service between controllers and the central database in order to propagate probe metadata to the UIs.

The UI takes care of all user interactions. It serves the pages for the web interface and handles the API calls. It also serves data download requests via the API; we will likely separate this activity into a separate component if the number of requests or the amount of data transfers creates a bottleneck.

The data streaming servers provide real-time access to the flow of result data, directly off the result queues, and include a few minutes of “short-term memory” to supply recent results. They can also replay results that have already been stored in the result store.

Finally, the *result store* is a Hadoop/HBase cluster for long-term storage of all results. It also handles periodic calculation of aggregates and various other tasks. The technology used allows for relatively cheap redundant storage of the dataset, as well as a simple way of executing *MapReduce*-type batch operations to extract information from datasets that are otherwise too large to download and analyse.

In addition, there are a number of auxiliary subsystems attached to the infrastructure that perform various functions, such as dealing with DNS (“SOS”) requests from probes, managing the administrative tasks, or monitoring and analysing the behaviour of the system in near real time. *RIPEstat*^[14] also closely cooperates with the UIs to visualise the stored datasets.

This architecture allows easy expansion if any one component becomes a bottleneck. For example, it’s very simple to add more controllers to the system to handle additional probes as needed.

Implementation

Over the years, RIPE Atlas has gone through numerous transitions, shaped both by interactions with the wider community and the challenge of managing so much data. At the start of the project, RIPE Atlas was quite static: result data was restricted to data collected by hosts’ own probes, with a handful of visualisations provided by the RIPE Atlas team based on data collected from the (then) small network of a few hundred probes.

Over time, however, we introduced the concept of user-defined measurements, which allowed individual probe hosts to use the growing network to do things we hadn’t initially considered. Slowly, and in consultation with the community, the options for these user-defined measurements grew, allowing for more protocols and more options within them, so that hosts can now take advantage of a global network to perform *ping*, *traceroute*, DNS, SSL, and NTP measurements with a plethora of options.

Interfaces

As we expanded the available features, we needed to change the ways in which users interfaced with the system. Where once we had a very data-heavy ExtJS-based website, we built a more user-friendly interface to access a variety of data visualisations. At the same time, we also gave access to our data to those wanting to create their own views by standardising on a *Representational State Transfer* (REST) ful API, streaming API, and result-parsing toolkit.

We also added a few new sections to the website to improve the user experience:

- A *credits* page with a chart to help users understand how many credits they were earning and spending
- A *keys* page to allow users to create API keys that they can use to create new measurements with the RESTful API or share existing result data
- Separate pages for different groups of users, including “ambassadors” (those who help us distribute probes), financial sponsors, and anchor hosts

The largest change was the way in which we display probe and measurement information. The first instances of this change were cluttered, grid-like interfaces, which we replaced with a searchable listing and highly visual renderings of measurement results and probe performance. Many of these new interfaces are powered by the publicly available APIs.

Lastly, we introduced an updated and much more user-friendly interface for creating measurements. Guided by feedback from users of the old ExtJS-based system, measurement creation became a single form with three sections, of which only the first required direct input. Users are left to decide whether they want to accept the defaults for the other sections or be more specific.

This new measurement form was coupled with numerous helper tools, including:

- A credit consumption visualiser that helps users gauge the long-term expense of their proposed measurement
- An elaborate probe selection wizard that allows users to search, filter, and select probes across networks and geographical space: This selector also implements a standard autocomplete that covers ASN, prefix, IP, address family, and current probe status.
- An API example panel that shows the equivalent request as if it were submitted via the API: This panel was designed to serve as a learning tool for those interested in working with the API for future measurement creation.

This new tool, combined with the availability of the RESTful API, made it much easier to create and manage measurements.

Visualisations

In addition to downloading results in *JavaScript Object Notation* (JSON) format or accessing them via the streaming API, users can also benefit from the visualisations we have created for some measurement types. These visualisations are usually made with JavaScript and *Scalable Vector Graphics* (SVG). The back end provides only the data, while the visualisation and the data correlation are done completely client-side and are accessible from a web browser without third-party plug-ins. They can be embedded in any HTML page or shared by means of permalinks. These visualisations include:

- Simple, tabulated layouts of key parameters extracted from measurement results: These layouts can give an immediate impression about how the target behaves according to the measurement.
- Maps of all kinds showing success rates, round-trip times, or measurement results, where each involved probe and its latest result are denoted by colour, shape, or size: These maps are constructed to work with practically all types of measurements that the system supports.
- Simple charts of packet loss and round-trip times for *ping* measurements, also featuring a shift and zoom function to explore past results.
- A “seismograph” that shows results of *ping* measurements from multiple probes: This tool allows users to compare results from multiple probes at the same time, making it really powerful to spot common behaviour across multiple ASNs, countries, or regions. The tool also supports zooming and exploring historical data.
- A complete rewrite of the RIPE NCC tool *DNS Monitoring* “(DNSMON)”^[15] to visualise long- and short-term behaviour and reachability of root DNS servers and important top-level DNS domains: In many aspects, the RIPE Atlas version of DNSMON goes well beyond the functionality of its predecessor, for example, by incorporating *traceroute* measurements alongside the DNS queries and offering this information to help users diagnose observed performance changes.
- A tool that shows common paths towards particular targets, based on *traceroute* measurements

There is a lot of further potential in providing more visualisations to our users. In particular, we are working on extracting more information from *traceroute* measurements. Combined with the ability to zoom in or out using ASN, prefix, or even geographical aggregations, this information can give an easy-to-understand, immediate explanation of where network bottlenecks or dysfunctional network paths are located.

Data Storage

A global measurement network as big as RIPE Atlas has unique requirements for storing and accessing the collected data.

As of July 2015, about 8,000 concurrently running measurements produce more than 2,700 results per second. Depending on the measurement type, the size of the result can vary from a few bytes to kilobytes. All measurements ever run since the start of RIPE Atlas have been kept. Hence it is not a surprise that the net size of all measurements until this point has grown to 24 TB. On top of this amount is another 4 TB worth of derived data, resulting in a total of 28 TB of active Internet measurement data. Keeping this data online, indexed, and accessible in real time is a challenge on its own.

Storage Solution

After a period of extensive testing and comparing available storage solutions, we decided on *Apache Hadoop*, because it seemed to be scalable and reliable. In addition, at the time of our decision in 2011, it was one of the few open-source solutions capable of dealing with data on a terabyte level. Related to the open-source nature of Hadoop was a choice of different distributions, and we selected the one created by Cloudera (CDH).

Hadoop, maintained as an Apache project, is a software framework that allows for the distributed processing of large datasets. Its design makes it possible to scale from a single server to thousands of machines, with each machine offering local computation and storage. High availability and data security are built into the library itself, so we didn't have to depend on expensive hardware and we could use inexpensive commodity hardware instead.

The Hadoop distributed file system allows for high-throughput access to the application data. Another key component is *MapReduce*, which is a simple programming model that breaks up large datasets and splits data-processing tasks so they can be run in parallel on multiple nodes in a cluster. On top of this stack we use *HBase*, another part of the Hadoop ecosystem, which provides a structured, table-like storage model for large, distributed datasets.

What we described earlier as the “result store” currently consists of one development cluster and two production clusters, one live and one standby. Each production cluster has 119 machines providing a total of 3.5 TB of memory and 952 CPUs. Of the 119 machines, 110 act as workers on which data is stored and jobs are executed. The other 9 machines schedule jobs and manage cluster resources. Each worker can store approximately 4 TB of data, providing a total of 400 TB of storage capacity (after formatting).

Each production cluster is roughly at two-thirds of its capacity, accounting for 260 TB. The cluster also stores other datasets, such as *Border Gateway Protocol* (BGP) routing data collected by *Routing Information Service* (RIS)^[16]. Nevertheless, the storage requirements for RIPE Atlas alone are significant because, in order to achieve reliable storage, Hadoop uses replication, which blows up the requirements for RIPE Atlas data to 75 TB using a replication factor of three.

It might be surprising that we run two production clusters, given that Hadoop has reliability built in, so one cluster might seem to be sufficient. In fact, only by using two clusters were we able to test new features and platform updates without running the risk of long service interruptions in case something went wrong. As with any software, Hadoop is not bug-free, and we especially noticed this reality when we used its first releases just as “big data” was becoming a buzzword. As it moves toward a more stable system, it might be an option in the future to combine the two clusters, resulting in double the current capacity.

Data Flow

From the message queue servers, the measurement data, in the form of *Advanced Message Queuing Protocol* (AMQP) messages, is loaded by daemons running on all worker nodes. The payload, in JSON format, is extracted and stored directly in HBase tables and saved as sequence files. Sequence files are a binary format of the collected data, which act as an efficient input for MapReduce jobs that create tables derived from raw data.

Data derivation is specifically necessary because Hadoop, like many other NoSQL solutions, is a key-value store and hence lacks elaborate concepts of data projection and selection. The key, which is the only available index, becomes very important, and different access use cases require different key layouts, resulting in data duplication.

An often-used derivation is time-based aggregation, which compacts data collected over a long period of time to a fraction of its original size. By extracting statistically relevant values like minimum, maximum, and median, users (via the UI) are still able to get an overview of the measurement result without having to download all of the measurement data.

Initially orchestrated by *cron* jobs, the execution of MapReduce jobs is now done with a software component called *Azkaban*. Azkaban can account for dependencies between datasets and—most importantly—data availability, and the result is much better data quality for the derived datasets.

Next to regularly running jobs, the system also supports ad hoc data processing, which enabled our data scientists to crunch volumes of data that would have never fit on anyone’s workstation.

Datasets

RIPE Atlas data consists of multiple tables. From the size value, one can see the difference between raw and aggregated tables, highlighting how aggregation saves a lot of space and makes overviews much faster.

- *Result blobs*: all messages fetched from the message queue servers; this data is the rawest form accessible as a table and acts as the input for most other tables (24 TB)

- *Latest results*: the latest measurement result per probe and measurement (50 GB)
- *Counters*: information about the amount of results delivered per probe and measurement, also used for credit billing (4 GB)
- *DNS details and aggregates*: all DNS measurements and their aggregates, also the ones used for DNSMON (800 + 200 GB)
- *Ping results and aggregates*: contains all *ping* measurements and all its aggregates used for *ping* visualisations (3.5 TB + 140 GB)
- *Traffic*: data on how much traffic a probe produced, upstream and downstream (12 GB)

The front-end servers (RESTful) gain access to the data via Apache *Thrift*. Thrift is a software framework that allowed us to build seamlessly integrated data types and service interfaces between the Hadoop Java environment and the front-end Python environment.

Measurements

RIPE Atlas performs two distinct sets of measurements. The first category is the “built-in measurements,” performed by all probes as soon as they are connected; it provides a baseline flow of generally useful results. The second category is the “user-defined measurements” that users specify themselves, which usually run on only a small subset of the probes.

Built-In Measurements

When a probe is plugged in, it initiates connection to the RIPE Atlas infrastructure and is connected to a controller, which sends a list of predefined, built-in measurements. These measurements are designed to provide useful data to the host for monitoring their connectivity and discovering potential local issues, but they also provide a wide array of generally useful results for network visualisations.

Built-in measurements include:

- *Pings* to first and second hops
- *Pings* and *traceroutes* to well-known destinations, such as DNS root servers and RIPE Atlas anchors
- DNS SOA, `version.bind`, `hostname.bind`, `id.server`, and `version.server` monitoring on the DNS root servers
- HTTP and SSL requests to some of the RIPE NCC servers

Built-in measurements are performed via both IPv4 and IPv6 if a probe seems capable of supporting both protocols. The measurements are ongoing, with most of them running every few minutes. The list of running built-in measurements is defined solely by the RIPE Atlas team; probe hosts have no influence over it. Data for the built-in measurements is publicly available.

User-Defined Measurements

The distinct feature that makes RIPE Atlas unique and provides value for all participants is its ability to let users schedule their own measurements using virtually all of the probes throughout the network with great flexibility. Users are free to choose:

- Measurement type (from the supported set)
- Type-specific options such as flags and parameters
- IP version
- Measurement target (for example, hostnames or IP addresses)
- Measurement source (that is, vantage points); this source is the set of probes defined by size and desired properties, such as geography, ASNs, prefixes, and tags. It is also possible to reuse the same sets of probes that were used in previous measurements.
- Measurement start/end time and the frequency of ongoing measurements

Each measurement can be ongoing (with a user-defined frequency) or a one-off measurement. One-off measurements are more expensive to handle, but they have a much faster reaction time, delivering results in a matter of seconds.

User-defined measurements can be created and maintained using the web interface, as well as the RESTful API. Users can stop measurements prematurely if they wish, and can also change the set of involved probes.

User-defined measurements are the most resource-consuming activity within RIPE Atlas, and we therefore need to balance the system capacity with our users' needs. To achieve this balance, we constantly increase the number of probes, throughput of the measurement result delivery, and storage. The credit system also plays a large role. It encourages users to keep their probes connected, so they earn credits to use on user-defined measurements, and to use the system with care. The more resource-intensive a measurement (number of probes, probe CPU, network activity), the more expensive it is.

Current Measurement Types

At the time of writing, RIPE Atlas supports the following measurement types:

- *Ping*: monitors network delays using *Internet Control Message Protocol* (ICMP) IP echo messages
- *Traceroute*: displays the route path and measuring transit delays
- *DNS*: queries Domain Name System servers or resolvers (provides users with similar functionality of well-known tools such as *dig* and *nslookup*)
- *SSL*: queries SSL/TLS certificates of remote servers
- *NTP*: queries Network Time Protocol servers, dumps the reply, and computes some statistics, such as reply time

Every measurement type allows the user to specify parameters for fine-tuning. For example, *ping* allows the user to change the number and size of packets, while DNS has a much wider set of options, allowing users, for example, to set query parameters, recursion, number of retries, and so on.

Future Measurement Types

We constantly work with the RIPE Atlas community to satisfy our users' demands for different measurement functionality. We have started to add new measurement types and continue to add new options for fine-tuning them, as long as they are consistent with the RIPE Atlas mission. The following measurements are likely to be introduced in the near future:

- *HTTP*: queries HTTP servers. The system is technically already capable of doing this task; it is used internally to deliver results, but it's not yet available for public use. Public availability will most likely be restricted to allowing users to perform GET and HEAD requests against a predefined list of targets (initially RIPE Atlas anchors).
- *WiFi*: an intentionally opt-in-only feature to verify the functionality of *Wireless LAN* (WLAN) access points: The intention is to check whether it's possible to connect to a requested, specific *Service Set Identifier* (SSID), and measure the IP connectivity of this interface. We do not intend to use WLAN connection for IP connectivity of the probe itself, and we don't plan to allow passive WiFi scans.

Day-to-Day Development

RIPE Atlas is developed by a team of software engineers with overlapping focuses. Although we don't follow a particular methodology, RIPE Atlas development is agile in the sense of iteratively delivering and improving upon working features, responding to feedback from the community, and continuously focusing on good design and architecture. Development is modular, with each type of component having its own *Git* repository, automated deployment mechanism, and release schedule. The frequency of these release cycles varies according to development intensity. For example, the UI has the highest rate of change and so has a new release almost every week—with larger stretches for fundamental changes that possibly include bug fixes and hot fixes in the interim—while the brain may go weeks between new features and releases.

In addition to the main RIPE Atlas system, two internal environments are fully functional, each made up of the various components necessary to make a working system. The first is a development environment, which is used to test new features, either directly or as a verification stage after modular, test-driven development. Test-driven development is particularly important and powerful when making changes that are cumbersome or time-consuming to test with a real RIPE Atlas network—even a scaled-down development version—where real components have to “talk” to each other at network speeds.

In such cases, it is helpful to write unit tests for each part that represents the desired or correct interaction between components, and to write code until the tests pass. The second environment is a test or preproduction network that runs the next release while it is being prepared for production. Depending on the magnitude of a release, this test can take anywhere from less than a day to a week or more.

Each of these environments, including the production system, has a suite of system tests that verify a range of behaviours, including logging in to the website, creating measurements, and downloading results. This suite of tests acts as an end-to-end sanity check and can catch things that manual testing and unit tests might miss, or issues that may crop up only after unpredictable real-world use. This suite is complemented by a dashboard, which enables interactive visualisation and analysis of patterns and spikes in error rates, and various bespoke statistical graphs.

Probe Hardware Experiences

The first version of RIPE Atlas probes was very limited. The probe was based on a Lantronix XPort Pro module.^[17] This module contains a FreeScale MCF5208 ColdFire processor, 8 MB of main memory, and 16 MB of flash storage. It is a 32-bit CPU with no *Memory Management Unit* (MMU). The module was complemented with a power board that takes power from USB (5V) and converts it to the 3.3V the module needs. The power board is then enclosed in a small black case.

Black-Box Model

The limitations of these first-generation probes led to a black-box model. The probes have no buttons; the Ethernet connector has link and activity LEDs and nothing else. Because of the limited amount of main memory, it would be difficult to run a web server on the probes for configuration.

The attractiveness of this model comes from the fact that a probe host has to connect only the USB connector to a USB port for power and plug in an Ethernet cable for network connectivity. The probe does not run any services, which is also good for security. Because the probes do not cost the hosts anything, we wanted to make them difficult to tamper with to avoid having people re-purpose them for their own uses.

Automatic Firmware Upgrades

Automatic firmware upgrades are another feature of the black-box model. Probe hosts do not have to care about upgrading the probe firmware. At first glance, firmware upgrades are easy enough. The flash memory of the probe is split into two parts; one part contains the firmware, and the other is used to temporarily store measurement results.

During a firmware upgrade, the new firmware is written to the partition that contains the measurement results, and the boot configuration is changed to boot the other partition.

Automatic firmware upgrades mean that almost all bugs can be fixed in later firmware versions, except those that prevent a firmware upgrade in the first place. We also want to use probes for as long as possible, so probes that may have been lying in a drawer for a long period of time should be able to upgrade to the latest firmware. This stipulation places rather tight restrictions on the backward compatibility of the firmware upgrade process.

One question that arises is whether it would be possible for an attacker to upgrade probes with malicious firmware. With the original firmware, this question meant attacking one of a few core servers or the SSH connection between the probe and the registration server. To further reduce the possibility of this attack, probes now verify a digital signature attached to the firmware. The digital signature is made offline and with secret splitting to make sure that multiple people are involved in signing the firmware.

Debugging a Black Box

A question that arises rather quickly is how to debug a black box. What do you do with a probe in a remote location that has no display and no buttons to press? Just about the only interaction possible is to power-cycle the probe. Because probes communicate over the network, we can distinguish two broad classes of problems: ones that prevent the probe from reporting results and ones that do not.

The second class can be solved most of the time by ensuring an appropriate amount of logging and taking advantage of the scale of the system. Over time, logging got more and more refined as a result of lessons learned trying to debug problems. For example, probes regularly log free memory and free disk space, making it possible to spot memory leaks.

For the first class, we have a few techniques and tricks. The first is that probes perform special DNS queries (called “SOS”) when they reboot; the queries include the message they want to send as part of the hostname they look up. In some cases, a probe can contact a registration server but nothing else. In that case, we can direct the probe, for example, to an IPv4 address literal if we suspect DNS problems or force the probe to use either IPv4 or IPv6 if we suspect that the problem is with one of the protocols.

All of these tasks can be done without involving the probe host, although they can assist in two ways. Some hosts can run *tcpdump* on their routers, in some cases possibly giving us a clue about what went wrong. The probe also logs details about what goes wrong when it tries to connect, so connecting the probe to a different network allows these logs to be reported. It should be noted that connecting a probe to a home router is more likely to work than most office or data centre setups, because home routers have rather simple dynamic configurations and a lack of firewalls compared to more strictly managed environments.

Static Network Configuration

Most probes obtain their network configuration dynamically, using *Dynamic Host Configuration Protocol* (DHCP) for IPv4 and *Router Advertisements* (RAs) for IPv6. In some networks, however, those services are not available. To support those networks, probes can also receive network configuration from the back-end servers, but this process creates a “Catch 22” because a probe needs network access to be able to obtain network configuration from the back-end servers.

To solve this problem, the probe first has to be connected to a network that dynamically configures the probe. The probe can then fetch the network configuration and store it in flash memory. After a static network configuration successfully communicates to the probe this way, the probe can be moved to the target network.

However, this process introduces two problems. The first is that static network configuration has to be carefully copied across firm-ware upgrades. The second is that if somehow the static network configuration does not work, the probe has to revert back to dynamic network configuration. This reversion is quite tricky to achieve in practice and, over time, quite a few bugs have caused problems with it. In many cases, they required carefully tweaking the affected probes to get them back on track. Even though this feature adds a lot of complications, it also allows deployment in networks that would otherwise be inaccessible for us, so we expect to support this model in the long run.

It’s worth noting that static configuration can also cause unexpected problems. We’ve seen many cases in which the addresses of DNS resolvers defined for the local network changed over time, but the probe was never informed about it. This change leaves the probe in an inconsistent state that requires manual intervention. For this reason, we do not recommend that hosts use static configuration unless there’s no other solution.

Network Problems

One challenge with the black-box model is that debugging problems typically requires the probe to have a working network connection. Unfortunately, misconfigured networks are among the most common problems.

One problem that is relatively easy to work around is misconfigured DNS. Probes have the names and public keys of two registration servers, which are used to bootstrap the connection to the back-end servers. By adding IPv4 and IPv6 addresses to the names, the probes can connect even if DNS resolution fails. The probes try addresses and names in random order until one succeeds. Obviously, DNS measurements are still doomed on such a probe.

It is possible that the probe simply did not get a lease from DHCP, or got the wrong address or default router, etc. In such a case, the infrastructure side can't detect any life signs from the probe, and it is entirely up to the probe host to resolve the problem. Something similar applies to firewalls; sometimes it is possible to spot a firewall if the DNS traffic from the probe is detected, but we see no SSH traffic.

Finally, there are *Path MTU Discovery* (PMTU) problems. IPv4 typically does not have PMTU problems, but IPv6 does. A quick hack to avoid the IPv6 PMTU problems then causes problems with some routers used by probe hosts that make mistakes in *TCP Maximum Segment Size* (MSS) clamping.

All of these issues make troubleshooting a probe that fails to connect a bit of a trial-and-error game. Again, it sometimes helps to ask the probe host to move the probe to a new network so that it can report what it logged about the first network.

Different Probe Versions

One problem caused by the lack of an MMU on the first-generation probes was memory fragmentation. On systems with an MMU, main memory fragmentation is no problem because it does not cause fragmentation of the virtual memory of a process. On systems without an MMU, fragmented main memory cannot be hidden and, essentially, the only way to deal with memory fragmentation is to reboot the probe. Certainly with early firmware versions, the 8 MB of memory would quickly fragment and probes would reboot, sometimes within one day.

Fortunately, Lantronix was responsive to this issue and released a version with 16-MB main memory. These devices became the second-generation probes.

However, the CPU in the version 1 and 2 probes remained slow, with it taking about 30 seconds to set up an SSH connection. The 8 MB that is available for storing measurement results was not a lot if the probes lost their connection for more than a few days. In addition, off-the-shelf travel routers are both more powerful and cheaper than the Lantronix modules, which are designed for industrial applications.

This situation led to the third-generation probes, which are based on the TP-Link TL-MR3020 travel routers (see Figure 3). They have a much faster CPU and 32-MB main memory, but only 4-MB flash memory. Fortunately, a USB connection was available where we could plug in a USB flash device, although this need required a redesign of the firmware. During normal operation, the probe runs from the external USB flash, which is encrypted to make the probe more tamper-resistant. On the built-in flash is a small amount of code that can switch to the external USB and can also fetch firmware over the network and write it to the USB flash device.

This approach has a disadvantage in that it is a lot more complex than what runs on the version 1 and 2 probes. However, an advantage is that, if the USB flash becomes corrupt or nonfunctional because of a bug, the built-in flash version can simply overwrite it with a fresh copy. Upgrading the built-in flash is also possible, but ensuring that all combinations work proves to be quite tricky.

Finally, a need for high-capacity probes that would be rack-mounted in data centres resulted in the anchors. Anchors are rack-mounted PCs running CentOS Linux. From a firmware point of view, the main differences are that the probe code runs as a regular application and all network management is left to normal CentOS configuration. To the host, an anchor is a black box just like the regular probes, but remote-management cards make it possible to configure the anchors directly. In contrast to normal probes, anchors also run various basic services, allowing them to act as measurement targets as well.

Figure 3: Atlas Probe Version 3

Hardware Problems

With the version 1 and 2 probes, hardware problems were, and remain, rare. A very small fraction of the devices have developed hardware failures, and those failures fall into three groups: power failures, Ethernet failures, and flash-memory failures. We have not looked into it deeply, but power failures are likely a failure of the power regulation board. A few probes developed problems with the Ethernet interface; typically, they can send packets but cannot receive them. Finally, with some probes, the flash memory has broken.

The situation is quite different with the version 3 probes. One of the first things that became apparent is that some USB ports used to power the probes did not supply enough power. The curious effect is that only the external USB flash device refuses to start, leaving the probe with a configuration as if no USB flash device is plugged in. We solved this problem by having the probe perform special DNS queries to indicate that it cannot find a USB flash device.

Some time later, the USB sticks once again proved to be a weak link, although we should note that the number of failures is a few dozen out of thousands of probes. The USB sticks sometimes fail to work in various ways: some become read-only, while others reset their configuration to a default state. Typically, they then show a capacity of only 64 MB and have simple patterns as serial numbers. Finally, actual data corruption has occurred in a few cases.

Far less frequently than broken USB flash devices, sometimes the TP-Link devices develop power failures or problems with the Ethernet interface.

IPv4 and IPv6

Probes support both IPv4 and IPv6; however, IPv4 and IPv6 differ in many subtle ways. One feature that does not occur in IPv6 (or at least we are not aware of any probe in the network that deploys it) is *Network Address Translation* (NAT)^[20]. When a probe reports a measurement result, the local IPv4 address is, in many cases, a local address defined by RFC 1918^[21]. The RIPE Atlas system tries to keep track of what the corresponding public IPv4 address is, and the back end inserts that address in the measurement results when they come in. For IPv6, that complexity is not implemented.

At first, all probes with a global IPv6 address were assumed to be IPv6-capable. However, it turns out that a significant fraction of those addresses have a *Unique Local Address* (ULA)^[22] and have no actual Internet connectivity. A second issue with IPv6 is that a probe may have multiple IPv6 addresses. The problem here is that, without special measures, it is not clear which address a probe will use in a measurement. A probe may use different addresses depending on the measurement target.

It is attractive to think of a probe being in a certain AS. However, each address can be in a different AS, meaning a probe can have different ASs for its IPv4 and IPv6 addresses, and a probe with multiple IPv6 addresses may, at least theoretically, also have different ASs for each address.

RIPE Atlas Community

From the beginning we knew that, in order to succeed, RIPE Atlas would need a strong community around it, both to help us grow the network by hosting probes and anchors and to help spread the word about the usefulness of the project for network operators, researchers, and interested users. We also rely on the Internet community and anyone using RIPE Atlas to give us feedback about new features we develop, useful functionality they would like to see, and the future direction of the project.

We regularly update the community about the development of RIPE Atlas via articles on RIPE Labs^[18] that explain new features and functionality and ask for feedback.

We also publish different use cases and analyses that employ RIPE Atlas data, and have a special collection on RIPE Labs^[19] that includes articles and blog posts written by external RIPE Atlas users about their own experiences, as well as scientific papers based on RIPE Atlas data, and presentations about RIPE Atlas given by members of the community at various conferences.

The RIPE Atlas network is essentially a volunteer-based project; it relies almost entirely on a community of probe and anchor hosts to install the hardware devices in their own networks. Most probe hosts initially heard about RIPE Atlas from the RIPE NCC directly, either via our website, mailing lists, or at various conferences, and applied online for their probe.

Initially, we distributed probes via post, free of charge, to anyone who applied, with the goal of reaching critical mass. As we've come closer to reaching our goal of 10,000 probes in the past year, we've started being more selective in distributing probes and have employed checks to ensure that probes are distributed to ASNs that don't already have a probe connected within them (although RIPE NCC members can receive a probe regardless of this stipulation). Anchor hosts also play an important role in strengthening the RIPE Atlas network and boosting its capacity, and, unlike regular probe hosts, they contribute to the project financially by purchasing the required hardware.

We also rely heavily on our ambassadors—currently more than 240 volunteers—who help us distribute probes and give presentations about RIPE Atlas at conferences all over the world. The RIPE NCC also has partnerships with the other *Regional Internet Registries* (RIRs) to help distribute probes in their service regions.

Each year, numerous organisations support RIPE Atlas by contributing to the project financially, and we are grateful to them for their support.

The RIPE Atlas website contains numerous “Community” pages that highlight new probe hosts, those hosts with the largest number of measurements and credits spent, anchor hosts, sponsors, and the different conferences where ambassadors will be available to answer questions and hand out probes.

RIPE NCC members enjoy several special benefits, including receiving extra credits for their own use and having access to a recently developed webinar on advanced use of RIPE Atlas measurements. During the webinar they have the opportunity to learn from and interact directly with RIPE Atlas developers.

In March 2015, we also hosted the first *RIPE Atlas Hackathon*, a three-day event in which developers, designers, computer science students, and open data enthusiasts were invited to use RIPE Atlas data to develop useful, creative, and stunning visualisations for the benefit of the entire Internet community.

The hackathon produced some very promising results, and we hope to host more such events in the future.

The past five years have been very exciting for the RIPE Atlas development team. It has been interesting to see the system grow from an idea into more fully realised concepts, then a prototype, and finally into a full service. RIPE Atlas is certainly still evolving, and its continued development is very much based on a steady stream of ideas and suggestions from the community.

It has also been nice to see how more and more people—network operators and researchers, but also regular Internet users—have started using RIPE Atlas to measure to their heart’s content. We are happy to see people build tools for their specific uses and share them. We are very grateful to all our users, probe and anchor hosts, sponsors, ambassadors, contributors and everyone who has helped build this network—and hope we can count on your continued involvement for the benefit of the entire Internet community. You can get involved with RIPE Atlas by visiting this website:

<https://atlas.ripe.net/get-involved/>

Conclusion

RIPE Atlas is a globally deployed tool to actively measure the IP layer of the Internet. It is a collaboration of many, led by the development team at the RIPE NCC. It is useful for both ad hoc observations and long-term data collection. The number of its permanently operating vantage worldwide points stands at more than 8,000 and is constantly increasing. Everyone can contribute, and anyone who does contribute can use the entire system worldwide. Measurement results are stored for many years and thus everything based on RIPE Atlas results can be independently verified.

THE RIPE NCC is the Regional Internet Registry for Europe, the Middle East, and parts of Central Asia. As such, it allocates and registers blocks of Internet number resources to its membership in this region, which consists mainly of Internet service providers, telecommunication organisations, and large corporations. It is a not-for-profit organisation that works to support the RIPE (*Réseaux IP Européens*) community and the wider Internet community. The following RIPE NCC staff have contributed to this article: Daniel Karrenberg (overall vision and probe firmware); Robert Kistelevi (architecture and team leader); Antony Antony and Philip Homburg (probe firmware); Christopher Amin, Massimo Candela, Viktor Naumov, Daniel Quinn, Andreas Strikos, Johan ter Beest and Christian Teuschel (infrastructure); Emile Aben and René Wilhelm (research); Suzanne Taylor Muzzin (communications); Mirjam Kühne and Vesna Manojlovic (community building). Rob Blokzijl Receives 2015 Postel Service Award

The Internet Society recently announced that its prestigious *Jonathan B. Postel Service Award* was presented to Rob Blokzijl for his pioneering work, 25 years of leadership at *Réseaux IP Européens* (RIPE), and for enabling countless others to spread the Internet across Europe and beyond. Dr. Blokzijl was selected by an international award committee, comprised of former Jonathan B. Postel award winners, which placed particular emphasis on candidates who have supported and enabled others in addition to their own specific actions.

During the 1980s, Dr. Blokzijl was active in building networks for the particle physics community in Europe. Through his experience at the *National Institute for Nuclear and High Energy Physics* (NIKHEF) and *The European Organization for Nuclear Research* (CERN), he recognized the power of collaborating with others building networks for research and travelled worldwide to promote cooperation across networkers. In the 1990s, Dr. Blokzijl was influential in the creation of the Amsterdam Internet Exchange, one of the first in Europe. His most widely recognized contribution is as founding member and 25-year chairman of RIPE, the European open forum for IP networking. Dr. Blokzijl was also instrumental in the creation of the *RIPE Network Coordination Centre* (RIPE NCC) in 1992, the first Regional Internet Registry in the world.

“Rob’s technical expertise and tireless work had a profound impact on the development of the Internet as we know it today,” said Kathy Brown, President and Chief Executive Officer of the Internet Society. “Beyond the breadth of his technical contributions, Rob is known across the Internet community for his strong leadership and unwavering commitment to collaboration and cooperation, exemplifying the spirit of this award.”

Internet Society

The Postel Award was established by the Internet Society to honor individuals or organizations that, like Jon Postel, have made outstanding contributions in service to the data communications community. The award is focused on sustained and substantial technical contributions, service to the community, and leadership.

The Internet Society presented the award to Dr. Blokzijl, including a US\$20,000 honorarium and a crystal engraved globe, during the 93rd meeting of the *Internet Engineering Task Force* (IETF) held in Prague, Czech Republic, July 19–24, 2015.

The Internet Society (www.internetsociety.org) is the trusted independent source for Internet information and thought leadership around the world. It is also the organizational home for the IETF. With its principled vision, substantial technological foundation and its global presence, the Internet Society promotes open dialogue on Internet policy, technology, and future development among users, companies, governments, and other organizations. Working with its members and Chapters around the world, the Internet Society enables the continued evolution and growth of the Internet for everyone.

IESG Statement on Maximizing Encrypted Access To IETF Information

The *Internet Engineering Task Force* (IETF) has recognised that the act of accessing public information required for routine tasks can be privacy sensitive and can benefit from using a confidentiality service, such as is provided by *Transport Layer Security* (TLS).^[1] The IETF in its normal operation publishes a significant volume of public data (such as Internet-drafts), to which this argument applies. The IETF also handles non-public data (such as comments to *NomCom*, the IETF's nominating committee) that requires confidentiality due to the nature of the data concerned.

The *Internet Engineering Steering Group* (IESG) and the broader community^[3] have further concluded that there can be other harmful effects in continuing to access public data as clear-text. Recent massive-scale man-on-the-side intermediary attackers have been seen to take advantage of the absence of security to mount active attacks that would be more difficult had a transport security mechanism such as TLS been used.^[2, 4]

The IESG has therefore agreed that all IETF information must, by default, be made available in a privacy-friendly form that matches relevant best current practices. Further, all future embedded interactions with the IETF (such as `<a>` tags in HTML) should default to causing access via that privacy-friendly form. For content currently accessed using the HTTP protocol, using HTTPS URIs and appropriate TLS cipher-suites^[5] will be the preferred access mechanism, however this direction encompasses more than HTTP traffic alone.

However, as there may be tools affected by this, and recognising that there are a number of IETF participants who prefer to continue to access materials via cleartext, or who have issues with using standard confidentiality services, the IESG are also requiring that public information continue to be made available in clear, for example via HTTP without TLS.

The changes caused by this statement should only need operational systems work and should be transparent to almost all consumers of IETF information. There are a small number of cases where these changes might cause some issues, for example, the current Internet-Draft boilerplate text, which uses the `http:` URI scheme. The IESG will work with the broader community, tools teams, and IETF Secretariat to make these adjustments while minimising disruption to the community.

Note that the “secure/privacy-friendly as the default according to best practices” principle set out in this statement applies to all IETF information, regardless of the protocol used to access that information.

IANA Transition Update

As announced in our March issue (Volume 18, No. 1), the United States *National Telecommunications and Information Administration* (NTIA) announced its intent to “...transition Key Internet Domain Name Functions to the global multistakeholder community” in March 2014. For the latest information on this process, please visit <https://www.icann.org/stewardship>

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

FROM THE EDITOR

The Internet continues to grow at an amazing pace. WiFi access to the Internet is now almost standard in every hotel room, business, home, and even onboard many airplanes. Mobile operators are offering improved Internet access for smartphones and tablets as well as “personal hotspots” through deployment of emerging *Long Term Evolution* (LTE) standards. Several of the *Regional Internet Registries* (RIRs) have now depleted their available IPv4 address pool, and IPv6 deployment is taking place in most parts of the world.

This growth of the Internet is not only the result of more *people* using the network, but also the result of more Internet-aware *things* being connected. These things can be anything from traditional computer systems and peripherals to home security systems, vehicles, sensors of all kinds, and even light bulbs. Collectively referred to as *The Internet of Things* (IoT), this emerging area of technology is receiving much attention, and efforts are underway to standardize the communication protocols used in IoT. William Stallings gives an overview of these efforts in our first article.

As with most emerging technologies, the potential for failure, misuse, and just “bad design” is always present. The article “The Internet of Stupid Things” by Geoff Huston illustrates some of the challenges in IoT. The article is available from APNIC’s website:

<https://labs.apnic.net/?p=620>

According to the RFC Editor website, the *Request for Comments* (RFC) series “...contains technical and organizational documents about the Internet, including the specifications and policy documents produced by four streams: the *Internet Engineering Task Force* (IETF), the *Internet Research Task Force* (IRTF), the *Internet Architecture Board* (IAB), and *Independent Submissions*.” Since 1969 these documents have been produced in ASCII-only format without the ability to include drawings (other than so-called “ASCII Art”) or other typographical refinements. This situation is about to change with the introduction of a new format for RFCs. We asked Heather Flanagan, the RFC Series Editor, to give us an overview of this effort.

We would love your feedback on anything you read in this journal. With your permission we can include your comments in the form of a Letter to the Editor, or you may consider writing a Book Review. Send your message to ipj@protocoljournal.org

The Internet of Things: Network and Security Architecture

by William Stallings, Independent Consultant

The *Internet of Things* (IoT) is the latest development in the long and continuing revolution of computing and communications. Its size, ubiquity, and influence on everyday lives, business, and government dwarf any technical advance that has gone before. IoT is a term that refers to the expanding interconnection of smart devices—ranging from appliances to tiny sensors. A dominant theme is the embedding of short-range mobile transceivers into a wide array of gadgets and everyday items, enabling new forms of communication between people and things, and between things themselves. The Internet now supports the interconnection of billions of industrial and personal objects, usually through cloud systems. The objects deliver sensor information, act on their environment, and in some cases modify themselves, to create overall management of a larger system, like a factory or city^[1].

The “things” in IoT are primarily deeply embedded devices, characterized by narrow bandwidth, low-repetition data capture, low-volume data usage. These devices communicate with each other and provide data via user interfaces. Some embedded appliances in the IoT, such as high-resolution video security cameras, video *Voice over IP* (VoIP) phones, and a handful of others, require high-bandwidth streaming capabilities. But countless products simply require packets of data to be intermittently delivered.

This article provides an overview of IoT, and then looks at IoT network and security architectures that will help guide the design, implementation, and deployment of IoT.

Background

The evolving Internet involves billions of objects that use standard communications architectures to provide services to end users. This evolution provides new interactions between the physical world and computing, digital content, analysis, applications, and services. The resulting IoT provides unprecedented opportunities for users, manufacturers, and service providers in a wide variety of sectors. Areas that will benefit from IoT data collection, analysis, and automation capabilities include health and fitness, healthcare, home monitoring and automation, energy savings and smart grid, farming, transportation, environmental monitoring, inventory and product management, security, surveillance, education, and many others.

Technology development is occurring in many areas. Not surprisingly, wireless networking research is being conducted and actually has been conducted for quite a while now, but under previous titles such as mobile computing, pervasive computing, wireless sensor networks, and cyber-physical systems.

Many proposals and products have been developed for low-power protocols, security and privacy, addressing, low-cost radios, energy-efficient schemes for long battery life, and reliability for networks of unreliable and intermittently sleeping nodes. These wireless developments are crucial for the growth of IoT. In addition, areas of development have also involved giving IoT devices social networking capabilities, taking advantage of machine-to-machine communications, storing and processing large amounts of real-time data, and application programming to provide end users with intelligent and useful interfaces to these devices and data.

Many have provided a vision for the IoT. Stankovic^[2] suggests personal benefits such as digitizing daily life activities; patches of bionic skin to communicate with surrounding smart spaces for improved comfort, health, and safety; and smart watches and body nodes that optimize access to city services. Citywide benefits could include efficient, delay-free transportation with no traffic lights and 3-D transportation vehicles. Smart buildings could not only control energy and security, but also support health and wellness activities. In the same ways people have been provided new ways of accessing the world through smartphones, the IoT will create a new paradigm in the ways we have continuous access to needed information and services.

Cisco estimates that over the next decade the value at stake (net profit) for the IoT economy is \$14.4 trillion^[3]. The company's research indicates that five main drivers of this value are at stake:

- *Asset use* (\$2.5 trillion): IoT reduces selling, general, and administrative expenses and cost of goods sold by improving business-process execution and capital efficiency.
- *Employee productivity* (\$2.5 trillion): IoT creates labor efficiencies that result in fewer or more productive man-hours.
- *Supply chain and logistics* (\$2.7 trillion): IoT eliminates waste and improves process efficiencies.
- *Customer experience* (\$3.7 trillion): IoT increases customer lifetime value and grows market share by adding more customers.
- *Innovation, including reducing time to market* (\$3.0 trillion): IoT increases the return on R&D investments, reduces time to market, and creates additional revenue streams from new business models and opportunities.

Similarly, a 2015 report from McKinsey Global Institute^[4] estimates that the IoT has a total potential economic impact of \$3.9 trillion to \$11.1 trillion per year by 2025. On the top end, the value of this impact—including consumer surplus—would be equivalent to about 11 percent of the world economy in 2025.

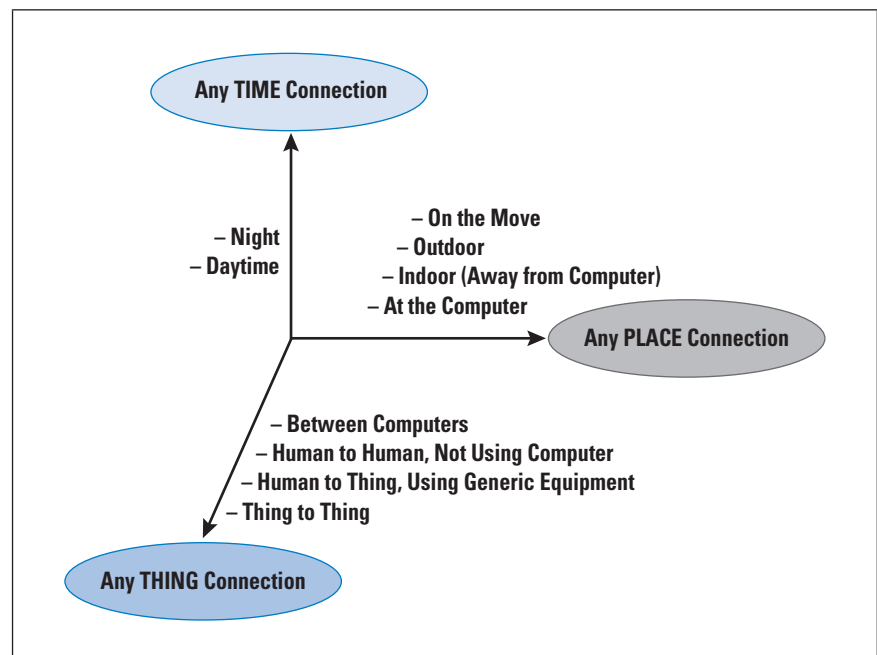

The Scope of the Internet of Things

The *Telecommunication Standardization Sector of the International Telecommunication Union* (ITU-T) has published Recommendation Y.2060, entitled “Overview of the Internet of Things.”^[5] The document provides the following definitions that suggest the scope of IoT:

- *Internet of Things* (IoT): A global infrastructure for the information society, enabling advanced services by interconnecting (physical and virtual) things based on existing and evolving interoperable information and communication technologies.
- *Thing*: With regard to the Internet of Things, this is an object of the physical world (*physical things*) or the information world (*virtual things*), which is capable of being identified and integrated into communication networks.
- *Device*: With regard to the Internet of Things, this is a piece of equipment with the mandatory capabilities of communication and the optional capabilities of sensing, actuation, data capture, data storage, and data processing.

Most of the literature views the IoT as involving intercommunicating smart objects. Recommendation Y.2060 extends this concept to include virtual things, a topic examined subsequently. Recommendation Y.2060 characterizes the IoT as adding the dimension “Any THING communication” to the information and communication technologies that already provide “any TIME” and “any PLACE” communication (Figure 1).

Figure 1: The New Dimension Introduced in the Internet of Things

In the book *Designing the Internet of Things*^[6], the elements of the IoT are condensed into a simple equation:

$$\text{Physical Objects} + \text{Controllers, Sensors, Actuators} + \text{Internet} = \text{IoT}$$

This equation neatly captures the essence of the Internet of Things. An instance of the IoT consists of a collection of physical objects, each of which:

- Contains a microcontroller that provides intelligence;
- Contains a sensor that measures some physical parameter and/or an actuator that acts on some physical parameter;
- Provides a means of communicating via the Internet or some other network.

One item not covered in the equation, and referred to in the Y.2060 definition, is a means of identification of an individual thing, usually referred to as a tag.

Note that although the phrase *the Internet of Things* is always used in the literature, a more accurate description would be an *Internet of Things*, or a *Network of Things*. A smart-home installation, for example, consists of numerous things in the home that are interconnected via Wi-Fi or Bluetooth with some central controller. In a factory or farm setting, a network of things may be enabling enterprise applications to interact with the environment and run applications to exploit the network of things. In these examples, remote access over the Internet is usually, but not invariably, available. Whether or not such Internet connection is available, the collection of smart objects at a site, plus any other local compute and storage devices, can be characterized as a network or an internet of things.

Table 1, on page 6, based on a graphic from Beecham Research^[7], gives an idea of the scope of IoT.

IoT Interoperability Standards

In the near term, disparate islands of solutions are likely to outpace deployment of interoperable standards-based solutions for IoT. This situation is common when any new technology or application area emerges. For example, Sutaria and Govindachari^[8] point out that two characteristics of networked IoT devices that pose challenges are the presence of low-power devices (which need to function for months or years without power recharge) and frequent data exchanges over lossy networks. Existing Internet standard protocols are suboptimal in this context. In a broader sense, there is a mismatch between the vast number of devices generating data at a rapid rate over a dispersed area and using a variety of network technologies and cloud-based systems that store vast amounts of data in a small number of locations with a relatively slow rate of data update. Integrating these two classes of systems to meet user needs requires specific protocol capabilities along the whole network/protocol architecture, from physical through middleware to application levels.

Table 1: The Internet of Things

Service Sectors	Application Groups	Locations	Example Devices
IT and Networks	Public	Services, e-commerce, data centers, mobile carriers, fixed carriers, ISPs	Servers, storage, PCs, routers, switches, PBXs
	Enterprise	IT/data center, office, private nets	
Security/Public Safety	Surveillance Equipment, Tracking	Radar/satellite, military security, unmanned, weapons, vehicles, ships, aircraft, gear	Tanks, fighter jets, battlefield comms, jeeps
	Public Infrastructure	Human, animal, postal, food/health, packaging, baggage, water treatment, building environmental, general environmental	Cars, breakdown-lane worker, homeland security, fire, environmental monitor
	Emergency Services	Equipment and personnel, police, fire, regulatory	Ambulances, public security vehicles
Retail	Specialty	Fuel stations, gaming, bowling, cinema, discos, special events	POS terminals, tags, cash registers, vending machines, signs
	Hospitality	Hotels, restaurants, bars, cafes, clubs	
	Stores	Supermarkets, shopping centers, single sites, distribution centers	
Transportation	Non-vehicular	Air, rail, marine	Vehicles, lights, ships, planes, signage, tolls
	Vehicles	Consumer, commercial, construction, off-road	
	Transportation Systems	Tolls, traffic management, navigation	
Industrial	Distribution	Pipelines, materials handling, conveyance	Pumps, valves, vats, conveyers, pipelines, motors, drives, converting, fabrication, assembly/packing, vessels, tanks
	Converting, Discrete	Metals, paper, rubber, plastic, metalworking, electronics assembly, test	
	Fluid/Processes	Petro-chemical, hydrocarbon, food, beverage	
	Resource Automation	Mining, irrigation, agricultural, woodland	
Healthcare and Life Science	Care	Hospital, ER, mobile PoC, clinic, labs, doctor office	MRIs, PDAs, implants, surgical equipment, pumps, monitors, telemedicine
	In-vivo, Home	Implants, home monitoring systems	
	Research	Drug discovery, diagnostics, labs	
Consumer and Home	Infrastructure	Wiring, network access, energy management	Digital camera, power systems, dishwashers, eReaders, desktop computers, washer/dryer, meters, lights, TVs, MP3, games console, lighting, alarms
	Awareness and Safety	Security/alert, fire safety, environmental safety, elderly, children, power protection	
	Convenience and Entertainment	HVAC/climate, lighting, appliance, entertainment	
Energy	Supply/Demand	Power generation, transportation and distribution, low voltage, power quality, energy management	Turbines, windmills, UPS, batteries, generators, meters, drills, fuel cells
	Alternative	Solar, wind, co-generation, electro-chemical	
	Oil/Gas	Rigs, derricks, well heads, pumps, pipelines	
Buildings	Commercial, Institutional	Office, education, retail, hospitality, healthcare, airports, stadiums	HVAC, transport, fire and safety, lighting, security, access
	Industrial	Process, clean room, campus	

To address these issues, several industry bodies and standards forums are working on extending or adopting the Internet protocols to the IoT devices. To provide for a common frame of reference and categorize needed functions and their location in the protocol stack, several of these groups are also addressing the issue of a formal architecture for IoT. While existing standards and the Internet make IoT possible, a suite of widely expected new standards that adapt or augment existing ones for IoT is likely not possible in the near term. Like many other developments made possible by the Internet, IoT will evolve in the wild for a while and pass through Darwinistic processes, with sensible technologies and protocol mechanisms gradually becoming visible. In this article, we look at two efforts at developing overall frameworks that may be useful in this ongoing standardization process.

ITU-T IoT Reference Model

Given the complexity of an IoT, it is useful to have an architecture that specifies the main elements and their interrelationship. An IoT architecture can have the following benefits:

- It provides the IT or network manager with a useful checklist with which to evaluate the functionality and completeness of vendor offerings.
- It provides guidance to developers as to which functions are needed in an IoT and how these functions work together.
- It can serve as a framework for standardization, promoting interoperability and cost reduction.

This section presents an overview of the IoT architecture developed by ITU-T. The next section looks at one developed by *IoT World Forum*. The latter architecture, developed by an industry group, offers a useful alternative framework for understanding the scope and functionality of IoT.

The ITU-T IoT Reference Model is defined in Recommendation Y.2060^[5]. Unlike most of the other IoT reference models and architectural models in the literature, the ITU-T model goes into detail about the actual physical components of the IoT ecosystem. This treatment is useful because it makes visible the elements in the IoT ecosystem that must be interconnected, integrated, managed, and made available to applications. This detailed specification of the ecosystem drives the requirements for the IoT capability.

An important insight the model provides is that the IoT is in fact not a network of physical things. Rather, it is a network of *devices* that interact with physical things, together with application platforms—such as computers, tablets, and smartphones—that interact with these devices. Thus, we begin our overview of the ITU-T model with a discussion of devices.

Terminology

The following is a list of definitions of key terms used in Recommendation Y.2060:

Communication Network: An infrastructure network that connects devices and applications, such as an IP-based network or internet.

Thing: An object of the physical world (*physical things*) or the information world (*virtual things*) that is capable of being identified and integrated into communication networks.

Device: A piece of equipment with the mandatory capability of communication and the optional capabilities of sensing, actuation, data capture, data storage, and data processing.

Data-carrying Device: A device attached to a physical thing to indirectly connect the physical thing with the communication networks. Active RFID tags are examples.

Data-capturing Device: A reader/writer device with the capability to interact with physical things. The interaction can happen indirectly via data-carrying devices, or directly via data carriers attached to the physical things.

Data Carrier: A battery-free data-carrying object attached to a physical thing that can provide information to a suitable data-capturing device. This category includes bar codes and *Quick Response* (QR) codes attached to physical things.

Sensing Device: A device that detects or measures information related to the surrounding environment and converts it into digital electronic signals.

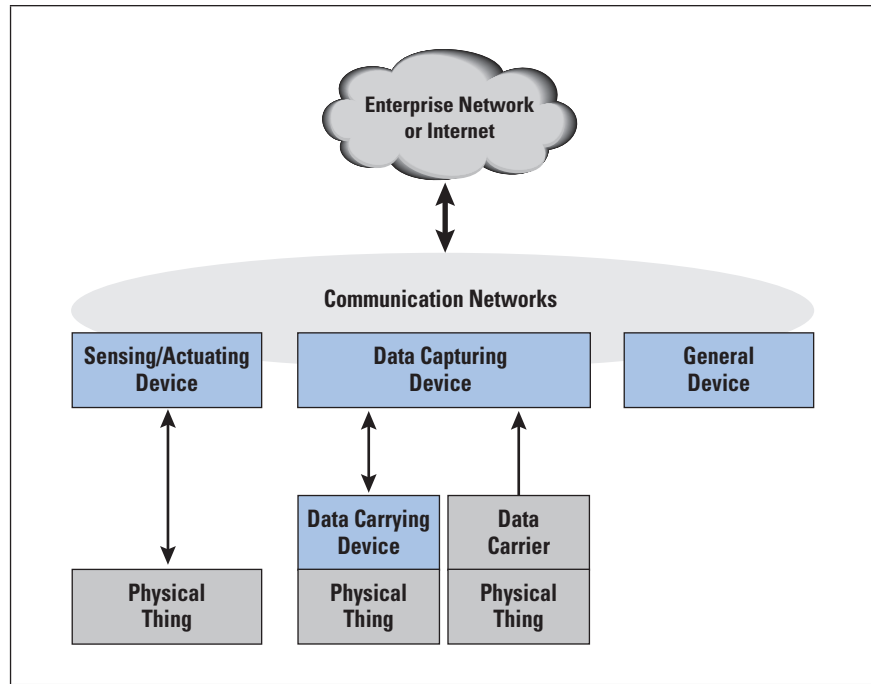

Actuating Device: A device that converts digital electronic signals from the information networks into operations.

General Device: A general device that has embedded processing and communication capabilities and may communicate with the communication networks via wired or wireless technologies. General devices include equipment and appliances for different IoT application domains, such as industrial machines, home electrical appliances, and smartphones.

Gateway: A unit in the IoT that interconnects the devices with the communication networks. It performs the necessary translation between the protocols used in the communication networks and those used by devices.

The unique aspect of an IoT, compared to other network systems, of course, is the presence of numerous physical things and devices other than computing or data processing devices. Figure 2, adapted from one in Recommendation Y.2060, shows the types of devices in the ITU-T model. The model views an IoT as functioning as a network of devices that are tightly coupled with things. Sensors and actuators interact with physical things in the environment. Data-capturing devices read data from and/or write data to physical things via interaction with a data-carrying device or a data carrier attached or associated in some way with a physical object.

Figure 2: Types of Devices and Their Relationship with Physical Things

The model makes a distinction between data-carrying devices and data carriers. A data-carrying device is a device in the Recommendation Y.2060 sense. A device at minimum is capable of communication and may include other electronic capabilities. An example of a data-carrying device is an RFID tag. By contrast, a data carrier is an element attached to a physical thing for the purpose of identification or providing some other sort of information.

Y.2060 notes that technologies used for interaction between data-capturing devices and data-carrying devices or data carriers include radio frequency, infrared, optical, and galvanic driving. Examples of each include:

- *Radio Frequency:* A *Radio-Frequency Identification* (RFID) tag is an example.
- *Infrared:* Infrared badges are used in military, hospital, and other settings where the location and movement of personnel need to be tracked. Examples include infrared reflective patches used by the military and battery-operated badges that emit identifying information. The latter can include a button that must be pressed so that the badge can be used as a means of passing through a portal, and a badge that automatically repeats the signal as a means of tracking personnel. Remote-control devices used in the home or other settings to control electronic devices can also easily be incorporated into an IoT.
- *Optical:* Bar codes and QR codes are examples of identifying data carriers that can be read optically.

- *Galvanic Driving*: An example is implanted medical devices that use the conductive properties of the body^[9]. In implant-to-surface communication, galvanic coupling sends signals from an implanted device to electrodes on the skin. This scheme uses very little power and reduces the size and complexity of the implanted device.

The final type of device shown in Figure 2 is the general device. These devices have processing and communications capabilities that can be incorporated into an IoT. A good example is smart-home technology that can integrate virtually every device in the home into a network for central or remote control.

Figure 3 provides an overview of the elements of interest in an IoT. The various ways that physical devices can be connected are shown on the left side of the figure. It is assumed that one or multiple networks support communication among the devices.

Figure 3: Technical Overview of the IoT (Recommendation Y.2060)

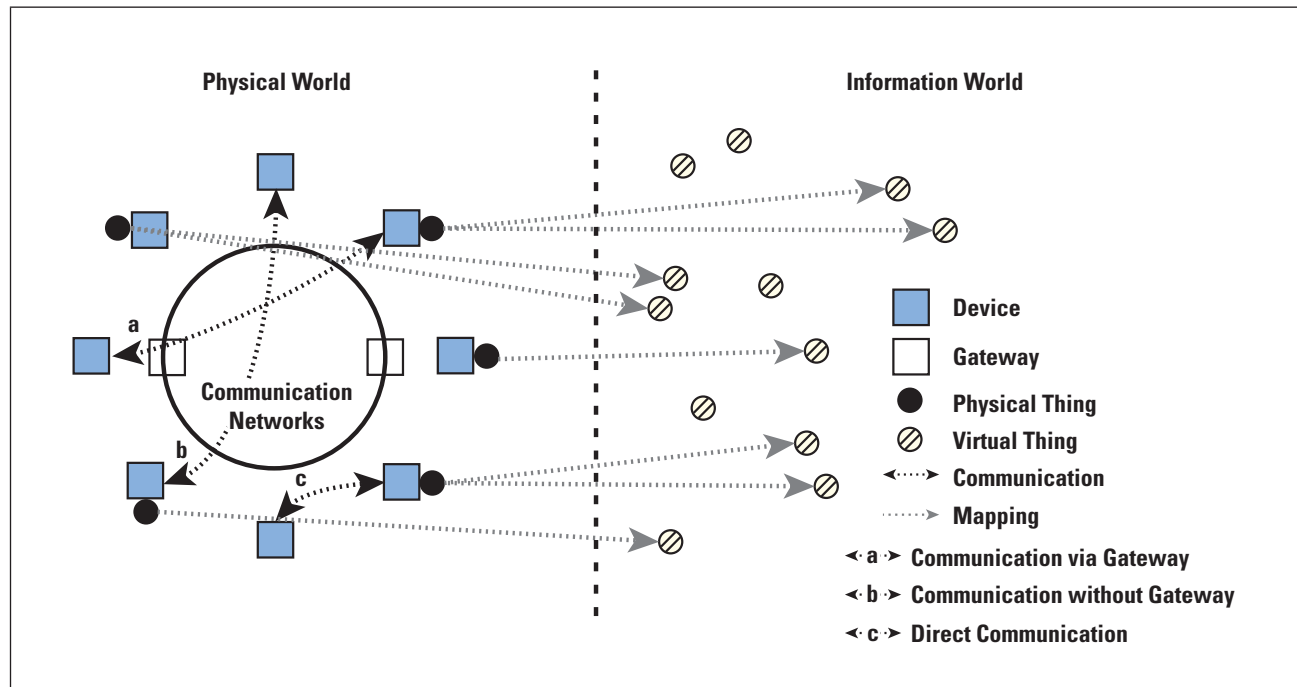

Figure 3 introduces one additional IoT-related device: the *gateway*. At minimum, a gateway functions as a protocol translator. Gateways address one of the greatest challenges in designing an IoT, which is connectivity, both among devices and between devices and the Internet or enterprise network. Smart devices support a wide variety of wireless and wired transmission technologies and networking protocols. Further, these devices typically have limited processing capability.

Recommendation Y.2067^[10] lays out the requirements for IoT gateways, which generally fall into three categories:

- The gateway supports a variety of device access technologies, enabling devices to communicate with each other and across an Internet or enterprise network with IoT applications. The access schemes could include, for example, ZigBee, Bluetooth, and Wi-Fi.
- The gateway supports the necessary networking technologies for both local and wide-area networking. These technologies could include Ethernet and Wi-Fi on the premises, and cellular, Ethernet, DSL, and cable access to the Internet and wide-area enterprise networks.
- The gateway supports interaction with application, network management, and security functions.

The first two requirements involve protocol translation between different network technologies and protocol suites. The third requirement is generally referred to as an *IoT agent* function. In essence, the IoT agent provides higher-level functionality on behalf of IoT devices, such as organizing and/or summarizing data from multiple devices to pass on to IoT applications, implementing security protocols and functions, and interacting with network management systems.

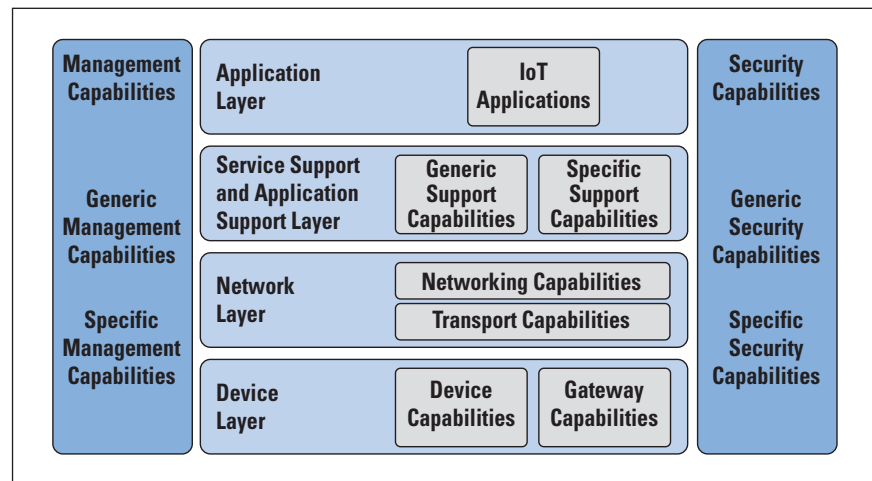

At this point, it should be noted that the term *Communication Network* is not directly defined in the Y.206x series of IoT standards. The communication network or networks support(s) communication among devices and may directly support application platforms. This may be the extent of a small IoT, such as a home network of smart devices. More generally, the device network(s) connect to enterprise networks or the Internet for communication with systems that host apps and servers that host databases related to the IoT.

We can now return to the left side of Figure 3, which illustrates the communication possibilities among devices. The first possibility is for communication between devices via the gateway. For example, a sensor or actuator with Bluetooth capability could communicate with a data-capturing device or general device that uses Wi-Fi by means of the gateway. The second possibility is communication across the communication network without a gateway. For example, all of the devices in a smart-home network may use Bluetooth and could be managed from a Bluetooth-enabled computer, tablet, or smartphone. The third possibility is devices that communicate directly with each other through a separate local network and then (not shown in the figure) communicate through the communication network via a local network gateway. An example of this third possibility follows: Numerous low-power sensor devices could be deployed in an extended area, such as farmland or a factory. These devices could communicate with one another to pass data on toward a device connected to a gateway to the communication network.

The right side of Figure 3 emphasizes that each physical thing in an IoT may be represented in the information world by one or more virtual things, but a virtual thing can also exist without any associated physical thing. Physical things are mapped to virtual things stored in databases and other data structures. Applications process and deal with virtual things.

Figure 4 depicts the ITU-T IoT Reference Model, which consists of four layers as well as management capabilities and security capabilities that apply across layers. We have so far been considering the device layer. In terms of communications functionality, the device layer includes, roughly, the OSI physical and data link layers. We now look at the other layers.

Figure 4: ITU-T Recommendation Y.2060 IoT Reference Model

The *Network Layer* performs two basic functions. Networking capabilities refer to the interconnection of devices and gateways. Transport capabilities refer to the transport of IoT service- and application-specific information as well as IoT-related control and management information. Roughly, these capabilities correspond to those of the OSI network and transport layers.

The *Service Support and Application Support Layer* provides capabilities that applications use. Many different applications can use generic support capabilities. Examples include common data processing and database management capabilities. Specific support capabilities are those that cater for the requirements of a specific subset of IoT applications.

The *Application Layer* consists of all the applications that interact with IoT devices.

The *Management Capabilities Layer* covers the traditional network-oriented management functions of fault, configuration, accounting, and performance management.

Recommendation Y.2060 lists the following as examples of generic management capabilities:

- *Device Management*: Examples include device discovery, authentication, remote device activation and de-activation, configuration, diagnostics, firmware and/or software updating, and device working-status management.
- *Local Network Topology Management*: An example is network configuration management.
- *Traffic and Congestion Management*: Examples include the detection of network overflow conditions and the implementation of resource reservation for time- and/or life-critical data flows.

Specific management capabilities are tailored to specific classes of applications. An example is smart-grid power-transmission-line monitoring.

The *Security Capabilities Layer* includes generic security capabilities that are independent of applications. Y.2060 lists the following as examples of generic security capabilities:

- *Application Layer*: authorization, authentication, and application data confidentiality and integrity protection, privacy protection, security audit, and anti-virus.
- *Network Layer*: authorization, authentication, user data, and signaling data confidentiality, and signaling integrity protection.
- *Device Layer*: authentication, authorization, device-integrity validation, access control, data confidentiality, and integrity protection.

Specific security capabilities relate to specific application requirements, such as mobile payment security requirements.

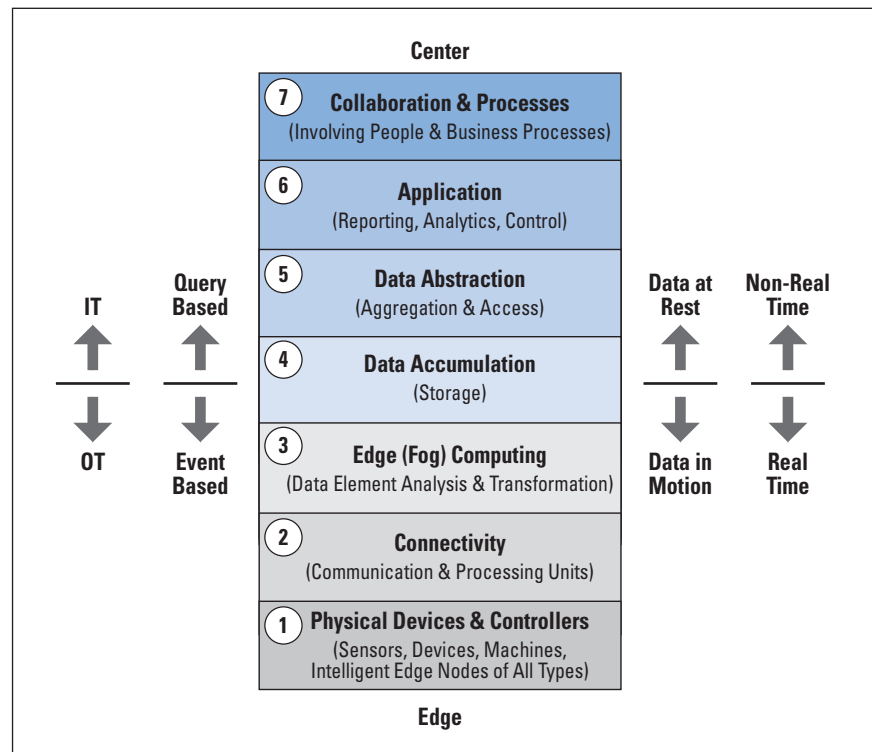

IoT World Forum Reference Model

The *IoT World Forum* (IWF) is an industry-sponsored annual event that brings together representatives of business, government, and academia to promote the market adoption of IoT. The IoT World Forum *Architecture Committee*, made up of industry leaders including IBM, Intel, and Cisco, released an IoT reference model in October 2014. This model serves as a common framework to help the industry accelerate IoT deployments. The reference model is intended to foster collaboration and encourage the development of replicable deployment models.

This reference model is a useful complement to the ITU-T reference model. The ITU-T documents focus on the device and gateway level with only a broad depiction of the upper layers. Indeed, Recommendation Y.2060 describes the application layer with a single sentence. The ITU-T Recommendation Y.206x series seems most concerned with defining a framework to support development of standards for interaction with IoT devices.

The IWF is concerned with the broader issue of developing the applications, middleware, and support functions for an enterprise-based IoT. Figure 5 depicts the seven-level model.

Figure 5: IoT World Forum Reference Model

The white paper on the IWF model issued by Cisco^[11] indicates that the model is designed to have the following characteristics:

- *Simplifies*: It helps break down complex systems so that each part is more understandable.
- *Clarifies*: It provides additional information to precisely identify levels of the IoT and to establish common terminology.
- *Identifies*: It identifies where specific types of processing are optimized across different parts of the system.
- *Standardizes*: It provides a first step in enabling vendors to create IoT products that work with each other.
- *Organizes*: It makes the IoT real and approachable, instead of simply conceptual.

Level 1 comprises physical devices and controllers that might control multiple devices. Level 1 of the IWF model corresponds approximately to the device level of the ITU-T model (Figure 4). As with the ITU-T model, the elements at this level are not physical things as such, but rather devices that interact with physical things, such as sensors and actuators. Among the capabilities that devices may have are analog-to-digital and digital-to-analog conversion, data generation, and the ability to be queried and/or controlled remotely.

From a logical point of view, this level enables communication between devices and between devices and the low-level processing that occurs at level 3. From a physical point of view, this level consists of networking devices such as routers, switches, gateways, and firewalls that are used to construct local and wide-area networks and provide Internet connectivity. This level enables devices to communicate with one another and to communicate, via the upper logical levels, with application platforms such as computers, remote-control devices, and smartphones.

Level 2 of the IWF model corresponds approximately to the network level of the ITU-T model. The main difference is that the IWF model includes gateways in level 2, whereas the ITU-T model puts the gateway at level 1. Because the gateway is a networking and connectivity device, its placement at level 2 seems to make more sense.

In many IoT deployments, massive amounts of data may be generated by a distributed network of sensors. For example, offshore oil fields and refineries can generate a terabyte of data per day. An airplane can create multiple terabytes of data per hour. Rather than store all of that data permanently (or at least for a long period) in central storage accessible to IoT applications, it is often desirable to do as much data processing close to the sensors as possible. Thus, the purpose of the edge computing level is to convert network data flows into information that is suitable for storage and higher-level processing. Processing elements at these levels may deal with high volumes of data and perform data-transformation operations, resulting in the storage of much lower volumes of data. The Cisco white paper on the IWF model^[11] lists the following examples of edge computing operations:

- *Evaluation*: Evaluating data for criteria as to whether it should be processed at a higher level.
- *Formatting*: Reformatting data for consistent higher-level processing.
- *Expanding/decoding*: Handling cryptic data with additional context (such as the origin).
- *Distillation/reduction*: Reducing and/or summarizing data to minimize the impact of data and traffic on the network and higher-level processing systems.
- *Assessment*: Determining whether data represents a threshold or alert; this process could include redirecting data to additional destinations.

Processing elements at this level corresponds to general devices in the ITU-T model (Figure 2). Generally, they are deployed physically near the edge of the IoT network; that is, near the sensors and other data-generating devices. Thus, some of the basic processing of large volumes of generated data is offloaded and outsourced from IoT application software located at the center.

Processing at the edge computing level is sometimes referred to as *Fog Computing*. Fog computing and fog services are expected to be a distinguishing characteristic of the IoT. Figure 6 illustrates the concept. Fog computing represents an opposite trend in modern networking from cloud computing. With cloud computing, massive, centralized storage and processing resources are made available to distributed customers over cloud networking facilities to a relatively small number of users. With fog computing, massive numbers of individual smart objects are interconnected with fog networking facilities that provide processing and storage resources close to the edge devices in an IoT. Fog computing addresses the challenges raised by the activity of thousands or millions of smart devices, including security, privacy, network-capacity constraints, and latency requirements. The term “Fog Computing” is inspired by the fact that fog tends to hover low to the ground, whereas clouds are high in the sky.

Figure 6: Fog Computing

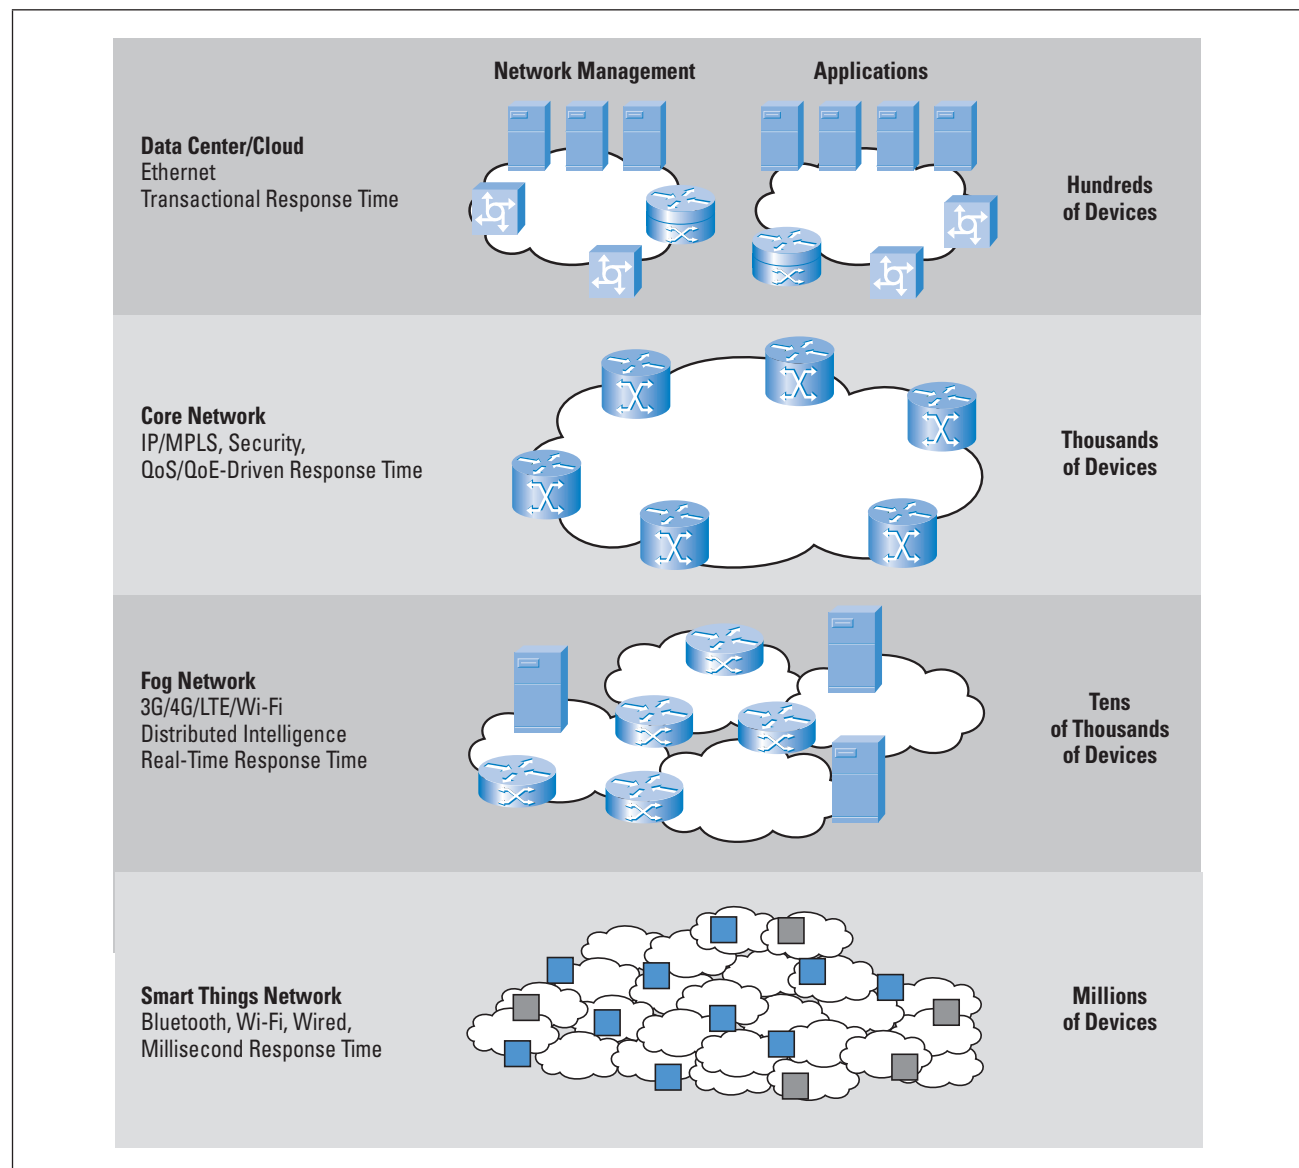

Table 2, based on one in [12], compares cloud and fog computing.

Table 2: Comparison of Cloud and Fog Features

	Cloud	Fog
Location of processing/ storage resources	Center	Edge
Latency	Low to high	Low
Access	Fixed or wireless	Mainly wireless
Support for mobility	Not applicable	Yes
Control	Centralized/hierarchical (full control)	Distributed/hierarchical (partial control)
Service access	Through core	At the edge/on handheld device
Availability	99.99%	Highly volatile/highly redundant
Number of users/devices	Tens/hundreds of millions	Tens of billions
Main content generator	Humans and devices	Devices/sensors
Content generation	Central location	Anywhere
Content consumption	End device	Anywhere
Software virtual infrastructure	Central enterprise servers	User devices

Level 4, the data accumulation level, is where data coming from the numerous devices, and filtered and processed by the edge computing level, is placed in storage that will be accessible by higher levels. This level marks a clear distinction in the design issues, requirements, and method of processing between lower-level (fog) computing and upper-level (typically cloud) computing.

Data moving through a network is referred to as *data in motion*. The rate and organization of the data in motion is determined by the devices generating the data. Data generation is event-driven, either periodically or by an event in the environment. To capture the data and deal with it in some fashion, it is necessary to respond in real time. By contrasts, most applications do not need to process data at network transfer speeds. As a practical matter, neither the cloud network nor the application platforms would be able to keep up with data volume generated by a huge number of IoT devices. Instead, applications deal with *data at rest*, which is data in some readily accessible storage facility. Applications can access the data as needed, on a non-real-time basis. Thus, the upper levels operate on a query or transaction basis, whereas the lower three levels operate on an event basis.

The following are listed as operations performed at the data-accumulation level in [13]:

- Converts data in motion to data at rest
- Converts format from network packets to database relational tables
- Achieves transition from event-based to query-based computing
- Dramatically reduces data through filtering and selective storing

Another way of viewing the data-accumulation level is that it marks the boundary between *Information Technology* (IT), which is the common term for the entire spectrum of technologies for information processing, including software, hardware, communications technologies and related services, and *Operational Technology* (OT), which refers to hardware and software that detects or causes a change through the direct monitoring and/or control of physical devices, processes, and events in the enterprise.

The data-accumulation level absorbs large quantities of data and places them in storage, with little or no tailoring to specific applications or groups of applications. Numerous different types of data in varying formats and from heterogeneous processors may be coming up from the edge computing level for storage. The data-abstraction level can aggregate and format this data in ways that make access by applications more manageable and efficient. Tasks involved could include:

- Combining data from multiple sources, including reconciling multiple data formats.
- Performing necessary conversions to provide consistent semantics of data across sources.
- Placing formatted data in an appropriate database; for example, high-volume repetitive data may go into a big data system such as Hadoop. Event data would be steered to a relational database management system, which provides faster query times and an appropriate interface for this type of data.
- Alerting higher-level applications that data is complete or has accumulated to a defined threshold.
- Consolidating data into one place (with ETL (*extract, transform, load*), ELT (*extract, load, transform*), or data replication) or providing access to multiple data stores through data virtualization.
- Protecting data with appropriate authentication and authorization.
- Normalizing or denormalizing and indexing data to provide fast application access.

The application level contains any type of application that uses IoT input or controls IoT devices. Generally, applications interact with level 5 and the data at rest, and so do not have to operate at network speeds. Provision should be available for streamlined operation that allows applications to bypass intermediate layers and interact directly with Layer 3 or even Layer 2. The IWF model does not strictly define applications, considering it beyond the scope of IWT model discussion.

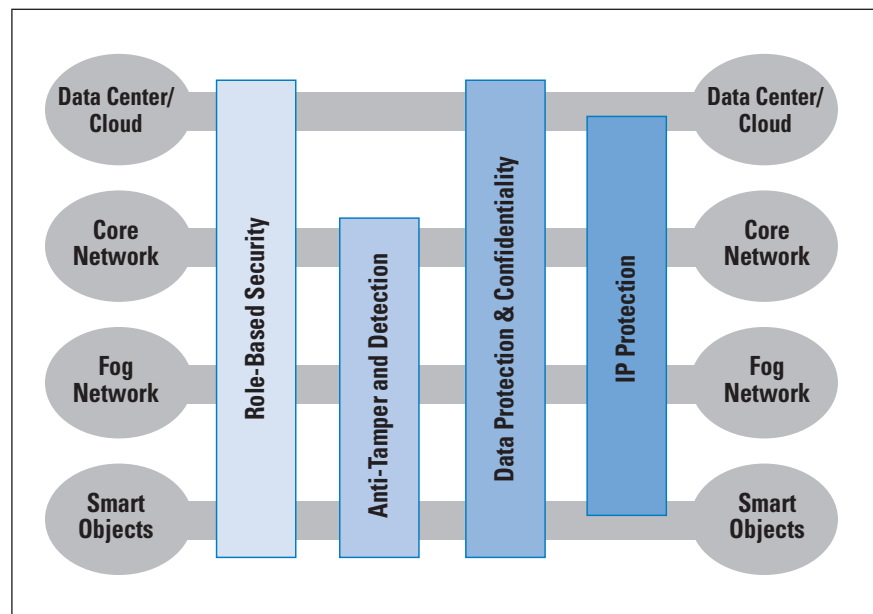

The collaboration and processes level recognizes that people must be able to communicate and collaborate to make an IoT useful. This level may involve multiple applications and exchange of data and control information across the Internet or an enterprise network.

The IWF views the IoT reference model as an industry-accepted framework aimed at standardizing the concepts and terminology associated with IoT. More importantly, the IWF model sets out the functionalities required and concerns that must be addressed before the industry can realize the value of the IoT. This model is useful both for suppliers who develop functional elements within the model and customers for developing their requirements and evaluating vendor offerings.

An IoT Security Framework

Cisco Systems, which has played a lead role in the development of the IoT World Forum Reference Model, has developed a framework for IoT security^[13] that serves as a useful complement to the World Forum IoT Reference Model. Figure 7 illustrates the security environment related to the logical structure of an IoT.

Figure 7: IoT Security Environment

The Cisco IoT model is a simplified version of the World Forum IoT Reference Model. It consists of the following levels:

- *Smart Objects/Embedded Systems*: This level consists of sensors, actuators, and other embedded systems at the edge of the network. This part of an IoT is the most vulnerable part. The devices may not be in a physically secure environment and may need to function for years. Availability is certainly of concern. Also network managers need to be concerned about the authenticity and integrity of the data generated by sensors and about protecting actuators and other smart devices from unauthorized use. Privacy and protection from eavesdropping may also be requirements.
- *Fog/Edge Network*: This level is concerned with the wired and wireless interconnection of IoT devices. In addition, a certain amount of data processing and consolidation may be done at this level. A key concern is the wide variety of network technologies and protocols that the various IoT devices use and the need to develop and enforce a uniform security policy.
- *Core Network*: The core network level provides data paths between network center platforms and the IoT devices. The security issues here are those confronted in traditional core networks. However, the vast number of endpoints to interact with and manage creates a substantial security burden.
- *Data Center/Cloud*: This level contains the application, data storage, and network management platforms. IoT does not introduce any new security issues at this level, other than the necessity of dealing with huge numbers of individual endpoints.

Within this four-level architecture, the Cisco model defines four general security capabilities that span multiple levels:

- *Role-Based Security*: *Role-Based Access Control* (RBAC) systems assign access rights to roles instead of individual users. In turn, users are assigned to different roles, either statically or dynamically, according to their responsibilities. RBAC enjoys widespread commercial use in cloud and enterprise systems and is a well-understood tool that can be used to manage access to IoT devices and the data they generate.
- *Anti-tamper and Detection*: This function is particularly important at the device and fog network levels but also extends to the core network level. All of these levels may involve components that are physically outside the area of the enterprise that is protected by physical security measures.
- *Data Protection and Confidentiality*: These functions extend to all levels of the architecture.
- *Internet Protocol Protection*: Protection of data in motion from eavesdropping and snooping is essential between all levels.

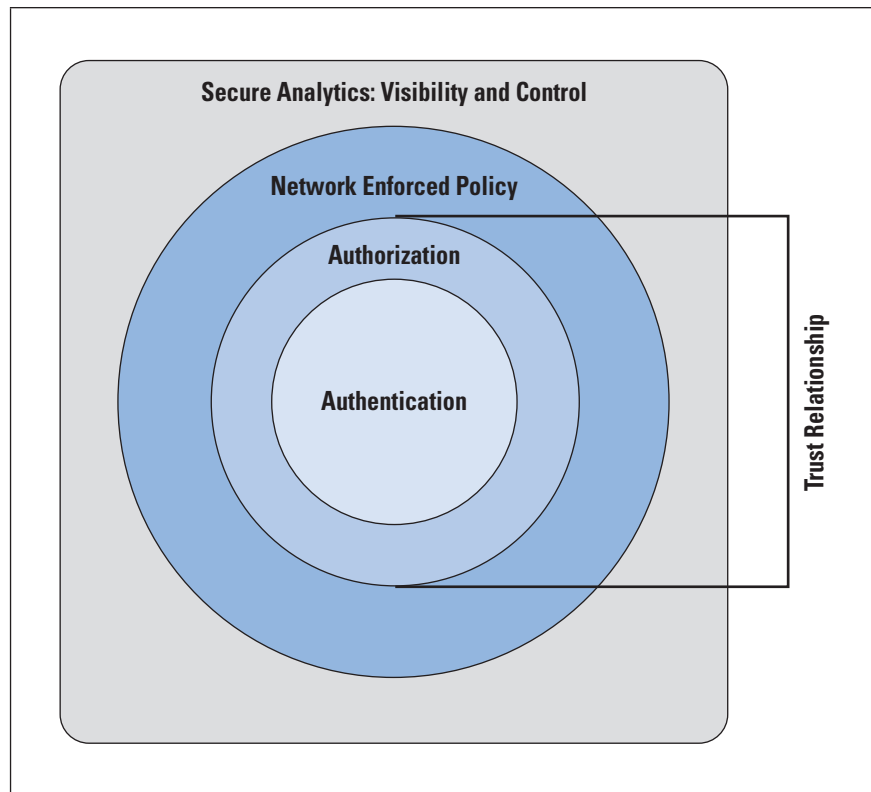

Figure 7, on page 19, maps specific security functional areas across the four layers of the IoT model. The Cisco white paper^[13] also proposes a secure IoT framework that defines the components of a security facility for an IoT that encompasses all the levels, as shown in Figure 8 on page 22. The four components follow:

- *Authentication*: This component encompasses the elements that initiate the determination of access by first identifying the IoT devices. In contrast to typical enterprise network devices, which may be identified by a human credential (for example, username and password or token), the IoT endpoints must be fingerprinted by means that do not require human interaction. Such identifiers include RFID, x.509 certificates, or the MAC address of the endpoint.
- *Authorization*: Authorization controls access of a device throughout the network fabric. This element encompasses access control. Together with the authentication layer, it establishes the necessary parameters to enable the exchange of information between devices and between devices and application platforms and enables IoT-related services to be performed.
- *Network Enforced Policy*: This component encompasses all elements that route and transport endpoint traffic securely over the infrastructure, whether control, management, or actual data traffic.
- *Secure Analytics, including Visibility and Control*: This component includes all the functions required for central management of IoT devices. It involves, firstly, visibility of IoT devices, meaning simply that central management services are securely aware of the distributed IoT device collection, including identity and attributes of each device. Building on this visibility is the ability to exert control, including configuration, patch updates, and threat countermeasures.

An important concept related to this framework is that of *trust relationship*. In this context, trust relationship refers to the ability of the two partners to an exchange to have confidence in the identity and access rights of the other. The authentication component of the trust framework provides a basic level of trust, which is expanded with the authorization component.

The Cisco white paper^[13] gives the example that a car may establish a trust relationship with another car from the same vendor. That trust relationship, however, may allow cars to exchange only their safety capabilities. When a trusted relationship is established between the same car and its dealer's network, the car may be allowed to share additional information such as its odometer reading and last maintenance record.

Figure 8: Secure IoT Framework

Conclusions

According to the McKinsey report cited earlier^[4], approximately 40 percent of the total economic value of the IoT is driven by the ability of all the physical devices to talk to each other via computers, that is, interoperability. If interoperability is limited, the IoT might be only a \$7 trillion opportunity, whereas widespread interoperability could achieve an IoT value to the global economy of over \$11 trillion by 2025. On average, 40 percent of the total value that can be unlocked requires different IoT systems to work together. Table 3, based on the McKinsey report, estimates the percent of economic value that requires interoperability between IoT systems for different sectors.

To achieve the type of interoperability needed to realize these benefits, standards need to be developed at all levels of IoT functionality, from the device layer to the application layer (Figure 4). While such standardization is still in its infancy, the architectural models described here provide a useful framework for future efforts.

Table 3: Value Added by IoT Interoperability

Setting	Value Potential Requiring Interoperability (\$ Trillion)	% of Total Value	Examples of How Interoperability Enhances Value
Factories	1.3	36	Data from different types of equipment used to improve line efficiency
Cities	0.7	43	Video, cellphone data, and vehicle sensors to monitor traffic and optimize flow
Retail	0.7	57	Payment and item-detection system linked for automatic checkout
Work sites	0.5	56	Linking worker and machinery location data to avoid accidents and exposure to chemicals
Vehicles	0.4	44	Equipment usage data for insurance underwriting, maintenance, and presales analytics
Agriculture	0.3	20	Multiple sensor systems used to improve farm management
Outside	0.3	29	Connected navigation between vehicles and between vehicles and GPS/traffic control
Home	0.1	17	Linking chore automation to security and energy system to time usage
Offices	>0.1	30	Data from different building systems and other buildings used to improve security

The RFC Series – Beyond ASCII

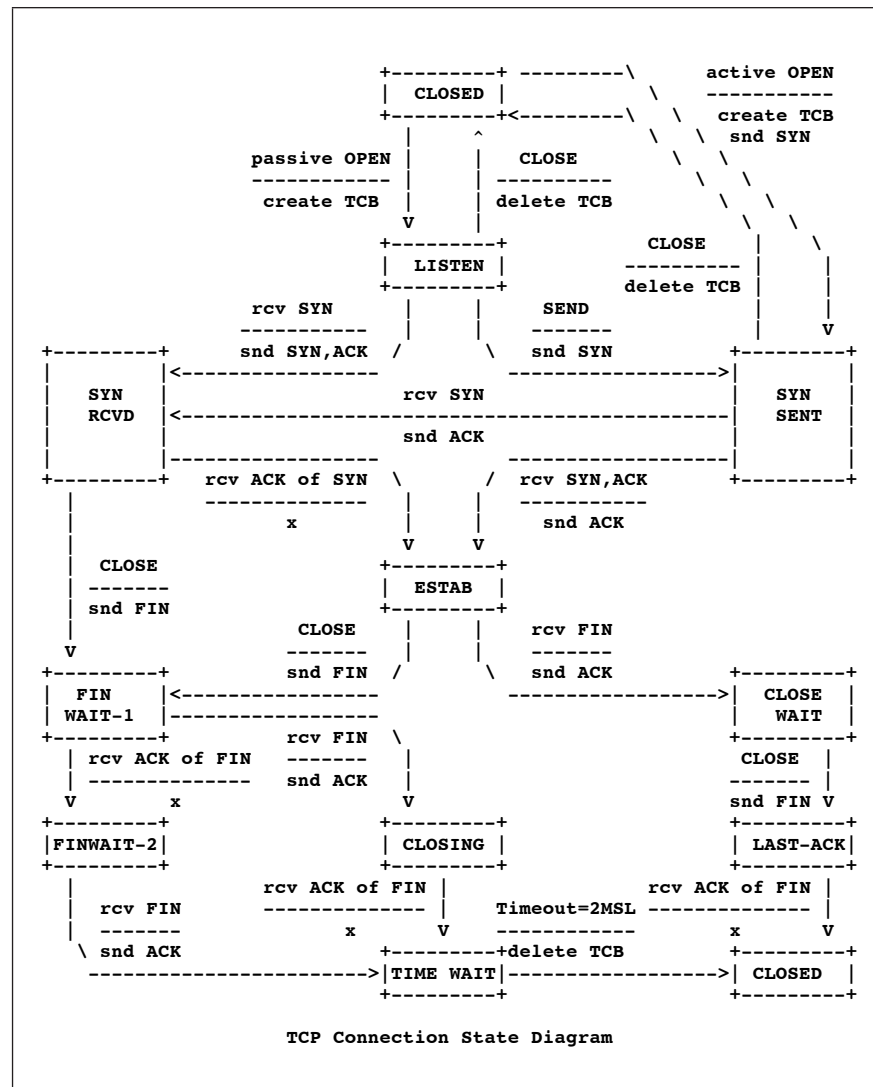

by Heather Flanagan, RFC Series Editor

The *Request for Comments* (RFC) Series began on April 7, 1969, with RFC 1^[1]. Since then, over 7,500 RFCs have been published. Most (though not all) of those RFCs have been in a plain text, *American Standard Code for Information Interchange* (ASCII)-only format. The RFC Series has always been a document series that focuses on archiving material and making sure it remains available far into the future.

The choice of plain text and ASCII-only was made for a variety of reasons. The format has stood the test of time in being readable as originally intended regardless of hardware and software changes. These documents can be read on just about any device, they take up very little bandwidth and disk space, and they provide a common experience for readers. However, while plain text and ASCII were undoubtedly the correct choice for the first few decades of the series, this format has reached the limits of its usefulness.

The Internet has evolved to the point that the restrictions imposed by the old format prevent reasonable information sharing. Networks are becoming more complicated than can be reasonably drawn via “ASCII art” (Figure 1). Internationalization brings in more characters than can be covered sensibly in ASCII. And, while people can read RFCs on just about any device, the experience is not always positive, as the format of the RFC cannot flow to match the different screen sizes. The plain text, ASCII-only format was the right choice, but it no longer meets the changing requirements of the Internet community.

In 2012, I started as RFC Series Editor. My intention was to quietly learn more about the community and its expectations for the series and the RFC Editor. That goal lasted about 3 months, at which point it became obvious that there was a decades-old demand for a change in the RFC format. The only thing that had prevented any changes in that time was the inability for the community to come to any kind of rough consensus on what the change should be. Should the format be *HyperText Markup Language* (HTML)? *Portable Document Format* (PDF)? Plain text but supporting a *UCS Transformation Format 8* (UTF-8) encoding? What about *Lamport TeX* (LaTeX)? Perhaps *Extensible Markup Language* (XML)? My job was to take the input and try to reach consensus within the community, and barring that, to make the best decision possible so we could stop having the debates.

Figure 1: Example of ASCII Art
from RFC 793^[6]

The first formal output of the discussion after I started to collect input was RFC 6949^[2]. That document captured the requirements to date, and led to the decisions described in an email to the community^[3]. Those two items in turn gave a design team, formed in July 2013 shortly after RFC 6949 was published, a baseline for determining the details of a new format.

The new RFC format will include a base, unchanging XML format using an enhanced *xml2rfc* vocabulary. From that file, the RFC Editor will render HTML, PDF/A-3, and plain text. *Scalable Vector Graphics* (SVG) diagrams in black and white will be supported, and non-ASCII characters used in a carefully prescribed manner. A list of commonly asked questions regarding the format, including a reading list that describes the details of each rendered format, profile, and general guidance, is available on the RFC Format FAQ^[4].

As an important tangent to the format work, a separate project is developing that more carefully looks at the future of the digital archive process for the series. The field of digital archiving has evolved significantly over the last decade, and the RFC Editor is poised to partner with official digital archives around the world to properly store and maintain copies of all RFCs and approved Internet Drafts as per best practice in that field. More information on the considerations that are involved with properly archiving RFCs is available in [5]. This draft is expected to be updated and moved towards publication as an RFC in 2016.

The RFC Format project has reached an important milestone, where the requirements drafts are starting their path towards publication: first, review by the *RFC Series Oversight Committee* (RSOC), then review by the *Internet Architecture Board* (IAB), and finally review by the community. Upon approval for publication, expected in early 2016, the associated Requests for Proposals will go out, and work on the necessary code base to implement the format changes can start. Coding the format tools and testing the output will be a major effort in 2016. By 2017, we will see a host of changes that make the RFC Series an easily read and still easily archived document series.

Rob Blokzijl Obituary

Dr. Robert Blokzijl, RIPE Chair Emeritus and founding member of the *Réseaux IP Européens* (RIPE) community, died aged 72 on December 1, 2015.

Dr. Robert Blokzijl

Photo by Olaf Kolkman
[Creative Commons NC-BY]

The Internet community has suffered a sad loss as the man who led RIPE during its first 25 years of bottom-up, consensus-driven collaboration and decision-making died at his home in the Netherlands.

As one of the founders of RIPE in 1989 and the Chair of the RIPE community for 25 years since then, Rob Blokzijl personified all the attributes that have seen the community grow into such a positive force for bringing together those who care about the development of the Internet.

Rob's roots were in the high-energy physics community, and earlier in his career he worked at the *High Energy Physics Institute* (Nikhef) in Amsterdam and later at the *European Organization for Nuclear Research* (CERN) in Geneva. He helped to build the computer networks that were essential for that branch of science. His work in this area would inform much of his contribution to the burgeoning IP networking community in Europe in the early 1980s.

Over the past 30 years, Rob has established a global reputation as a leader and a pioneer, respected for his work with organisations such as RIPE, the *RIPE Network Coordination Centre* (RIPE NCC), the *Amsterdam Internet Exchange* (AMS-IX), the *Internet Corporation For Assigned Names and Numbers* (ICANN), Nominet, and the *North Atlantic Treaty Organization* (NATO).

In 1989, Rob was co-author of the *RIPE Terms of Reference*, which stated, "The object of RIPE is to ensure the necessary administrative and technical coordination to allow the operation and expansion of a pan-European IP network." In his role as the Chair of RIPE, his vision, expertise, and effort were essential for the tremendous growth and spread of this world-respected forum, which acted as a model for many subsequent community organisations.

Rob was also one of the key figures in creating the RIPE NCC, the body responsible for managing the IP address space in Europe, the Middle East, and parts of Central Asia and coordinating the technical community in those regions. The RIPE NCC was the first *Regional Internet Registry* (RIR) in the world, and this model has become the accepted way to organise the Internet infrastructure in a more regionally specific, responsive, and efficient way.

Rob had a particular talent for being able to engage with all elements of the Internet community, from government and experienced operators to more recent members of the RIPE community to whom he could impart his insight and wisdom on the issues of the day. He brought much common sense to otherwise complicated discussions in the Internet community, and his mantra of “keep it simple” is one that he will be remembered for.

Those who knew Rob personally will miss his sense of humour. He was a storyteller with an outstanding ability to recall and relate the events from his working life, which not only amused his listeners but also enlightened them and informed their discussions. The recent RIPE 71 Meeting was the first not to be attended by Rob due to his illness, and so it was the first where he was not to be found with a cigarette and glass of wine in hand, enjoying the company of those who typically gathered outside the venue entrance to talk about serious matters in a very non-serious way.

His contributions were often officially recognised, notably in receiving Dutch royal honours by being awarded with the title *Officer in the Order of Oranje-Nassau* in 2010. He also received the *Jonathan B. Postel Service Award* in 2015 for outstanding contributions in service to the data communications community. Since standing down as RIPE Chair in 2013, he has enjoyed the title RIPE Chair Emeritus.

To many of us in the RIPE community and beyond, Rob was a mentor, a friend, a trusted confidante and always the voice of reason. His legacy stretches from the physical networks the Internet is made of to the community he built and the wisdom he injected into that community’s make-up from the very beginning. His legacy will continue to be felt as the community continues to grow and its participants often ask themselves, “What would Rob do?”

The RIPE NCC has set up a webpage where you can leave your own tribute to Rob:

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

FROM THE EDITOR

This *Internet Engineering Task Force* (IETF) has just completed its meeting in Buenos Aires, Argentina. This meeting was the first time the IETF has met in South America, and while Buenos Aires is “far away” from many parts of the world, the technical community seems to agree that this historic meeting was well worth the journey. You can read more about this meeting on the IETF and Internet Society websites, as well as in the latest issue of the *IETF Journal*, which on this special occasion is available in both English and Spanish.

This year, the IETF will meet in Berlin, Germany, in July and in Seoul, Korea, in November. If you are involved with developing or deploying Internet protocols, I recommend that you attend an IETF meeting if you have not done so already. There are also ways to participate remotely in these meetings if you are unable to attend in person, and the IETF now has many resources for first-time attendees at its meetings. For more information about the IETF, visit <http://ietf.org>

The *Domain Name System* (DNS) is the “human face” of the Internet, allowing us to use terms such as **facebook.com** or **isoc.org** to access a service over the Internet. A small number of these names are “reserved” in the sense that they do not appear in the global DNS system. In our first article, Geoff Huston discusses the *Special-Use Domain Name* registry, which has sparked quite a bit of debate in recent months.

Quality of Service (QoS) has been discussed in several articles in this journal over the years. In our second article, William Stallings and Florence Agboma describe QoS and the more recent concept of *Quality of Experience* (QoE) as it relates to IP networks.

We would like to remind you that this journal depends on the generous support of numerous individuals and organizations. If you would like to help support IPJ, please contact us for further details. Comments, suggestions, book reviews, and articles are always welcome. Send your messages to ipj@protocoljournal.org

What's in a DNS Name?

by Geoff Huston, APNIC

What's the difference between `.local` and `.here`? Or between `.onion` and `.apple`? All four of these labels are capable of being represented in the Internet's *Domain Name System* (DNS) as *generic Top Level Domains* (gTLDs), but only two of these are in fact delegated names. The other two, `.local` and `.onion` not only don't exist in the delegated name space, but by virtue of a registration in the *Internet Assigned Numbers Authority* (IANA)'s *Special Use Domain Name* registry^[1], these names cannot exist in the conventional delegated domain name space.

It seems that Internet does not have a single coherent name space, but instead it has a name space that contains a number of silent and unsignalled fracture lines, and instead of being administered by a single administrative body there are numerous people who appear to want to have a hand on the tiller! Let's look at the Internet's domain name space and try to gain some insight as to how we've managed to get ourselves into this somewhat uncomfortable position.

A Very Brief History of the DNS

It is probably an impossible challenge to consider many years of development and take the outcome of many discussions, conferences, as well as countless millions of mail messages and generate a brief but complete history of the domain name system. Here I'll offer a personal interpretation of what I recall, supplemented with reference to numerous useful sources, but nevertheless it's still a somewhat subjective narrative.

A good place to start is probably RFC 920^[2], authored by Jon Postel and Joyce Reynolds, and published in October 1984. The name model of the Internet had broken away from many other contemporary "flat" or limited hierarchy naming models used in other computer networks by adopting a hierarchical name scheme that imposed no a priori limit on the depth of the hierarchy. This meant that the apex level of the name hierarchy could be limited to a number of generic category names, leaving the lower levels of the name space hierarchy to be populated by individual name instances.

This document, RFC 920, specified a division of the apex level of the name space into a small set of so-called *Top Level Domains*. These were the category-based names of `.com`, `.edu`, `.gov`, `.mil` and `.org`, the collection of two-letter country codes as administered by the *International Organization for Standardization* (ISO) and published as ISO-3166^[22], and a temporary name of `.arpa`.

By the time RFC 1034^[3] was published in 1987, there was no distinction drawn between the name space itself and the technology of resolution of these names.

The name space and the name resolution technology that operated on this name space was collectively referred to as the *Domain Name System* (DNS). At the time, the name space was a collection of top-level names overseen by the IANA. Even in those early days there was pressure to expand the set of delegated top-level domains. Initially **.net** was added, then **.int**, but these additions appeared to exacerbate the issue rather than relieve these growing pressures. As well as efforts to clarify the nature and administration of the domain name space at the time^[4], the debate over who and how the name space could be further expanded continued as a sometime vexatious topic, particularly as the set of stakeholders and interested parties began to grow. Subsequent investigation to expand the DNS name space was undertaken by the *International Ad Hoc Committee* (IAHC)^[5], sponsored by the IANA, the *Internet Architecture Board* (IAB) and the Internet Society, with membership drawn from a number of bodies including the *Telecommunication Standardization Sector of the International Telecommunication Union* (ITU-T) and the *World Intellectual Property Organization* (WIPO). This committee produced a report that advocated the limited expansion of the collection of gTLDs by adding a further seven top-level labels to the domain name space, as well as proposing some structural changes in the name registration function to delineate the roles of name registrars and name registry operators.

However, perhaps of greater interest were other activities that were underway at the same time as the committee was undertaking its investigation. In 1995 the *National Science Foundation* (NSF) had authorized a company called Network Solutions to operate the names registry for the Internet, and permitted the company to charge an annual fee to maintain a name registry entry, and to keep the proceeds from this operation. This situation caused a significant level of discontent, as there was a general perception that the registration fee was unrelated to the cost of operation of the registry and that the registry operator was exploiting a de facto monopoly position to its benefit. A number of activities emerged in alternate name systems. These alternate name systems used the same name structure, and the same name resolution tools, but used a different set of “root” name servers. These systems were so defined to sit alongside the incumbent name system, but added a number of additional top-level labels (see, for example the Wikipedia account of AlterNIC’s brief history^[5]). At issue here was the coherence of the Internet’s name system. A user whose domain name resolvers were positioned within the name space as defined by one of these alternate name systems could use a name in a communication to another user where the same name may have been defined in a different name system and resolved in an entirely different manner.

In May 2000 the IAB published RFC 2826^[7], which argued strongly for the presentation of a single root system and thereby argued strongly for a single coherent name system: “There is no getting away from the unique root of the public DNS.”

Rather than having the DNS name space grow from the “bottom up” in several uncoordinated grass roots efforts to expand the name space, and allowing each effort to fail or survive on the level of public interest and commercial uptake, the IAB was espousing a view that any such expansion of the name space was to be a top-down effort. All such new top level names were to be implemented in a coherent manner such that all such names were visible to all Internet users at the same time. Any expansion of the domain name space was intended to be a process that included all parts of the Internet, and that at all times all public DNS names were to be equally and uniformly available to all users.

However, at much the same time as this statement was made, mid-2000, the IAB was also attempting to extricate itself and the *Internet Engineering Task Force* (IETF) from the fraught debate about the accountability of the IANA, and the nature of the role of the US Government agencies that had been funding the work of the IANA. This debate also folded in the discussion of the further expansion of this domain name space. Evidently many people at the time were interested in seeing a distinct community of interest focus on the issue of the policy of the domain name space in a manner similar to the evolution of the addressing community and the emergence of the *Regional Internet Registry* model in the 1990s. In June 2000 the IAB entered into an agreement with The *Internet Corporation for Assigned Names and Numbers* (ICANN) that effectively passed over the administrative purview of the domain name space, apart from “assignments of domain names for technical uses,” to ICANN, RFC 2860^[8].

From that point onward the focal point for the debate about the expansion of the name space, and the related debate about the monopoly position of Network Solutions was essentially ICANN. Over the ensuing years ICANN made a number of decisions in the interest of addressing perceived needs that were voiced from the community of interest. The roles of the registry and the front-end registrar function were cleaved apart and competition between registrars allowed the retail price of name registrations to be subject to competitive market pressures. In addition, a number of new gTLDs were added in a relatively ponderous and deliberative process. In 2000 the gTLDs of **.aero**, **.biz**, **.coop**, **.info**, **.museum**, **.name** and **.pro** were added to the delegated name set of the root zone of the Domain Name System. Four years later a second round saw the addition of **.asia**, **.cat**, **.jobs**, **.mobi**, **.port**, **.tel**, **.travel** and **.xxx**.

This conservative approach to augmenting this root zone delegated name set changed with the so-called “new gTLD” program, that started in 2008 with the adoption by the ICANN Board of a number of policy recommendations relating to the expansion of the gTLD delegated name space, and the subsequent 2011 launch of this program.

The application window opened on January 12, 2012, and ICANN received 1,930 applications for new gTLDs. On December 17, 2012, ICANN held a prioritization draw to determine the order in which applications would be processed during initial evaluation and subsequent phases of the program. One view is that these names were effectively sold into the market, with an application fee of \$185,000 USD per name. An alternate view was that the application process now entailed significant levels of analysis of the impact on the broader environment, including considerations of competition, security, collisions, potential trademark infringement and similar subjects, and that this fee was intended to cover some portion of the costs of this investigation of the potential impact of the delegation of this particular name as a new gTLD.

Name Tensions and Collisions

Expanding the gTLD name space did not address all of the outstanding issues, and to some extent these tensions were exacerbated by the chosen mechanism for this expansion. The new names and their “owners” were defined essentially by the actions of bidding for names. Without putting too fine a point on it, the expansion of the Domain Name System was passed to a market-based mechanism that was based on foundations of a commercial model of monetization of the name space. This shift appears to have prompted other forms of use of non-delegated top-level domain names to be a little more visible.

There are a number of examples of this change in the landscape of the domain name space.

Local Names

The first of these is the use of the name space in *private* domains. Although the public name space is held together with the coordinated set of root name servers and a common convention that all public name resolvers use these root name servers to establish content, this is only a convention for the public name space. Within private environments it is quite common to see name servers that define a local name environment as a local convenience. For example, you could call the local data server in your home network **server.home**. Not only is that name convenient for the home user, it's convenient for a vendor of home equipment, who can preconfigure server equipment and use these local private names in a pre-configured mode. There are a many names that are commonly used in private environments, probably as a result of vendors in this market domain adopting particular name conventions. The names **.home**, **.hometown**, **.belkin**, **.lan**, **.dlink**, and **.local** are all popular names in locally defined private DNS domains^[9].

What happens if ICANN were to delegate a new gTLD that was the same as a name that enjoyed considerable levels of private use? The two different interpretations of the name would interact.

These days mobility is an important consideration, and a mobile end-system configured with the name of a resource in the private name space would anticipate a “no such domain” response when the system was relocated into the public space where the name was not delegated. Delegation of the name in the public DNS may cause an unanticipated response. Equally, the public space, and the services and resources accessible via these public DNS names would not be visible within the local scope where the name is defined in a private use context. Of course this situation poses some rather challenging policy issues in the name space. Does “squatting” on a name in a private use context confer any rights on tenure of the public name? Should the public name space avoid all names used in private contexts? Given the uncoordinated use of names in private contexts is any form of common regulation of the name space even possible in this context?

Non-DNS Names

The second example is the name space that is associated with non-DNS resolution mechanisms. One of these mechanisms is *multicast DNS* (mDNS), defined in RFC 6761^[10], which replaces the conventional unicast DNS query to a specific DNS resolver with a multicast group query, directed to the link local multicast address (224.0.0.251 or ff02::fb). All members of the multicast group receive the query and the holder of the queried name can identify itself in a multicast answer. All members of the group can learn the answer in this manner. In addition to the change of the resolution mechanism from unicast to link local multicast, RFC 6762^[11], requested that the IETF (not ICANN) reserve the generic top-level domain **.local** for use by mDNS, and thereby prevent ICANN from making a conventional unicast global public DNS delegation of the same top-level name. A related specification, *Link Local Multicast Name Resolution*, defined in RFC 4795^[12] using the Multicast group address of 224.0.0.252 and ff02::1:3, elected not to define an associated name space, so the mDNS approach was unique in some respects.

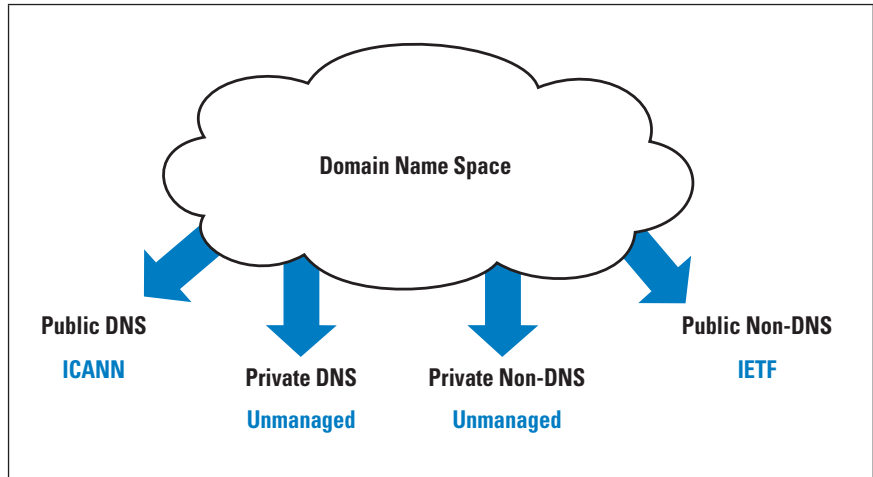

Another approach of non-DNS use of names in the domain space is the *The Onion Ring's* (TOR) use of names in the **.onion** space. Here the names within the **.onion** name space are in effect the base 32 encoded version of the public key of a defined service point, and the TOR-defined Service Directory servers are capable of performing a mapping from an encoded public key (the **.onion** name) and the desired service address. These names are not directly resolved by the DNS and connection requests for **.onion** services need to be passed into the TOR network space for resolution, RFC 7686^[13].

A third name falls into this category, and it predates the other two names by many years. The name **.localhost** refers to the local systems without further recourse to any name resolution process. It is the canonical name used to refer to oneself in the name system.

The Domain Name Space

The overall result of this process of drawing names for use out of the overall domain name space, and the entities that have some level of purview over this process is shown in Figure 1.

Figure 1: Domain Name Space Delegations

The ICANN process views the domain name space as a public good in an economic sense, and uses monetization as an intrinsic component of the name allocation function. In theory, the name space is accessible to those with an exploitation model that can recoup of expenses of acquisition of the name. In practice, the name space is accessible to those with the means to purchase a name, and there is no particular assurance that any of these names will be used in a public context. While second level names are pretty much universally accessible in `.com` or `.net`, for example, the same is probably not the case for `.google`. What was a relatively uniform common public space at the apex level of the delegated name space is now being fenced into a number of realms, many of which are private.

The publication of RFC 6761^[10] by the IETF in February 2013 essentially opened up a competing and uncoordinated channel for drawing of top-level domain names from the domain name pool. In publishing this document the IETF took what was until then a relatively static view of reserved DNS names as described in RFC 2606^[14] in 1999, and replaced it with a process that reopened up the IETF-managed name registry, using the criteria that:

“If a domain name has special properties that affect the way hardware and software implementations handle the name, that apply universally regardless of what network the implementation may be connected to, then that domain name may be a candidate for having the IETF declare it to be a Special-Use Domain Name and specify what special treatment implementations should give to that name.”
[RFC 6761]

This action is effectively unilaterally rephrasing (or “recanting”) the agreement expressed in RFC 2860 and re-defining it to mean that ICANN has purview of only those domain names that use the DNS resolution protocol, and that if the domain name uses a name resolution mechanism that does not rely on this protocol, then the name can be assigned by the IETF, via the IETF publication process. Evidently there is a set of names that are queued up to be listed using this IETF process instead of undertaking the ICANN new gTLD path^[15]. These include **.bit** (using *namecoin* resolution), **.exit** (another TOR-related name) **.gnu** and **.zkey** (using *GNU Name System* resolution), **.i2p**, **.tor** and **.carrots**.

In addition to these two parallel channels of name assignment, the private use activity continues, and names are co-opted into local use domains without any degree of effective coordination.

Clearly this story does not look good. The existence of numerous of uncoordinated activities all drawing out names from a common domain name pool is not a stable situation, nor is it in the interests of the Internet’s users. How is a user to know that names drawn from **.bit** are to be resolved using a namecoin resolution mechanism, whereas names in **.bi** or **.bid** are to be resolved using the DNS resolution protocol?

Differentiating Names?

Are there better ways to signal the resolution protocol that should be applied to a name using some additional signalling?

Should we be thinking about using a *Uniform Resource Identifier* (URI)-like syntax and using distinct schemes, such as **DNS:www.example.com** and **GNS:test.gnu**? Or using a “selector” field in a URI and using URIs of the form: **http:/namecoin/namecoin-string**?

Alternatively, we could try to push these alternate names into a single distinguished gTLD, such as **.alt**, and allow the registrars for **.alt** to register such non-DNS names in a single location in the DNS name space^[16].

We could borrow a technique used by *Internationalized Domain Names* (IDNs) and use a common prefix to denote a non-DNS name, in the same way that the character string prefix “**xn--**” denotes that the following parts of this label require pre-processing in order to produce the equivalent Unicode string. This possibility would imply that all other name forms would form part of a single name space with a single name resolution protocol, while the exception space would be clearly denoted by such a distinguished name prefix, such as, hypothetically, **.xs--gnu** for *Gnu Name System* names and **.xs--bit** names, and so on.

Behind these approaches lies a common question: What are these alternate name forms and name resolution protocols really addressing? What is the underlying issue here? If they are addressing shortfalls in the DNS, such as its lack of privacy for example, then is the appropriate answer one that includes the use of a parallel alternative name resolution protocol, or should we be looking towards the evolution of the DNS protocol to accommodate these emerging requirements? If they are addressing the ICANN position that has apparently monetized the gTLD name space and thereby blocked various other interests from accessing a gTLD name, then is the most appropriate measure for the IETF to set up of a parallel name allocation mechanism? Should the names community within ICANN undertake some deeper introspection and examine whether the gTLD program is actually catering for the full spectrum of interests in securing names for their various needs?

One Name Space?

What may be useful here is the observation that this is not a unique problem.

The radio spectrum has gone through the same process a number of times during its 100-year history, looking at the competing interests wanting access to the radio-frequency spectrum. The current spectrum allocation model contains a mix of exclusive use access arrangements. There are commercial exploitation models where actors bid for exclusive use licenses and public interest allocation models where various public sector agencies are assigned spectrum space. There are public interest and scientific use allocations, such as those used by emergency services and radio astronomers. There are also unlicensed radio spectrum allocations where there is no arrangements for exclusive access, such as are used by WiFi systems. Although a national spectrum management body is not raising revenue from these unlicensed allocations, the economic benefits of WiFi are doubtless substantial, and there is a net benefit to national economies in having this diversity of spectrum access models. The insight here is the admission that the common pool of radio spectrum space does not necessarily admit to a single exploitative model of exclusive access arrangements, and allowing a diversity of models, including that of unlicensed access, has proved to be a useful framework.

What is evident is that ICANN's gTLD process has evidently not encompassed the plurality of demand for domain names. One characterization of the outcomes of the policy for new gTLDs is that it has encouraged competitive access within a relatively narrow model of use. Access to further gTLDs within this process has many barriers, including not inconsiderable financial outlays and process overheads. The reaction has been for numerous parties to look to the IETF's management of the Special-Use Domain Name registry as an alternate means of reserving a domain name and precluding it from being used by ICANN's new gTLD program.

The rationale for entry into the IETF's Special Use Names registry—namely that the name in question uses a non-DNS resolution protocol—could be argued to be a superficial artifice that hides a more significant issue about the broad variety of the natural demand for use of names drawn from the common pool of the domain name space, and the consequent pressure for a range of means for such demands to be satisfied.

There is no doubt that the Internet's users benefit from a single coherent name space. There is considerable benefit in having the same 'name' encompass the same semantic intent and thereby 'name' the same set of services irrespective of the context, locale or time of use of that name. At the same time, the underlying technologies of name resolution, including not only the DNS resolution protocol but also other forms and means of name resolution, are subject to evolutionary pressures. It is valuable to have a means to expose these exploratory efforts in an environment of scale of use, and clearly the IETF has a role to play here. But the current mechanism of having these two bodies making uncoordinated allocations from a common name pool is not an ideal situation.

What leads to some level of unease here about the coherence of the name space is the radically different processes of evaluation of the name itself.

In the ICANN case the new gTLD process requires evaluation of the name to ensure that does not unduly infringe on existing name use, including consideration of existing brands and trademarks, designation of origin and geographic terms, issues of consumer protection through consideration of name similarity and forms of intentional passing off, potential clashes with names used by recognized international organizations, offensive terms, potential name collisions and similar environmental concerns. One could argue with the effectiveness of the process used by ICANN to evaluate these considerations, but there is some merit in the intent of ensuring that there is a process that is mindful of the larger environment of name use when considering adding a further name into this pool of use by the Internet.

The IETF's evaluation process described in RFC 6761 for admission to the Special Use Names Registry appears to admit no such similar consideration. The seven questions posed in RFC 6761 are concerned primarily with the impact of this hidden "switch" that directs applications, name resolvers, and users to understand that this name is not to be resolved by the DNS. None of these questions are concerned with the name itself, and the consequent concern is that this process could be readily abused to legitimate name squatting, and be the source of various forms of name collision. For example, the reservation of the label `.local` in the Special Use Names Registry collides with extensive conventional DNS use in local contexts^[9].

There is no record of any evaluation by the IETF of the consequences of a registration of **.local** as a reserved name for use in non-DNS contexts, with its implicit switch to a different resolution protocol of multicast DNS, that collides with pre-existing use of **.local** names in conventional local DNS contexts. Nor was there any evidence that there was consideration given to mobile users who may move in and out of environments where names in **.local** have entirely different properties and meanings, and the security issues that could result from such confusion.

However, this situation is definitely not a case of “ICANN good, IETF bad!” Far from it! But it does illustrate that there is much more to a name than might appear at the outset. The name space is indeed larger than just the DNS name resolution protocol, and this is perhaps something for ICANN to consider. At the same time names exist in a larger context of social and technical use, and this is something for the IETF to consider if it wishes to accept further reservations in the Special Use Name registry. There is also the consideration of the larger issue of whether implicit (and largely invisible) name-triggered resolution protocol switches are really in the best interests of Internet users. And for those vendors and network administrators looking for local use names to support various form of plug and play, there is the consideration of name collisions and the potential security concerns for unsuspecting users when end systems move in and out of local environments where certain name forms take on altered meanings and altered contexts of use.

If we think that a coherent and consistent name space for the Internet still has some intrinsic value, then we simply have to make some changes here to allow for a broader diversity of name use for the Internet. At the same time we must avoid stomping wilfully on each other’s toes!

Quality of Service and Quality of Experience: Network Design Implications

by William Stallings, Independent Consultant
Florence Agboma, BSkyB

The Internet and enterprise IP-based networks continue to see rapid growth in the volume and variety of data traffic. Cloud computing, big data, the pervasive use of mobile devices on enterprise networks, and the increasing use of video and image traffic all contribute to the increasing difficulty in maintaining satisfactory network performance. Two key tools in measuring the network performance that an enterprise desires to achieve are *Quality of Service* (QoS) and *Quality of Experience* (QoE). QoS and QoE enable the network manager to determine if the network is meeting user needs and to diagnose problem areas that require adjustment to network management and network traffic control. This article provides an overview of QoS and QoE concepts, the relationship between the two, and the design implications of a QoE/QoS architecture.

Background and Overview

Historically, the Internet and other IP-based networks provided a *best-effort* delivery service. The term “best effort” refers to the connectionless, datagram nature of the interconnected set of networks. With best effort, a packet may be lost, duplicated, delayed, or delivered out of order, and the network does not inform sender or receiver. Traditionally, a best-effort network attempts to allocate its resources with equal availability and priority to all traffic flows, with no regard for application priorities, traffic patterns and load, or customer requirements. To protect the network from congestion collapse and to guarantee that some flows do not crowd out other flows, congestion-control mechanisms were introduced; they tended to throttle traffic that consumed excessive resources. As the intensity and variety of traffic increased, various QoS mechanisms were developed, including *Integrated Services Architecture* (ISA) and *Differentiated Services* (DiffServ) (for example, see [1]). *Service-Level Agreements* (SLAs) were also developed so that the service provided to various customers was tunable and somewhat predictable. These mechanisms and services serve two purposes: (1) allocate network resources efficiently so as to maximize effective capacity; and (2) enable networks to offer customers different levels of QoS on the basis of their requirements.

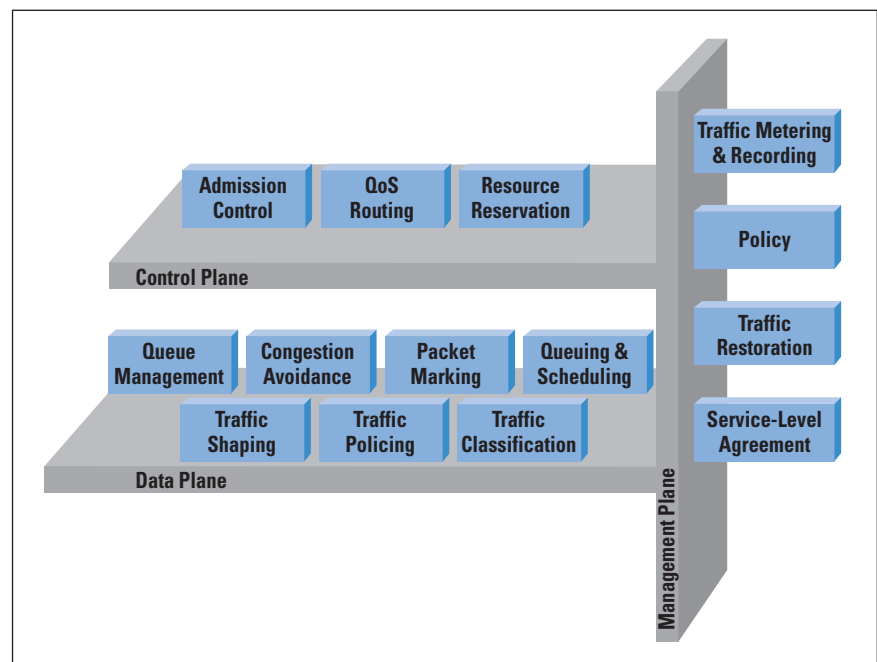

QoS is an important but increasingly insufficient tool for providing network services for many of today’s high-volume applications. To meet the needs of such applications, QoS has recently been augmented with the concept of QoE, which is a subjective measure of performance as reported by the user. Unlike QoS, which can be precisely measured, QoE relies on human opinion. QoE is important particularly when dealing with multimedia applications and multimedia content delivery.

Because QoE extends the concept of QoS to more fully tailor network services and performance to customer and user needs, it is garnering increasing attention by network protocol and system designers. The management of QoE has become a crucial concept in the deployment of future successful applications, services, and products. The greatest challenges in providing QoE are developing effective methods for converting QoE features to quantitative measures and translating QoE measures to QoS measures. Whereas now it is easy to measure, monitor, and control QoS at both the networking and application layers, and at both the end system and network sides, its management is still quite intricate.

QoS Architectural Framework

The *Telecommunication Standardization Sector of the International Telecommunication Union* (ITU-T) Recommendation Y.1291 provides an overall architectural framework that relates the various elements that go into QoS provision^[2]. Figure 1 shows the relationship between these elements, which are organized into three planes: data, control, and management. This architectural framework is an excellent overview of QoS functions and their relationships and provides a useful basis for summarizing QoS.

Figure 1: Architectural Framework for QoS Support

The *Data Plane* includes those mechanisms that operate directly on flows of data. The following discussion briefly describes each mechanism in turn.

Queue Management algorithms manage the length of packet queues by dropping packets when necessary or appropriate. Active management of queues is concerned primarily with congestion avoidance. In the early days of the Internet, the queue management discipline was to drop any incoming packets when the queue was full; it was referred to as the *tail-drop* technique. This technique has many drawbacks, including^[3]:

- There is no reaction to congestion until it is necessary to drop packets, whereas a more aggressive congestion-avoidance technique would likely improve overall network performance.
- Queues tend to be close to full, causing an increase in packet delay through a network and possibly resulting in a large batch of dropped packets for bursty traffic, necessitating many packet retransmissions.
- Tail drop may allow a single connection or a few flows to monopolize queue space, preventing other connections from getting room in the queue.

One noteworthy example of queue management is *Random Early Detection* (RED)^[4]. RED drops incoming packets probabilistically based on an estimated average queue size. The probability for dropping increases as the estimated average queue size grows.

Queuing and Scheduling Algorithms, also referred to as “queuing discipline algorithms,” determine which packet to send next; they are used primarily to manage the allocation of transmission capacity among flows.

Congestion Avoidance deals with means for keeping the load of the network sufficiently under its capacity such that the network can operate at an acceptable performance level. The specific objectives are to avoid significant queuing delays and, especially, to avoid congestion collapse.

Packet Marking encompasses two distinct functions. First, packets may be marked by network edge nodes to indicate some form of QoS that the packet should receive. An example is the *DiffServ* (DS) field in the IPv4 and IPv6 packets and the *Traffic Class* field in *Multiprotocol Label Switching* (MPLS) labels^[5]. An edge node can set the values in these fields to indicate a desired QoS. Such markings may be used by intermediate nodes to provide differential treatment to incoming packets. Second, packet marking can be used to mark packets as nonconforming; such packets may be dropped later if congestion occurs.

Traffic Classification refers to the assignment of packets to a traffic class at the edge of the network. Typically, the classification entity looks at multiple fields of a packet, such as source and destination address, application payload, and QoS markings, and determines the aggregate to which the packet belongs. This classification provides network elements a method to weigh the relative importance of one packet over another in a different class. All traffic assigned to a particular flow or other aggregate can be treated similarly. The flow label in the IPv6 header can be used for traffic classification.

Traffic Policing determines whether the traffic being presented, is on a hop-by-hop basis compliant, with prenegotiated policies or contracts. Nonconforming packets may be dropped, delayed, or labeled as nonconforming. As an example, ITU-T Recommendation Y.1221^[6] recommends the use of token bucket to characterize traffic for purposes of traffic policing.

Traffic Shaping controls the rate and volume of traffic entering and transiting the network on a per-flow basis. The entity responsible for traffic shaping buffers nonconforming packets until it brings the respective aggregate in compliance with the traffic. The resulted traffic thus is not as bursty as the original and is more predictable. For example, Y.1221 recommends the use of leaky bucket and/or token bucket for traffic shaping.

The *Control Plane* is concerned with creating and managing the pathways through which user data flows. *Admission Control* determines what user traffic may enter the network. This decision may be in part determined by the QoS requirements of a data flow compared to the current resource commitment within the network. But beyond balancing QoS requests with available capacity to determine whether to accept a request, there are other considerations for admission control. Specifically, network managers and service providers must be able to monitor, control, and enforce use of network resources and services based on policies derived from criteria such as the identity of users and applications, traffic/bandwidth requirements, security considerations, and time of day or week. RFC 2753^[7] discusses such policy-related issues.

QoS Routing determines a network path that is likely to accommodate the requested QoS of a flow. This function contrasts with the philosophy of traditional routing protocols, which generally are looking for a least-cost path through the network. RFC 2386^[8] provides an overview of the issues involved in QoS routing, which is an area of ongoing study.

Resource Reservation reserves network resources on demand for delivering desired network performance to a requesting flow. The resource-reservation mechanism that has been implemented for the Internet is the *Resource Reservation Protocol* (RSVP)^[9].

The *Management Plane* contains mechanisms that affect both control- and data-plane mechanisms. It deals with the operation, administration, and management aspects of the network. A *Service-Level Agreement* (SLA) is the agreement between a customer and a provider of a service that specifies the level of availability, serviceability, performance, operation, or other attributes of the service. SLAs are discussed subsequently.

Traffic Metering and Recording concerns monitoring the dynamic properties of a traffic stream using performance metrics such as data rate and packet-loss rate. It involves observing traffic characteristics at a given network point and collecting and storing the traffic information for analysis and further action. Depending on the conformance level, a meter can invoke necessary treatment (for example, dropping or shaping) for the packet stream. A subsequent section discusses the types of metrics that are used in this function.

Traffic Restoration refers to the network response to failures. It encompasses numerous protocol layers and techniques.

Policy refers to a set of rules for administering, managing, and controlling access to network resources. The rules can be specific to the needs of the service provider or reflect the agreement between the customer and service provider, which may include reliability and availability requirements over a period of time and other QoS requirements.

Service-Level Agreements

An SLA is a contract between a network provider and a customer that defines specific aspects of the service that is to be provided. The definition is formal and typically defines quantitative thresholds that must be met. An SLA typically includes the following information:

- *A description of the nature of service to be provided:* A basic service would be IP-based network connectivity of enterprise locations plus access to the Internet. The service may include additional functions such as web hosting, maintenance of domain name servers, and operation and maintenance tasks.
- *The expected performance level of the service:* The SLA defines numerous metrics, such as delay, reliability, and availability, with numerical thresholds.
- *The process for monitoring and reporting the service level:* This function describes how performance levels are measured and reported.

The types of service parameters included in an SLA for an IP network are similar to those provided for *Frame Relay* and *Asynchronous Transfer Mode* (ATM) networks. A key difference is that, because of the unreliable datagram nature of an IP network, it is more difficult to realize tightly defined constraints on performance, compared to the connection-oriented Frame Relay and ATM networks.

Figure 2 shows a typical configuration that lends itself to an SLA. In this case, a network service provider maintains an IP-based network. A customer has many private networks (for example, LANs) at various sites. Customer networks are connected to the provider via access routers at the access points. The SLA dictates service and performance levels for traffic between access routers across the provider network. In addition, the provider network links to the Internet and thus provides Internet access for the enterprise.

Figure 2: Typical Framework for Service-Level Agreement

For example, the standard SLA provided by Cogent Communications for its backbone networks includes the following items:

- *Availability*: 100% availability
- *Latency (delay)*: Monthly average Network Latency for packets carried over the COGENT Network between Backbone Hubs for the following regions: Intra-North America: ≤ 45 ms; Intra-Europe: ≤ 35 ms; New York to London: ≤ 85 ms; Los Angeles to Tokyo: ≤ 120 ms.

Latency is defined as the average time taken for an IP packet to make a round trip between Backbone Hubs within a region. COGENT monitors aggregate latency within the COGENT Network by monitoring round-trip times between a sample of Backbone Hubs on an ongoing basis.

- *Network Packet Delivery (reliability)*: Average monthly Packet Loss no greater than 0.1% (or successful delivery of 99.9% of packets). Packet Loss is defined as the percentage of packets that are dropped between Backbone Hubs on the COGENT Network.

An SLA can be defined for the overall network service. In addition, SLAs can be defined for specific end-to-end services available across the carrier's network, such as a virtual private network, or differentiated services.

IP Performance Metrics

The *IP Performance Metrics Working Group* (IPPM) is chartered by the *Internet Engineering Task Force* (IETF) to develop standard metrics that relate to the quality, performance, and reliability of Internet data delivery. Two trends dictate the need for such a standardized measurement scheme:

- The Internet has grown and continues to grow at a dramatic rate. Its topology is increasingly complex. As its capacity has grown, the load on the Internet has grown at an even faster rate. IP-based enterprise networks have exhibited similar growth in complexity, capacity, and load. The sheer scale of these networks makes it difficult to determine quality, performance, and reliability characteristics.
- The Internet serves a large and growing number of commercial and personal users across an expanding spectrum of applications. Similarly, private networks are growing in terms of user base and range of applications. Some of these applications are sensitive to particular QoS parameters, leading users to require accurate and understandable performance metrics.

A standardized and effective set of metrics enables users and service providers to have an accurate common understanding of the performance of the Internet and private internets. Measurement data is useful for a variety of purposes, including:

- Supporting capacity planning and troubleshooting of large complex internets
- Encouraging competition by providing uniform comparison metrics across service providers
- Supporting Internet research in such areas as protocol design, congestion control, and quality of service
- Verification of service-level agreements

The metrics are defined in three stages:

- *Singleton metric*: The most elementary, or atomic, quantity that can be measured for a given performance metric. For example, for a delay metric, a singleton metric is the delay experienced by a single packet.

- *Sample metric*: A collection of singleton measurements taken during a given time period. For example, for a delay metric, a sample metric is the set of delay values for all of the measurements taken during a one-hour period.
- *Statistical metric*: A value derived from a given sample metric by computing some statistic of the values defined by the singleton metric on the sample. For example, the mean of all the one-way delay values on a sample might be defined as a statistical metric.

The measurement technique can be either *active* or *passive*.

Active techniques require injecting packets into the network for the sole purpose of measurement. This approach has several drawbacks. The load on the network is increased, in turn possibly affecting the desired result. For example, on a heavily loaded network, the injection of measurement packets can increase network delay, so that the measured delay is greater than it would be without the measurement traffic. In addition, an active measurement policy can be abused for denial-of-service attacks disguised as legitimate measurement activity.

Passive techniques observe and extract metrics from existing traffic. This approach can expose the contents of Internet traffic to unintended recipients, creating security and privacy concerns. So far, the metrics defined by the IPPM working group are all active.

For the sample metrics, the simplest technique is to take measurements at fixed time intervals, known as periodic sampling. There are several problems with this approach. First, if the traffic on the network exhibits periodic behavior, with a period that is an integer multiple of the sampling period (or vice versa), correlation effects may result in inaccurate values.

Also, the act of measurement can perturb what is being measured (for example, injecting measurement traffic into a network alters the congestion level of the network), and repeated periodic perturbations can drive a network into a state of synchronization (for example, [10]), greatly magnifying what might individually be minor effects. Accordingly, RFC 2330^[11] recommends Poisson sampling. This method uses a Poisson distribution to generate random time intervals with the desired mean value.

Figure 3 illustrates the packet-delay variation metric. This metric is used to measure jitter, or variability, in the delay of packets traversing the network. The singleton metric is defined by selecting two packet measurements and measuring the difference in the two delays. The statistical measures use the absolute values of the delays.

Figure 3: Model for Defining Packet-Delay Variation

QoS for Streaming Video

It is worthwhile to comment on the relationship between QoS concerns and streaming video, which perhaps accounts for the greatest volume of traffic on the Internet. First, consider the network transmission requirements for real-time video, such as video teleconferencing. For such applications QoS metrics such as latency and jitter are important, and they impose significant requirements on the networks through which the real-time traffic passes.

For streaming video, in contrast, such QoS requirements can be relaxed by equipping the application to handle a wider range of responses. A motivation for this approach is that QoS is not ubiquitously deployed in networks and thus is not available for all possible streams between content deliverers and content consumers. In the case of streaming video in particular, applications have come to assume that the receiving device is equipped with generous levels of memory, and the application uses this memory as a playback buffer. This system allows the application to use TCP for reliable delivery. The TCP connection can be exposed to far higher levels of network jitter and even packet loss than would be tolerable by a real-time packet stream. Thus, to a significant extent, this approach to video streaming avoids the need to use QoS as a strict precondition for streaming video over the Internet.

From QoS to QoE

The literature contains numerous different, though similar, definitions of QoE. To provide a common working definition, the EU-sponsored *European Network on Quality of Experience in Multimedia Systems and Services* (see [12]) has developed a definition of QoE that reflects broad industry and academic consensus:

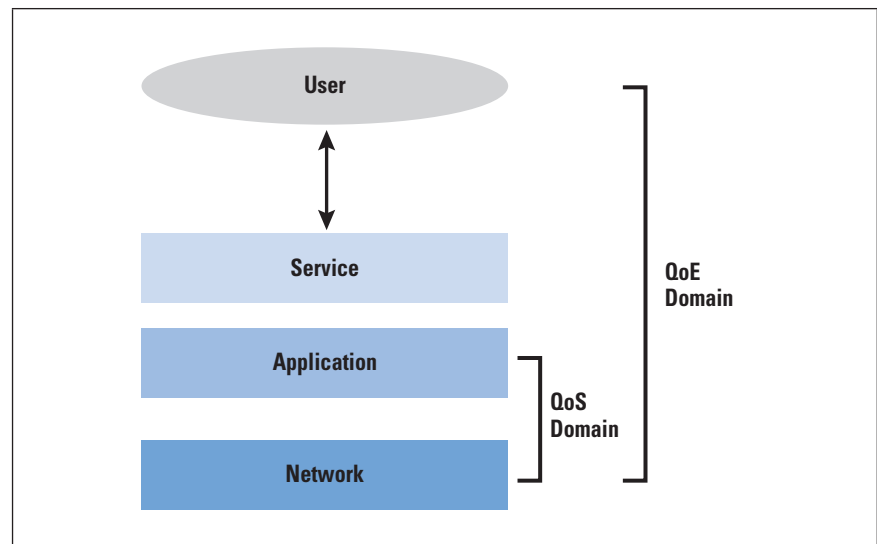

“Quality of Experience (QoE) is the degree of delight or annoyance of the user of an application or service. It results from the fulfillment of his or her expectations with respect to the utility and/or enjoyment of the application or service in the light of the user’s personality and current state.”

The QoE methods to measure this degree of delight or annoyance are discussed later in this article.

The Layers of QoE

For any type of service (for example, IPTV), multiple QoS parameters contribute to the overall user’s perception of quality. The concept of QoE in addition to QoS mechanisms has been proposed in [13], [14], [15], and [16] as a QoE/QoS layered approach by which the requirements of the users drive network-dimensioning strategies. The QoE/QoS layered approach does not substitute the QoS aspect of the network, but instead, user and service-level perspectives are both complementary as shown in Figure 4.

Figure 4: QoE/QoS Layered Model

The levels from the layered approach follow:

- *User*: The user interacts with the service. It is the user’s degree of delight or annoyance from using the service that is to be measured.
- *Service*: This level is the virtual level where the user’s experience of the overall performance of the service can be measured. It is the interface where the user interacts with the service (for example, the visual display to the user).
- *Application-level QoS (AQoS)*: This level deals with the control of application-specific parameters such as content resolution, bitrate, frame rate, colour depth, codec type, layering strategy, sampling rate, and number of channels.

- *Network-level QoS (NQoS)*: This level is concerned with the low-level network parameters such as service coverage, bandwidth, delay, throughput, and packet loss.

Background on the Layers of QoE

Being linked to human perception, QoE is hard to describe quantitatively, and it varies from person to person. The complexities of QoE at the user level stem from the differences between individual user characteristics, of which some might be of a variant nature (that is, changing often with time), whilst others are of a relatively stable nature. Examples could include gender, age, attitudes, prior experience, expectations, socio-economic status, cultural background, educational level, etc. Thus, it becomes a challenge to derive unified QoE metrics for all users and their contexts. Reiter et al.^[17] provide more details on the human factors that may influence QoE. The current practice in any QoE measurement is to identify and control the relatively stable characteristics of a user in a way that is satisfactory to at least a large proportion of the potential user group.

Multiple layers might impact the user QoE for any application. The service level provides a virtual level where the user's tolerance thresholds for a particular service could be measured. As an illustration, the QoE measures from the user perspective for streaming applications could be a) start-up time, b) audiovisual quality, c) channel-change delay, and d) buffering interruptions, whilst the QoE measures for web-browsing applications could be waiting times.

Quite often, the network capacity will dictate the bandwidth that may be used for transmission. At the application-level QoS, there might be a trade-off between quality and size. For audio, a higher sampling rate, for example, 96 kHz, might allow for more information to be perceived compared with 48 kHz, but at the expense of a bigger file size. Traditional telephony speech might be limited to 8 kHz because of the bandwidth capacity. For video, a high resolution might require more bandwidth than low resolution. There are huge varieties of device screens in all kinds of sizes, featuring varied aspect ratios. The one commonality in this array of equipment is that they are all capable of rescaling the video, as is the case for a native player going to the full-screen mode. For a given bitrate, there might be a trade-off between lower resolutions in pixels (images being slightly blurred) with fewer artifacts versus higher resolutions that provide a sharper image but possibly with more artifacts. Most compression standards might use a block-based and motion-compensation coding scheme, and as a result additional compression artifacts are added to the decoded video.

Network-level QoS parameters could impact QoE in a variety of ways.

The network delay could impact QoE, especially for interactive services. For instance, the interactive nature of web browsing that requires multiple retrieval events within a certain window of time might be affected by delay variations of the network. *Voice over IP* (VoIP) services might have the stringent response-time demands, whereas email services might tolerate much longer delays. The different distribution methods of streaming video over the network might affect QoE in different ways. HTTP-based adaptive streaming, which uses TCP, might react to bandwidth constraints and CPU capacity in two ways: either the streaming switches between streaming the different bitrate encodings depending on available resources, or a frame freeze (rebuffering) due to incoming packet starvation in the player buffer. The continuous bitrate switches and rebuffering affect QoE badly. The other distribution method, *User Datagram Protocol* (UDP), might use multicast to replicate the streams throughout the network. Quite often, a resilient coding scheme and a flow-control mechanism might be implemented to maintain the viewing experience despite the effects of poor network conditions.

For reasons that should now be apparent, the background on the layers of QoE suggests that the effect of QoE could be an attribute of only the application layer or a combination of both the application and network layers. Although the trade-offs between quality and network capacity may begin with application-level QoS due to network capacity considerations, an understanding of the user requirements at the service level (that is, in terms of QoE measures) would enable a better choice of application-level QoS parameters to be mapped onto the network-level QoS parameters. A scenario that aims at controlling QoE using QoS parameters as actuators is discussed later in this article. Taking the QoE/QoS approach as a whole entity rather than single entities might aid in providing better QoEs, and potentially could lead to a better-managed delivery infrastructure.

Key Factors That Determine QoE

The nature of QoE, which comprises many layers of interaction between the enabling elements of service delivery and the human user, makes measuring and improving user experiences a challenging task. To understand QoE we must account for both technical and nontechnical factors. Many factors contribute to producing a good QoE. Moller et al.^[18] provide useful perspectives on factors that influence QoE. Here, we discuss the following key factors that might influence QoE:

User Demographics: The context of demographics herein refers to the relatively stable characteristics of a user that might indirectly influence perception, and intimately affects other technical factors to determine QoE. The findings from [19] suggest that user demographics may influence QoE. In the context of adopting HD voice telephony, the different user groups had significantly different quality ratings.

The grouping of users was based on demographic characteristics such as their attitudes towards adoption of new technologies, socio-demographic information, socio-economic status, and prior knowledge. Cultural background is another user demographic factor that might also influence perception due to cultural attitude to quality^[20].

Type of Device: Different device types possess varying characteristics that may affect QoE. An application designed to run on more than one device type, for example on a connected TV device such as Roku and on an iOS device such as an iPhone, may not deliver the same QoE on every device.

Content: The content being distributed via Internet delivery can range from interactive content specifically curated according to personal interests to content that is produced for linear TV transmission. The different characteristics of the video might require different system properties in terms of the quality being produced. According to [21], people tend to watch *Video on-Demand* (VoD) content with a higher level of engagement than its competing alternative, linear TV. This trend may be because users make an active decision to watch a particular VoD content, and as a result, give their full attention to it. One could infer that for VoD, users might be less tolerant of any quality degradations because of their high level of engagement.

Connection Type: The type of connection used to access the service influences users' expectations and their QoEs. Users have been found to have lower expectations when using 3G in contrast to a wireline connection when in fact both connection types were identical in terms of their technical conditions^[22]. Agboma et al.^[23] found users' expectations to be considerably lowered and more tolerant to visual impairments on small devices. Conventional QoS management practices cannot account for these psychological factors.

Media (audiovisual) Quality: This factor may be observed as a significant one affecting QoE, because it is the part of a service that users notice most. The integration of audio and video quality appears to be content-dependent. For less-complex scenes (for example, head and shoulder content), audio quality is slightly more important than video quality. In contrast, for high-motion content, video quality has been found to be significantly more important than audio quality^[24]. Other studies^[25] suggest that the optimum audio/video bitrate allocation depends on scene complexity. For instance, visually complex scenes would benefit from the allocation of higher bitrates, with relatively more bits allocated towards audio, because high-audio bitrates seem to produce the best overall audiovisual quality.

Network: Content delivery via the open Internet is highly susceptible to the effects of delays, jitter, packet loss, and available bandwidth. For users, delay and jitter cause frame freeze and the lack of lip synchronization between what is heard (audio) and what is seen (video). Content delivery is guaranteed using a TCP/IP delivery mechanism. However, under bad network conditions, the frequency of rebuffering, and the implementation of a video player heuristics, might affect QoE. Rebuffering interruptions in IP video playback is considered the worst degradation on user QoE and should be avoided at the cost of startup delay^[26]. On the same note, QoE for a given startup delay strongly depends on the concrete application context and user expectations^[27]. In spite of the different QoE factors that are concerned with the network, reliability and a strong wireless signal is crucial for consuming TV-like services anytime, anywhere, and from any device.

Usability: Another QoE factor is the amount of effort that is required to navigate through the service. The design should render good quality without a great deal of technical input from the user before or after service consumption.

Cost: The long-established practice of judging quality by price implies that expectations are price-dependent. If the tariff for a certain service quality is high, users may be highly sensitive to any quality degradations. A scenario of QoE-based charging is demonstrated in [28] and [29] to analyze a situation where price is used to reflect the value of a service, and at the same time, part of the user-context factor. While [28] offers a trade-off between user expectations and price, its deployment may yield unexpected complexities.

QoE Measurement Methods

QoE measurement techniques evolved through the adaptation and application of psychophysics methods during the early stages of television systems (See [30] for more details). Here, we introduce three QoE measurement methods: subjective assessment methods, objective assessment methods, and end-user device analytics as an alternative to measure QoE. Hereafter, streaming video will be the focus of discussion.

Subjective Assessment

In *Subjective Assessment* of QoE, experiments are carefully designed to a high level of control (such as in a controlled laboratory, field tests, or crowdsourcing environments) so that the validity and reliability of the results can be trusted. It might be useful to consult expert advice during the initial design of the subjective experiment, because the topics of experimental design, experimental execution, and statistical analysis are complex. The different phases discussed in the following paragraphs are an abstract. A methodology to obtain subjective QoE data might consist of the following phases:

Characterize the Service: The task at this stage is to choose the QoE measures that affect the users' experience the most. As an example, consider a multimedia conferencing service; previous studies have shown that the quality of the voice takes precedence over the quality of video^[31]. Also, the video quality required for such applications does not demand a very high frame rate, provided that audio-to-video synchronization is maintained. Thus, the resolution of individual frames can be considerably lower than the case of other video streaming services, especially when the size of the screen is small (such as that of a mobile phone). Therefore, in multimedia conferencing, the QoE measures might be prioritized as voice quality, audio-video synchronization, and image quality.

Design and Define Test Matrix: Once the service has been characterized, the QoS factors that affect the QoE measures can be identified. For instance, the video quality in streaming services might be directly affected by network parameters such as bandwidth, packet loss, and encoding parameters such as frame rate, resolution, and codec. The capability of the rendering device will also play a significant role in terms of screen size and processing power. However, testing such a large combination of parameters may not be feasible. This draft matrix could be reduced to more achievable realistic test conditions by eliminating the combinations that have similar effects on QoE.

Specify Test Equipment and Materials: Subjective tests should be designed to specify test equipment that will allow controlled enforcement of the test matrix. For instance, to assess the correlation between NQoS parameters and the perceived QoE in a streaming application, at least a client device and a streaming server separated by an emulated network are needed. If the objective is to evaluate how different device capabilities impact QoE, then a video content is chosen to produce formats that can run in each of the client devices under scrutiny.

Identify Sample Population: A representative sample population is identified, possibly covering different classes of users categorized by the user demographics that are of interest to the experimenter. Depending on the target environment for the subjective test, at least 24 test subjects (that is, participants) have been suggested for a controlled environment (for example, a laboratory) and at least 35 test subjects for a public environment. Fewer subjects may be used for pilot studies to indicate trending^[32]. The use of *crowdsourcing* in the context of subjective assessment is still nascent, but it has the potential to further increase the size of the sample population and could reduce the completion time of the subjective test.

Subjective Methods: The recommendations include several subjective assessment methodologies, for example [33], [34], and [35]. A recent recommendation^[32] addresses the context of Internet video and distribution of quality television in any environment. These recommendations provide guidelines on topics such as the different subjective test designs, rating scales, and experiment durations.

There has also been some interest in developing alternative subjective methodologies for time-varying system characteristics, see [36] and [37]. Typically, each test subject is presented with the test conditions under scrutiny along with a set of rating scales that allows the correlation of the users' responses with the actual QoS test conditions being tested. There are several rating scales, depending on the design of the experiment. Other scale methods can be found in [32], and acceptance methods in [38].

Analysis of Results: When the test subjects have rated all QoS test conditions, a post-screening process might be applied to the data to remove any erroneous data from a test subject who appears to have voted randomly. Depending on the design of the experiment, a variety of statistical approaches could be used to analyze results. For the sake of brevity, statistical analysis of the results is outside the scope of this article. The most common quantification method is the *Mean Opinion Score* (MOS), which is the average of the opinions collected for a particular QoS test condition. The results from subjective assessment experiments are used to quantify QoE, and to model the impacts of QoS factors. Other authors^[39] have gone beyond deriving QoS MOS functions to QoE management. The rationale and limitations of MOS are discussed later in this article.

Subjective experiments require significant planning and design so as to produce reliable subjective MOS ratings. However, they are time-consuming and expensive to carry out and are not feasible for real-time in-service monitoring. Therefore, the use of objective models is often desirable.

Objective Assessment

In *Objective Assessment* of QoE, computational algorithms provide estimates of audio, video, and audiovisual quality as perceived by the user. Each objective model targets a specific service type. For example, ITU-T P.1201 predicts the impact of IP network impairments for IPTV applications and multimedia streaming applications^[40]. ITU-T J.341 targets video-quality measurement in *High-Definition Television* (HDTV) noninteractive applications^[41]. Other proprietary objective models do exist. For a given scope of quality features, the goal of any objective model is to find the optimum fit that strongly correlates with data obtained from subjective experiments. The following phases presented here should not be considered exhaustive, but they are meant to illustrate a process of obtaining objective QoE data. A methodology to obtain objective QoE data might consist of the following phases:

Database of Subjective Data: A starting point might be the collection of a group of subjective datasets as this list could serve as benchmark for training and verifying the performance of the objective model. A typical example of one of these datasets might be the subjective QoE data generated from well-established subjective testing procedures, as discussed earlier. The selection of the subjective datasets should typically reflect the use cases of the objective model.

Preparation of Objective Data: The data preparation for the objective model might typically include a combination of the same QoS test conditions as found in the subjective datasets, as well as other complex QoS conditions. A variety of pre-processing procedures might be applied to the video data prior to training and refinement of the algorithm.

Objective Methods: Various algorithms in the literature could provide estimates of audio, video, and audiovisual quality as perceived by the user. Some algorithms might be developed, and test subjects trained, for a specific perceived quality artifact, whilst other algorithms and test subjects might be trained for a wider scope of perceived quality artifacts. Examples of the perceived artifacts might include blurring, blockiness, unnatural motion, pausing, skipping, rebuffering, and imperfect error concealment after transmission errors. See [42] for a good overview, and for the development of objective video-quality prediction.

Verification of Results: After the objective algorithm has processed all QoS test conditions, the predicted values might benefit from a post-screening process to remove any outliers, the same concept as applied to the subjective datasets. The predicted values from the objective algorithm might be in a different dimension compared to the subjective QoE datasets. The predicted values might be transformed to the same scale as obtained in the subjective experiments (for example, into the MOSs) to allow for a linear comparison, and so that the optimum fit between the predicted QoE values and subjective QoE data can be obtained. This transformation might be an integral module of the objective model. The statistical analysis that might be applied to calibrate the scale of an objective model is outside the scope of this article.

Validation of Objective Model: The objective data analysis might be evaluated with respect to its prediction accuracy, consistency, and linearity by using different subjective datasets. It may also be worth noting that the performance of the model might depend on the training datasets and the verification procedures. See [43] for more details on calibrating and validating objective models. The *Video Quality Experts Group* (VQEG) validates the performance of objective perceptual models that result in ITU recommendations and standards for objective quality models for both television and multimedia applications^[44]. The practical deployment of such objective models is discussed in the background of QoE measurement methods.

End-User Device Analytics

End-user device analytics could provide an alternative to measuring QoE as experienced by the end user. Real-time data such as the connection time, bytes sent, and average playback rate are collected by the video player application for each video viewing session and fed back to a server module where the data is pre-aggregated and then turned into actionable QoE measures.

Some of the metrics reported for per-user and aggregate viewing sessions include startup delay, rebuffering delays, average bitrates, and frequency of bitrates switches. Operators might be more inclined to associate viewers' engagement to QoE because better QoEs might make viewers less likely to abandon a viewing session, leading to increased monetization of assets and low subscriber turnover.

The definition of viewer engagement may have different meanings for different operators and contexts. First, operators might like to know which viewer engagement metrics affect QoE the most in order to guide the design of the delivery infrastructures. Secondly, they might also like to quickly identify and resolve service outages and other quality issues. A minute of encoder glitch could replicate throughout the *Internet Service Providers* (ISPs) and the various delivery infrastructures, and affect all their customers. Operators might like to know the scale of this impact, and how it affects users' engagement. The cost of getting the viewer experience wrong often makes the news headlines^[45]. Finally, they would like to understand their customers' demographics (connection methods, type of device, and bitrates of the consumed asset) within a demographic region so that they can fully monetize their assets, and use their other resources strategically.

QoE enthusiasts advocate QoE measurement to be a multidisciplinary approach that seeks to explain its findings, building on general laws of perception, sociology, and user psychology^[39]. If the end-user device analytics is used as a means of QoE measurement, many unexplained variables may not be accounted for (for example, why a user exits a service). For instance, the viewer's tolerance thresholds of QoS parameters for live and VoD might have different QoE patterns, and another dimension of complexity to include might be premium vs. free content. Also, a lack of interest in watching the content, not necessarily an effect of poor QoE, might make a user exit a service. Viewer engagement metrics is measured objectively bypassing subjective studies and surveys.

Some attempts at addressing these unexplained variables can be found in the literature. For example, [46] used the fraction of video viewed as a measure of engagement because this factor can be measured objectively. The data that appeared to belong to early quitters were systematically removed from their analysis to provide a clearer understanding of how the QoE measures affected viewer engagement. A slightly different approach to measuring viewer engagement can be found in [47]. However, with a huge database of aggregated data in the range of millions of viewing session logs, some profile classes of how the QoE measures affect viewer engagement might emerge.

Background on QoE Measurement Methods

The MOS appears to be the *de facto* standard metric for QoE. The possible reasons could be its long-term establishment in telephony networks, perhaps its widespread acceptance on the merits that it can be easily understood, and a metric for benchmarks. There are different types of MOS values, and different test methodologies to produce them, (see [32] for more details). Figure 5 shows the five-point absolute category rating MOS scale that is commonly used.

Figure 5: Five-Point Rating Scale

Score	Label
5	Excellent
4	Good
3	Fair
2	Poor
1	Bad

The MOS value is the average opinion for a given QoS tests condition, not necessarily for the individual users because different users have different opinions. Additional information such as statistical uncertainty in terms of confidence intervals is usually encouraged. The MOS is considered to be characteristic of only the experiment and the group of test subjects from which it was derived.

While there is a reference methodology to produce MOS, it has to be interpreted within context. First, the MOS value obtained for a particular QoS test condition in a subjective experiment may depend on the range of the QoS test conditions used in the experiment. This dependence might be due to test subjects who re-calibrate their use of the rating scale to the conditions in the experiment. An appropriately designed experiment that has a practice period at the start of the experiment, and the test conditions include the best and worst conditions, minimizes the effects of the aforementioned behavior.

Secondly, direct comparisons of MOS scores obtained from separate experiments are generally not meaningful. They are meaningful only if the experiments have been specially designed to enable such comparisons. Data from such specially configured experiments must be studied and shown that their MOS comparisons are statistically valid. Biases in the rating scale interpretation might exist such as differences in interpretation and use of rating scales across cultures; test subject profile, for example, age and technology exposure; test environment; and the presentation order of the test conditions^[48].

Thirdly, it is possible that different objective models that have been trained and optimized using different subjective contexts will predict non-identical MOS values for the same QoS conditions. Objective models are usually developed and optimized for a specific scope of quality features. As a consequence, comparisons between MOS predictions and thresholds can be reliably made only if the thresholds are chosen in the context of the MOS model. See [46] for MOS interpretation and reporting.

The ITU standardization activities^[49] classify objective quality assessment methods into five main categories: media-layer models, parametric packet-layer models, parametric planning models, bitstream-layer models, and hybrid models. Depending on the input parameters to the model and the specific service type (for example, speech, audio, video, and multimedia), each category is aimed at predicting QoE.

The practical deployment of such objective models might benefit in-service monitoring positioned at any one node, or at all nodes, within the content-delivery ecosystem. The node(s) could be at the headend incoming feeds, distribution networks, and at locations of endpoints that are customer equipment. For example, the media-layer model (also known as the perceptual model) might be best suited for quality assurance at the headend, and for benchmark purposes. The media-layer model uses both the source video and the impaired video to predict QoE. The parametric-packet layer model uses only packet-header information such as IP packets, for example, UDP, and extracts the required information to predict QoE. It does not consider encoding distortions, but owing to its light-weight implementation it might be appropriate for in-service monitoring distribution networks. On the other hand, the bitstream-layer models might be appropriate for locations of endpoints that are customer equipment, because they analyze up to the bitstream level. This model in turn does not consider the decoded (impaired) output. The perceptual hybrid model, which combines the media layer and bitstream layer, might use both the bitstream information and the decoded output to predict QoE. While objective assessment seems to offer real-time QoE measurements, some categories might not meet industry demands. Hence, end-user device analytics as a method to QoE measurement appears to be an alternative approach.

Currently, there is the lack of a reference methodology for end-user device analytics as a method of QoE measurement, analogous to MOSs found in subjective assessments^[32] and objective assessments^[42]. A limiting factor to this development might be the restricted rights governing service providers, or the likes, on the usage of such databases. This situation makes it challenging for researchers, service providers, and delivery infrastructures to focus their efforts on developing better delivery infrastructures.

Subjective experiments could still be the most accurate way to measure perceived QoE, and the only way to obtain reliable ground-truth data used in benchmarking objective QoE models.

Linking QoS to QoE

A first glance indicates a considerable mismatch between the concepts of QoS and QoE. This mismatch can be seen in the ITU-T definitions of the two terms. QoS is defined in ITU-T E.800^[50] as the “totality of characteristics of a telecommunications service that bear on its ability to satisfy stated and implied needs of the user of the service.” These characteristics are objective measures consisting of quantitative variables and attributes that may be present or absent. Thus, QoS characteristics are objective and can be objectively measured. By contrast, ITU-T P.10^[51] defines QoE as “the overall acceptability of an application or service, as perceived subjectively by the end-user.” Thus, QoE is called out specifically as consisting of subjective measures.

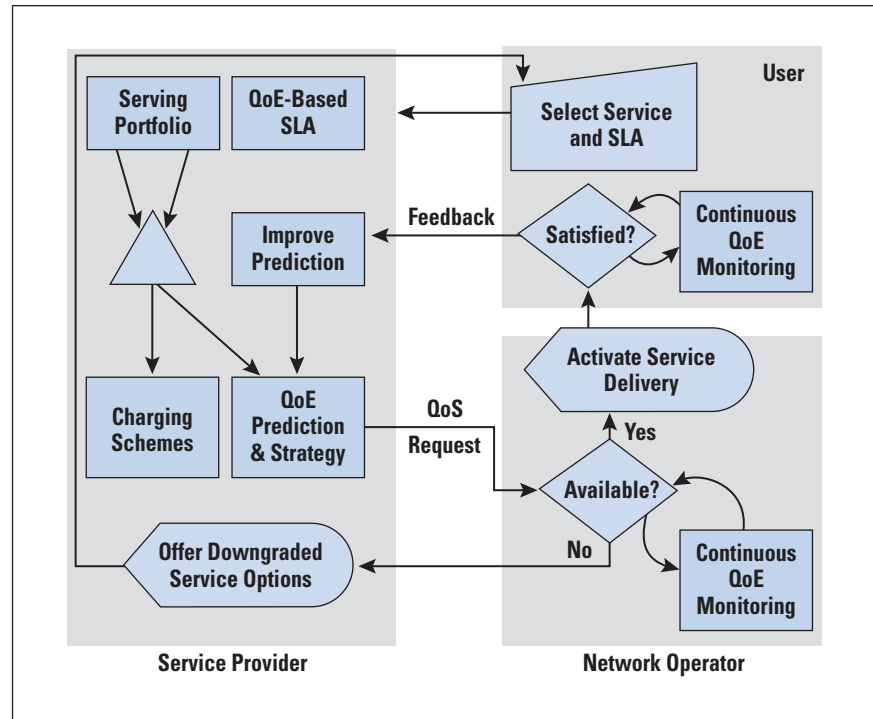

Both network service providers and customers have become accustomed to developing SLAs based on QoS measures. Recent years have seen a growing awareness on the part of both providers and customers that QoE is the more important concept, and that ways must be found to tie network performance parameters, as committed in an SLA, to the desired user QoE. For a typical network and service environment for a particular customer, numerous QoS metrics will impact overall QoE. The focus of ongoing research and product development is on developing reliable techniques, acceptable to both service provider and customer, for correlating QoS performance metrics with QoE as measured by MOS. ITU-T G.1080 identifies two ways in which such correlations can be exploited:

- Given a QoS measurement, predict the expected QoE for a user, with appropriate assumptions.
- Given a target QoE for a user, deduce the required network service performance, with appropriate assumptions.

Service providers can take the first approach and provide a range of QoS offerings with an outline of the QoE that their customers might reasonably expect. Customers can take the second approach by defining the required QoE and then determining what level of service will meet their needs.

Figure 6 illustrates a scenario for the second approach, where the user can make a selection from a range of services, including the required *level of service* (SLA). By contrast to the purely QoS-based management, the SLA here is not expressed in terms of raw network parameters. Instead, the user indicates a QoE target; it is the service provider that maps this QoE target together with the type of service selected, onto QoS demands.

Figure 6: User-Centric Service Delivery

For instance, in the case of multimedia streaming service, the user may simply choose between two QoE levels (high or low). The service provider selects the appropriate quality-prediction model and management strategy (for example, minimize network resource consumption) and forwards a QoS request to the operator. It is possible that the network cannot sustain the required level of QoS, making it impossible to deliver the requested QoE. This situation leads to a signal back to the user, prompting a reduced set of services/QoE values.

Assuming that the network can support the service, delivery can be activated. During service operation, two monitoring and control loops run concurrently: one at network level and the other at service level. The latter allows the user to switch to a different level of QoE (for example, to get a cheaper service or to request higher quality). If the user generates no explicit feedback, it means that the user is satisfied, confirming that the quality-prediction model is working. In this way, the quality-prediction model continues to be redefined during service delivery, allowing it to evolve as user needs and devices change over time.

There are so many varied components with this approach, which extends from the management complexity of a *Content-Delivery Network* (CDN) service based on QoE SLAs to service billing. However, focusing on integrating QoE as part of the management methodology during the design and development of services ensures a user-centric perspective, and helps to move beyond the current network design principles.

IANA Stewardship Transition Moves to Final Phase

An historic proposal for the global community to assume stewardship of the *Internet Assigned Numbers Authority* (IANA) functions, produced after nearly two years of work by the global Internet community, has been delivered to the U.S. Government for its consideration. The proposal would remove U.S. Government oversight over a set of fundamental Internet administrative functions, including management of the global pool of Internet number resources (IPv4 and IPv6 addresses and *Autonomous System Numbers*), and replace it with a set of arrangements for community-based oversight.

The proposal, developed by the *IANA Stewardship Transition Coordination Group* (ICG), is based on input from three operational communities, including the *Internet Number Community* (those with an interest in the global management of Internet number resources). The contributions of the Internet Number Community were coordinated via a *Consolidated RIR IANA Stewardship Proposal* (CRISP) Team made up of community members drawn from each of the five RIR regions.

While the ICG published the final draft of its proposal in October 2015, elements of the proposal relied upon the adoption of a set of recommendations regarding the accountability of ICANN to its community. These recommendations were developed separately by a *Cross Community Working Group on Enhancing ICANN Accountability* (CCWG) and were adopted by the ICANN Board at its meeting in March 2016 in Marrakech, Morocco. The Board was at that point able to pass on both the ICG and CCWG documents to the *National Telecommunication and Information Administration* (NTIA), an agency of the U.S. Government.

The U.S. Government will now review the proposal to ensure that it meets the criteria set out by the NTIA when they first announced their intention, in March 2014, to pass stewardship of the IANA functions to the global community. If approved, the *Regional Internet Registries* (RIRs) and ICANN will continue their work towards implementation of the proposal, which will be completed prior to the expiration of ICANN's current contract with NTIA in September 2016.

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

FROM THE EDITOR

A major design feature of the *Internet Protocol* (IP) is its ability to run over a variety of underlying network technologies. If you look through the *Request For Comments* (RFC) document series, you will find numerous specifications of the form “IP over xxx,” where “xxx” is anything from Ethernet to X.25, Frame Relay, Bluetooth, WiFi, and even “Avian Carriers” (pigeons), the latter being one of the more famous April Fools RFCs. Because each of these technologies has different capabilities in terms of how much data can be carried in a “packet” or datagram, IP employs the concept of *fragmentation* and *reassembly* in cases where the originating datagram is larger than what the underlying network medium can support. In our first article, Geoff Huston explains fragmentation and reassembly for both IPv4 and IPv6. Special thanks go to Mansour Ganji of Vodafone New Zealand for suggesting this topic.

We’ve covered various aspects of the *Internet of Things* (IoT) in previous editions of this journal. This time, Akbar Rahman and Chonggang Wang discuss ongoing work within the *Internet Engineering Task Force* (IETF) and elsewhere to develop Resource Discovery mechanisms for IoT devices.

The long-awaited proposal to transition the *Internet Assigned Numbers Authority* (IANA) Stewardship Functions from the U.S. Government to a new entity was finally submitted in early March of this year. Vint Cerf explains the history and background of this process. At the end of his article you will find pointers to further information about this important Internet milestone.

As always, we welcome your feedback, suggestions, book reviews, articles, and sponsorship support. You can contact us by e-mail to ipj@protocoljournal.org and visit our website for subscription information, back issues, author guidelines, sponsor information, and much more.

Fragmentation

by Geoff Huston, APNIC

One of the more difficult design exercises in packet-switched network architectures is that of the design of packet fragmentation. In this article I will examine *Internet Protocol* (IP) *packet fragmentation* in detail and look at the design choices made by IP Version 4, and then compare that with the design choices made by IP Version 6.

Packet-switched networks dispensed with a constant time base, in turn allowing individual packets to be sized according to the needs of the application as well as the needs of the network. Smaller packets have a higher ratio of packet header to payload, and are consequently less efficient in data carriage. On the other hand, within a packet-switching system the smaller packet can be dispatched faster, reducing the level of *head-of-line blocking* in the internal queues within a packet switch and potentially reducing network-imposed jitter as a result. Larger packets allow larger data payloads, in turn allowing greater carriage efficiency. Larger payloads per packet also allows a higher internal switch capacity when measured in terms of data throughput. But larger packets take longer to be dispatched, potentially causing increased jitter.

Various network designs have adopted various parameters for packet size. Ethernet, standardized in the mid-1970s, adopted a variable packet size, with supported packet sizes of between 64 and 1,500 octets. *Fiber Distributed Data Interface* (FDDI), a fibre ring local network, used a packet size of up to 4,478 octets. Frame Relay used a variable packet size of between 46 and 4,470 octets. The choice of variable-sized packets allows applications to refine their behaviour. Jitter and delay-sensitive applications, such as digitised voice, may prefer to use a stream of smaller packets to attempt to minimise jitter, while reliable bulk data transfer may choose a larger packet size to increase carriage efficiency. The nature of the medium may also have a bearing on this choice. If there is a high *Bit Error Rate* (BER) probability, then reducing the packet size minimises the impact of sporadic errors within the data stream, possibly increasing throughput.

IPv4 and Packet Fragmentation

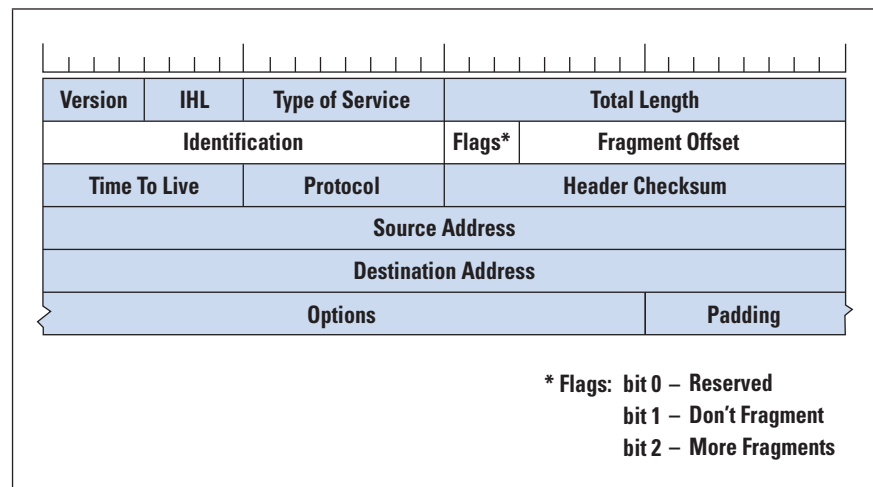

In designing a network protocol that is intended to operate over a wide variety of substrate carriage networks, the designers of IP could not rely on a single packet size for all transmissions. Instead the IP designers of the day provided a packet-length field in the IP Version 4 header^[1]. This field was a 16-bit octet count, allowing for an IP packet to be anywhere from the minimum size of 20 octets (corresponding to an IP header without any payload) to a maximum of 65,535 octets. So IP itself supports a variable size packet format. But which packet size should an implementation use?

The tempting answer is to use the maximum size permitted by the network interface of the local device, with the caveat that an application may nominate the explicit use of smaller-sized packets. But there is a complication here. The Internet was designed as an “inter-network” network system, allowing an IP packet to undertake an end-to-end journey from source to destination across numerous different networks. For example, consider a host connected to a FDDI network, which is connected to an Ethernet network. The FDDI-connected host may elect to send a 4,478-octet packet, which will fit into a FDDI network, but the packet switch that attempts to pass the packet into the Ethernet network will be unable to do so because it is too large.

The solution adopted by IPv4 was *forward fragmentation*. The basic approach is that any IP router that is unable to forward an IP packet into the next network because the packet is too large for this network may split the packet into a set of smaller IP fragments, and forward each of these fragments. The fragments continue along the network path as autonomous packets, and the addressed destination host is responsible for reassembling these fragments back into the original IP packet.

The behaviour is managed by a 32-bit field in the IPv4 header, which is subdivided into three sub-fields (Figure 1).

Figure 1: IPv4 Packet Header
Fragmentation Fields

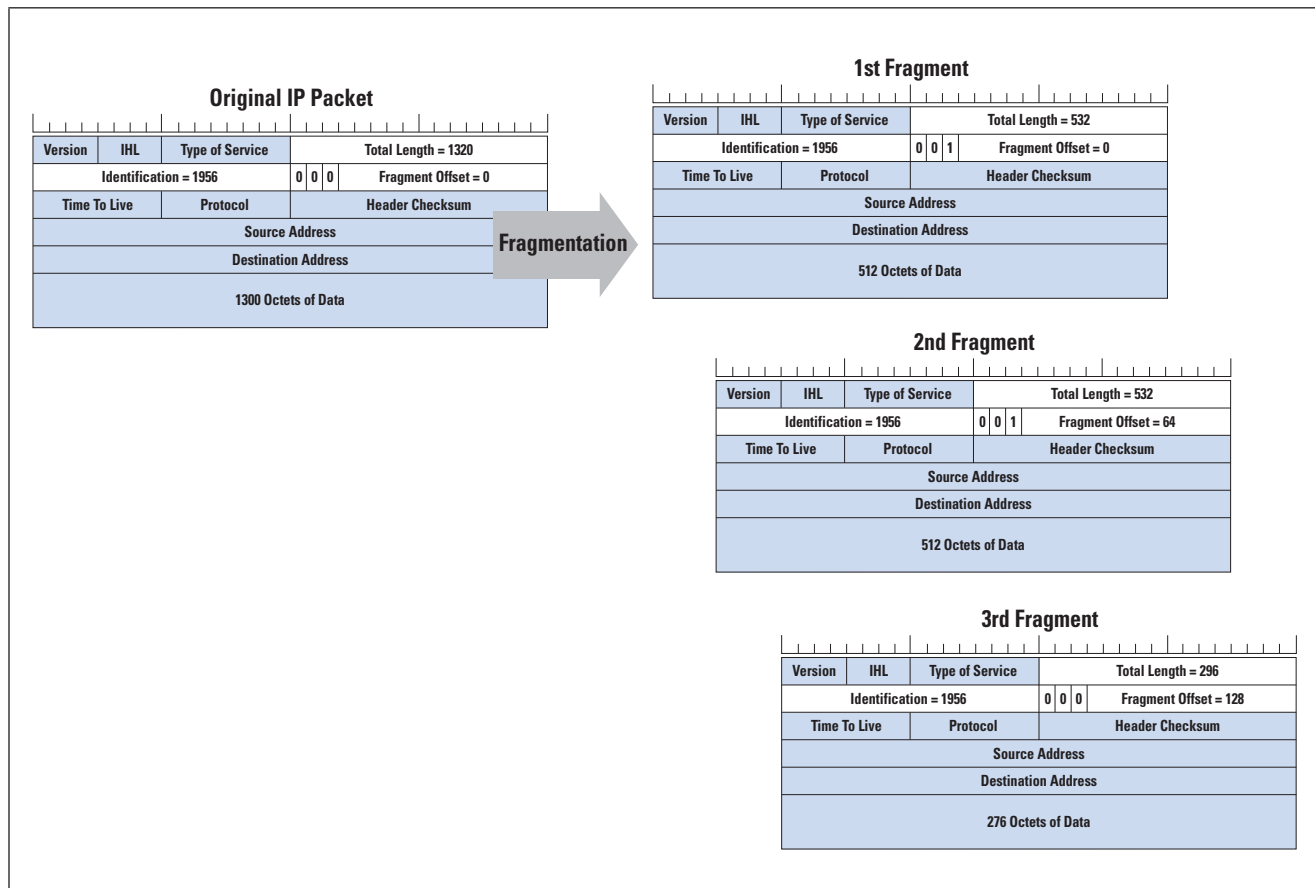

The first sub-field is a 16-bit packet identifier which allows fragments that share a common packet-identifier value to be identified as fragments of the same original packet.

The second sub-field is a 3-bit vector of flags. The first bit is unused. The second is the *Don't Fragment* flag. If this flag is set the packet cannot be fragmented, and must be discarded when it cannot be forwarded. The third bit is the *More Fragments* field, and is set for all fragments except the final fragment.

The third sub-field is the fragmentation offset value that is the offset of this fragment from the start of the IP payload of the original packet, measured in *octawords* (64-bit units).

For example, a router attempting to pass a 1320-octet IP packet into a network whose maximum packet size is 532 octets would need to split the IP packet into three parts. The first packet would have a fragmentation offset of 0 and the *More Fragments* bit set. The total length would be 532 octets, and the IP payload would be 512 octets, making a total of 532 octets for the packet. The second packet would have a fragmentation offset value of 64, the *More Fragments* bit set, total length of 532, and an IP payload of 512 octets, making a total of 532 octets for the packet. The third packet would have a fragmentation offset value of 128, the *More Fragments* bit clear, total length of 296, and an IP payload of 276 octets, making a total of 296 octets for the packet (Figure 2).

Figure 2: Example of IPv4 Packet Fragmentation

The advantage of this approach is that as long as it is permissible to fragment the IP packet, all packet flows are “forward,” meaning that the sending host is unaware that packet fragmentation is occurring, and all the IP fragment packets continue to head towards the original destination, where they are reassembled.

Another advantage is that while the router performing the fragmentation has to expend resources to generate the packet fragments, the ensuing routers on the path to the destination have no additional processing overhead, assuming that they do not need to further fragment these IP fragments. Fragments can be delivered in any order, so the fragments may be passed along parallel paths to the destination.

To complete the IPv4 story we must describe the IPv4 behaviour when the *Don't Fragment* bit is set. The router that is attempting to fragment such a packet is forced to discard it. Under these circumstances the router is expected to generate an *Internet Control Message Protocol* (ICMP) “Unreachable” error (type 3, code 4), and in later versions of the IP specification it was expected to add the *Maximum Transmission Unit* (MTU) of the next-hop network into the ICMP packet. The original sender would react to receiving such an ICMP message by changing its local maximum packet size associated with that particular destination address, and thus it would “learn” a viable packet size for the path between the source and destination.

Evaluating IPv4 Fragmentation

A case has been made that the IP approach to fragmentation contributed to its success. This design allowed transport protocols to operate without consideration of the exact nature of the underlying transmission networks, and avoid additional protocol overhead in negotiating an optimal packet size for each transaction. Large *User Datagram Protocol* (UDP) packets could be transmitted and fragmented in real time as required without requiring any form of end-to-end network path packet size discovery. This approach allowed IP to be used on a wide variety of substrate networks without requiring extensive tailoring.

But it wasn't all good news.

Cracks in the IP fragmentation story were described in a 1987 paper by Kent and Mogul, “Fragmentation Considered Harmful.”^[2]

TCP has always attempted to avoid IP fragmentation. The initial opening handshake of *Transmission Control Protocol* (TCP) exchanges the local and remote *Maximum Segment Size* (MSS), and the sender will not send a TCP segment larger than that notified by the remote end at the start of the TCP session. The reason that TCP attempted to avoid fragmentation was that fragmentation was inefficient under conditions of packet loss in a TCP environment. Lost fragments can be repaired only by resending the entire packet, including resending all those fragments that were successfully transmitted in the first place. TCP can perform a data repair more efficiently if it limits its packet size to one that does not entail packet fragmentation.

This form of fragmentation also posed vulnerabilities for hosts. For example, an attacker could send a stream of fragments with a close to maximally sized fragment offset value, and random packet identifier values.

If the receiving host believed that the fragments represented genuine incoming packets, then a credulous implementation might generate a reassembly buffer for each received fragment that may represent a memory buffer starvation attack. It is also possible, either through malicious attack or by poor network operation, that fragments may overlap or overrun, and the task of reassembly requires care and attention in implementation of fragment reassembly.

Lost fragments represent a slightly more involved problem than lost packets. The receiver has a packet reassembly timer upon the receipt of the first fragment, and will continue to hold this reassembly state for the reassembly time. The reassembly timer is a factor in the maximal count of packets in flight, because the packet identifier cannot be recycled within a period defined by the sender-receiver path delay plus the reassembly timer of the receiver. For higher-delay high-capacity network paths, this limit of 65,535 packets in flight can be a potential performance bottleneck^[3].

Fragmentation also consumes router processing time, forcing the processing of oversized packets from a highly optimised fast path into a processor queue.

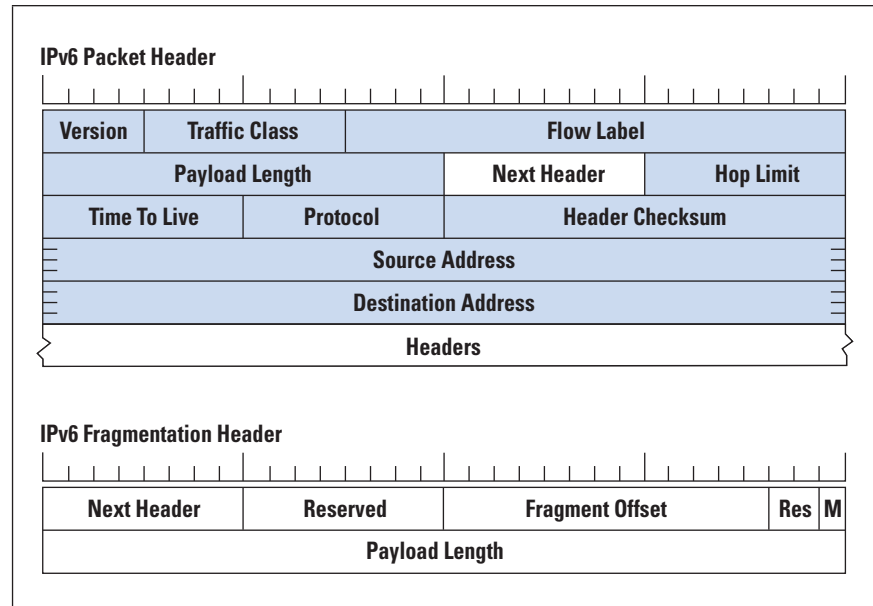

And then there is the “middleware problem.” Filters and firewalls perform their function by applying a set of policy rules to the packet stream. But these rules typically require the presence of the transport layer header. How can a firewall handle a fragment? One option is to pass all trailing fragments through without inspection, but this process exposes the internal systems to potential attack[4]. Another option is to have the firewall rebuild the original packet, apply the filter rules, and then refragment the packet and forward it on if the packet is accepted by the filter rules. However, this process now exposes the firewall to various forms of memory starvation attack. *Network Address Translators* (NATs)[5] that use the transport-level port addresses as part of the NAT binding table have a similar problem with trailing fragments. The conservative approach is for the NAT to reassemble the IP packet at the NAT, apply the NAT transform, and then pass the packet onward, fragmenting as required.

IPv6 and Fragmentation

When it came time to think about the design of what was to become IPv6, the *forward fragmentation* approach was considered to be a liability, and while it was not possible to completely discard IP packet fragmentation in IPv6, there was a strong desire to redefine its behaviour.

The essential change between IPv4 and IPv6 is that in IPv6 the *Don't Fragment* bit is always on, and because it's always on, it's not explicitly contained in the IPv6 packet header (Figure 3). There is only one fragmentation flag in the Fragmentation Header, the *More Fragments* bit, and the other two bits are reserved. The other change was that the packet-identifier size was doubled in IPv6, using a 32-bit packet identifier field.

Figure 3: IPv6 Packet Header and Fragmentation Header

An IPv6 router cannot fragment an IPv6 packet, so if the packet is too large for the next hop the router is required to generate an ICMPv6 type 2 packet, addressed to the source of the packet with a *Packet Too Big* (PTB) code, and also providing the MTU size of the next hop. While an IPv6 router cannot perform packet fragmentation, the IPv6 sender may fragment an IPv6 packet at the source.

Evaluating IPv6 Packet Fragmentation

The hope was that these IPv6 changes would fix the problems seen with IPv4 and fragmentation.

Our experience appears to point to a different conclusion.

The first problem is that there is widespread ICMP packet filtering in today's Internet. For IPv4 this approach was basically a reasonable defense tactic, and if you were willing to have a packet fragmented you cleared the *Don't Fragment* bit before sending the packet so that you didn't rely on receiving an ICMP message to indicate a path sender MTU problem. But in IPv6 the equivalent *Don't Fragment* bit function is jammed in the "on" position, and fragmentation can be performed only if the original sender receives the ICMPv6 PTB message and then resends the packet fragmented into a size that meets the specified MTU size. But when ICMPv6 PTB messages are filtered, the large packet is silently discarded within the network without any discernible trace. Attempts by the sender to time out and resend the large IPv6 packet will meet with the same fate, so this situation can lead to a wedged state.

This scenario has been seen in the context of the HTTP protocol, where the path MTU is smaller than the MTU of the host systems at either end. The TCP handshake completes because none of the opening packets is large. The opening HTTP GET packet also makes it through because this packet is normally not a large one.

However, the first response may be a large packet. If it is silently discarded because of the combination of fragmentation required and ICMPv6 filtering, then neither the client nor the server can repair the situation. The connection hangs.

The second problem is that the ICMPv6 PTB message is sent backwards to the source from the interior of a network path. Oddly enough, the IPv6 ICMP PTB message is perhaps the one critical instance in the entire IP architecture in which the IP source address is interpreted by anything other than the intended destination. The problems here include path asymmetry, in that the source address may be unreachable from the point of the generation of the ICMP packet. There is also the case of tunneling IP-in-IP. Because IPv6 fragmentation can be performed only at the source, should the ICMP message be sent to the tunnel ingress point or to the original source? Using the tunnel ingress assumes that the tunnel egress performs packet reassembly, potentially burdening the tunnel egress. This situation is further confounded in the cross protocol case of IPv6-in-IPv4 and IPv4-in-IPv6.^[6]

The third problem is the combination of IPv6 packet fragmentation and UDP. UDP is an unreliable datagram delivery service, so a sender of a UDP packet is not expected to cache the packet and be prepared to resend it. A UDP packet-delivery error can occur only at the level of the application, not at the IP or UDP protocol level. So what should a host do upon receipt of an ICMP PTB message if resending the IP packet is not an option? Given that the sender does not cache sent UDP packets, the packet header in the ICMPv6 message is unhelpful. Because the original packet was UDP, the sender does not necessarily have a connection state, so it is not clear how this information should be retained and how and when it should be used. How can a receiver even tell if an ICMPv6 PTB packet is genuine? If the sender adds an entry into its local IPv6 forwarding table, it is exposing itself to a potential resource starvation problem. A high volume flow of synthetic PTB messages has the potential to bloat the local IPv6 forwarding table. If the sender ignores the PTB message, the application is left to attempt to recover the transaction.

If it makes little sense in the context of an attempt to fragment a UDP packet, it makes less sense to fragment a TCP packet. In the context of a TCP session, a received ICMPv6 PTB message can be interpreted as a redefinition of the remote end MSS value, and the outgoing TCP segments can be reframed to conform to this MSS.

Wither Fragmentation?

The basic problem here is that the network was supposed to operate at the IP level and be completely unaware of transport, implying that IP-level fragmentation was meant to work in a manner that does not involve transport protocol interaction.

So much of today's network (firewalls, filters, etc.) is transport-aware and the trailing fragments have no transport context, meaning that transport-aware network middleware needs to reassemble the packet, and this process could represent a problem and a *Denial of Service* (DoS) vulnerability in its own right.

So is fragmentation worth it at all?

I'd still say that it's more useful to have it than not. But the IPv4 model of *forward fragmentation* in real time has proved to be more robust than the IPv6 model because the IPv4 model requires only that traffic flows in one direction and is an IP-level function. It has its problems, and no doubt the papers that warned that IP fragmentation was "harmful" were sincere in taking that view^[2]. But it is possible to make it worse, and the IPv6 model requiring a *backward* ICMPv6 message from the interior of the network was in retrospect a decision that did just that!

So what should we do now?

It is probably not a realistic option to try to alter the way that IPv6 manages fragmentation. There was an effort in 2013 in one of the IETF's IPv6 Working Groups to deprecate the IPv6 Fragment Header^[7]. That's possibly an overreaction to the problem of packet fragmentation and IPv6, but there is no doubt that the upper-level protocols simply should not assume that IPv6 fragmentation operates in the same manner as IPv4, or even operates in a reliable manner at all!

The implication is that transport protocol implementations, and even applications, should try to manage their behaviour on the assumption that ICMP message filtering is sufficiently prevalent that it is prudent to assume that all ICMP messages are dropped. The result is a default assumption that large IPv6 packets that require fragmentation are silently dropped.

How can we work around this problem and operate a network that uses variable-sized packets but cannot directly signal when a packet is too large? RFC 4281^[8] describes a *Path MTU Discovery* process that operates without relying on ICMP messages, and IPv6 TCP implementations should rely on this mechanism to establish and maintain a viable MTU size that can support packet delivery. In this way TCP can manage the path MTU and the application layer need not add explicit functions to manage persistent silent drop of large segments.

Path MTU Discovery

Path MTU discovery was specified in RFC 1191^[9]. The approach was to send packets with the *Don't Fragment* bit set. When a router on the path is unable to forward the packet because it is too large for the next hop, the *Don't Fragment* field directs the router to discard the packet and send a *Destination Unreachable* ICMP message with a code of "Fragmentation Required and DF set" (type 3, code 4).

RFC 1191 advocated the inclusion of the MTU of the next-hop network in the next field of the ICMP message.

A host receiving this form of ICMP message should store the new MTU in the local forwarding table, with an associated time to allow the entry to time out. Also the host should identify all active TCP sessions that are connected to the same destination address as given in the IP packet header fragment of the ICMP message, and notify the TCP session of the revised path MTU value.

RFC 1981^[10] defined much the same behaviour for IPv6, relying on the MTU information conveyed in the ICMPv6 PTB message in exactly the same manner as its IPv4 counterpart.

The problem of filtered ICMP messages is a difficult one, and attention has turned to path MTU Discovery ideas that do not rely on an ICMP message to operate correctly. RFC 4821 describes a mechanism that refines the RFC 1191 ICMP-based process by adding an alternate process that is based on detection and reporting of packet loss as an inference of path MTU problems when there is no ICMP feedback. This process uses a probe procedure that attempts to establish a working MTU size through probing the path with various sized packets to establish the upper-bound MTU. The trade-off here is the number of round-trip intervals taken to perform the probes and the accuracy of the path MTU estimate.

Because these probes take time, the entire exercise tends to be of value only in long-held TCP and TCP-like flows. For shorter sessions the pragmatic advice is to clamp the local MTU to a conservative value (1,280 is a good first choice for IPv6, and RFC 4821 also suggests 1,024 for IPv4) and try to avoid the entire issue of fragmentation in the first place.

UDP is a different story. The lightweight UDP protocol shim does not admit much in the way of additional functions, and one possible approach is to insist that UDP-based applications limit themselves to the local MTU size, or to be even more conservative, limit themselves to the 1,280-octet IPv6 minimum unfragmented packet size.

The major issue with such advice for UDP lies in the *Domain Name System* (DNS). Efforts to improve the security of the DNS with *Domain Name System Security Extensions* (DNSSEC) have added additional data into DNS responses. In addition, if you want to maintain the lightweight efficiency of the DNS, then it's not possible to keep DNSSEC responses under 1500 octets all the time, let alone under 1,280 octets. One option here is to insist that larger DNS responses use TCP, but this option imposes some considerable cost overhead on the operation of the DNS. What the DNS has chosen to do appears to represent a reasonable compromise.

The first part of the approach is that the management of the packet MTU is passed into the application layer. The application conventionally operates with a maximum UDP payload size that assumes that UDP fragmentation is working, and a DNS query normally offers an *Extension Mechanisms for DNS* (EDNS) buffer size of 4,096 octets. The responder uses this information to assemble its UDP response of up to 4,096 octets in length, a process that conventionally causes the source to perform UDP packet fragmentation for large responses. This fragmented response may not reach the querier for a variety of reasons, in which case the EDNS buffer size is dropped back to a more conservative value that is not expected to trigger UDP fragmentation, but may not be able to contain the complete response. The intended result is that if the network cannot complete a UDP transaction that entails a fragmented UDP response, the transaction is repeated using a smaller maximum UDP packet size, and the truncated response explicitly signals to the client to retry the query using TCP^[12]. This process is protocol-agnostic, in that it operates as intended in the case of IPv4 forward fragmentation, where trailing fragments are filtered out by middleware, and in the case of IPv6, where there is no forward fragmentation, and it operates whether or not the responder receives any ICMP PTB messages.

Conclusion

What we have learned through all this discussion is that packet fragmentation is extremely challenging, and is sensibly avoided if at all possible.

Rather than trying to bury packet fragmentation to an IP-level function performed invisibly at the lower levels of the protocol stack, a robust approach to packet fragmentation requires a more careful approach that lifts the management of Path MTU into the end-to-end transport protocol and even into the application.

IPv6 UDP-based applications that want a lightweight operation should look at keeping their UDP packets under the IPv6 1,280-octet unfragmented packet limit. And if that's not possible, then the application itself needs to explicitly manage Path MTU, and not rely on the lower levels of the protocol stack to manage it.

IPv6 TCP implementations should never assume that IPv6 PTB messages are reliably delivered. High-volume flows should use RFC 4821 Path MTU Discovery and management procedures to ensure that the TCP session can avoid Path MTU blackholing. For short flows, MSS clamping still represents the most viable approach.

I'm not sure that we should go as far as deprecating IP fragmentation in IPv6. The situation is not that dire. But we should treat Path MTU with a lot more respect, and include explicit consideration of the trade-offs between lightweight design and robust behaviour in today's network.

Resource Discovery in the Internet of Things

by Akbar Rahman and Chonggang Wang,
InterDigital Communications, Inc.

The *World Wide Web* (WWW or Web) is a global collection of connected documents and other resources that reside on the Internet. The introduction of the *Internet of Things* (IoT) is expected to dramatically increase the size of the Web in the near future and thus necessitates a fundamental change to the existing mechanisms of discovering resources. In IoT, the vision is that a significant number of new types of devices (or “things”) such as fridges, car sensors, traffic lights, and so on will be dynamically connected to the Web for communication and control. These IoT devices will have radically different characteristics from existing Web servers and users. This article looks at a key protocol development occurring in the *Internet Engineering Task Force* (IETF) for allowing IoT devices to discover resources via a new logical node called a *Resource Directory* (RD).

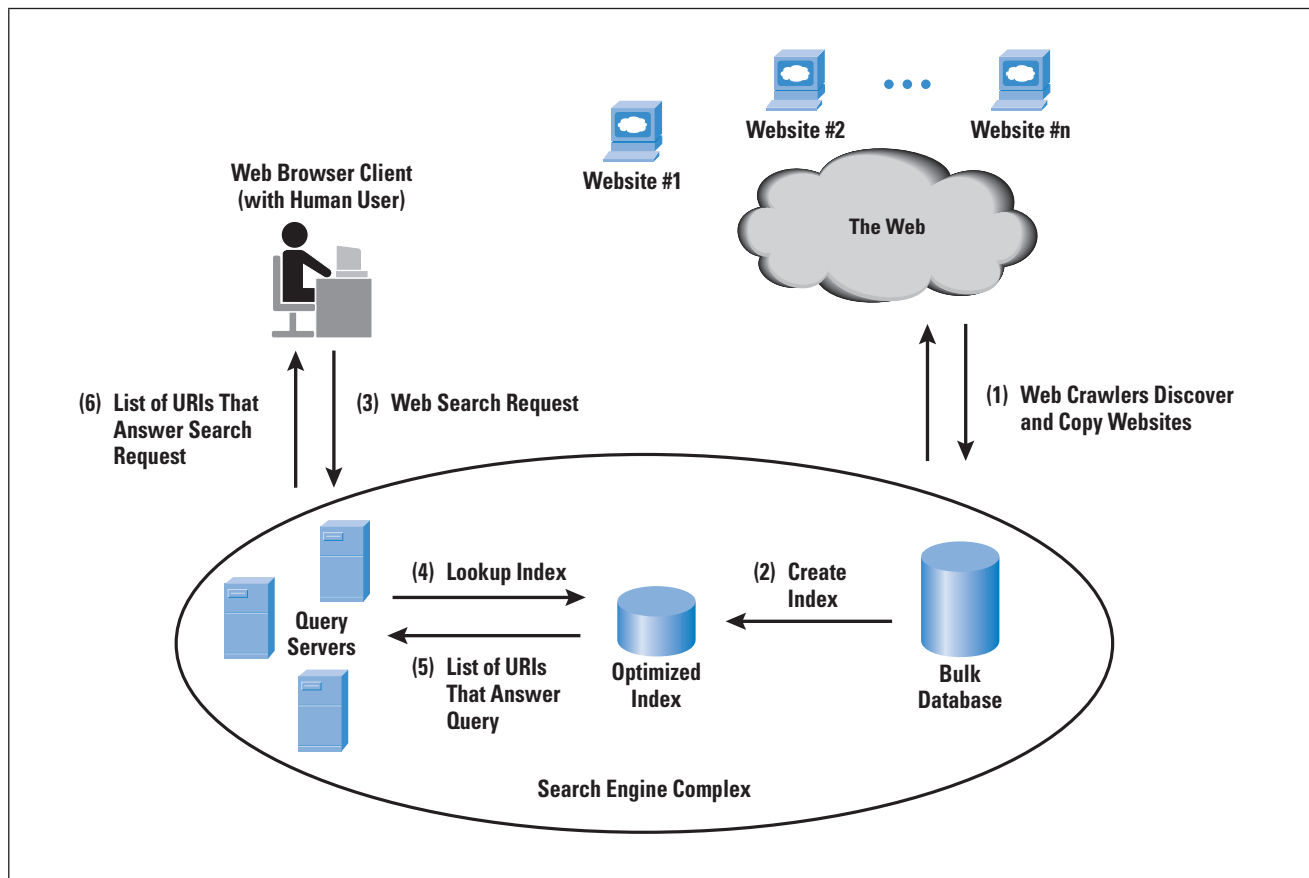

Resource Discovery in the Traditional Web

The basic unit of addressing on the Web is the *Uniform Resource Identifier* (URI), which identifies a resource^[1]. The resource may, for example, be a restaurant-review website page for a human user to read. Or in a more abstract form, the resource may be a software process to be triggered by a *Business-to-Business* (B2B) Web application as part of an automated stock market trading system. The key challenge in all cases is how users can quickly find the correct URI for the resource that they are interested in out of all possible URIs in the entire Web space. This process is referred to as *resource discovery*.

The most well-known and powerful resource discovery mechanism in the current Web is the one employed by Web search engines such as *Baidu*, *Bing*, *Google*, *Yahoo*, etc. Specifically, search engines use the mechanism of Web *crawlers* (also called spiders, ants, or robots) to periodically browse the Web to create a dynamic index of the resources of most publicly available websites. A website is defined as a server that hosts resources users can access with the *Hypertext Transfer Protocol* (HTTP)^[2]. Human users can then send a search request, via a Web browser client, to look up the specific resources that they are interested in.

Figure 1 shows the overall resource discovery process based on Web crawlers. Figure 1 is given in the context of a search engine, but academic researchers, market research companies, and others follow very similar processes. However, unlike a search engine, these other entities typically do not send crawlers to cover the entire Web to discover all possible resources. Instead, they send crawlers to cover parts of the Web to discover the specific type of resource that they are interested in.

Figure 1: Overview of Traditional Resource Discovery Process by Web Search Engines

For example, a market research company may send its Web crawlers to discover all the resources related to a specific type of product in a given geographic area as part of a pricing comparison study.

In Figure 1, Web crawlers start crawling out from the search engine server to an initially provisioned seed list of URIs. This seed list typically consists of very popular websites with a lot of URIs to other sites (that is, *hyperlinks*). From these initial websites, the Web crawlers then crawl outward to all connected hyperlinks. At each new website that it discovers, the Web crawler creates a copy of the website, which it sends back to the search engine^[3]. The search engine records all the received information in a bulk database and later processes it to create an optimized index for fast lookups. Then when a given search request comes from a Web browser client looking for some specific resource, the search engine can go quickly through its index using its own proprietary algorithm to find one or more matches.

Finally, the search engine will return to the client a list of URIs and selected application content pertaining to the resources that match the client's search parameters. This information is then displayed on the user's Web browser interface. Human users will then select ("click") the URI(s) that they want to visit.

Following are some key observations about resource discovery in the traditional Web:

- In terms of network configuration, the search engine functionality, or whichever entity dispatches the Web crawler, is typically located on a set of centralized servers and related databases with high-speed and large-bandwidth Internet connectivity. The resources that the Web crawlers discover may be widely distributed across the entire Internet. The Web browser-based clients that interface with the human users and send the search (lookup) requests are typically located at the edge of the network.
- Search engines primarily use a *pull model* to get resource information. In this approach, the receiving node (that is, search engine) goes out and explicitly requests information (via Web crawlers) from the sending node (content websites). However, a small number of URIs such as the initial seed list of URIs (for example, very popular websites) may be obtained without using the pull model, but these URIs are always a small fraction of the URIs in a search engine index.
- The list of resources the search engine returns for a given Web search (lookup) request may vary from a few URIs to potentially hundreds or even thousands of URIs. The order that these URIs are presented to the human user via the search engine Web interface is called the *ranking* of the resources. This ranking is critical because when a large number of URIs are returned to users for a given search request, users will typically select (“click”) only the top few ranked URIs.
- The ranking of resources is ultimately an algorithmic decision internal to the search engine. However, it can be affected by external input such as *Search Engine Optimization* (SEO) techniques that website developers use to try to get search engines to rank their specific URIs higher than other URIs with similar application content. For example, a simple SEO technique is to have website content clearly tagged (titles, section headings, etc.) and correlated to the website metadata. This metadata is an important input for the search index engine. A more sophisticated SEO technique is to have hyperlinks to a given website from as many other websites as possible because search engines consider this factor a measure of content popularity. There are many other SEO techniques^[4].

The Resource Discovery Problem in IoT

As mentioned previously, a key characteristic of current Web discovery technology is the use of Web crawlers to fan out and discover resources across the Internet. The implicit assumption in this approach is that Web servers are always active and available for Web crawlers that arrive in an unscheduled manner to discover easily. However, this assumption conflicts with the expected nature of many IoT devices that may have only intermittent connectivity to the Web.

The primary reason for this intermittent connectivity is that many IoT devices have a limited power supply (for instance, battery or solar power). To conserve their power they may “wake up” or become active only when required to perform a specific function. For example, a fire-detection sensor acting as a mini Web server may wake up and connect to the Web only to send a warning message to a remote controller when it senses a certain amount of smoke in its vicinity. At most other times, the fire-detection sensor is “asleep” (that is, in a low power state and not active) and unreachable via the Web. A secondary reason for intermittent connectivity is that many IoT devices are connected to the Web by low-power and lossy wireless networks. These wireless networks are more susceptible to interference and temporary loss of connectivity than traditional wired or cellular networks^[5].

Another key difference between IoT devices and other Web infrastructure is that most IoT devices may be deployed in semi-closed networks. For example, the IoT devices such as a lighting or heating control system in a home may have Internet connectivity only through a fire-walled home gateway. So the IoT devices and their associated resources may be accessible by the home owner through a smart phone control application with the proper security credentials from anywhere in the Internet. However, Web crawlers dispatched by a search engine will not discover the home IoT devices because they will not be able to traverse the fire-walled home gateway.

Therefore, the current pull model of Web discovery cannot be applied directly to the expected deployments of IoT networks. In other words, current Web crawler technology is unable to reliably discover a significant percentage of IoT devices that may be asleep or unconnected for significant periods of time, or may be located in semi-closed networks. The result is that traditional Web discovery techniques will not produce accurate discovery results for IoT scenarios.

Resource Directories to Solve the IoT Discovery Problem

The solution currently being standardized in the IETF to address the IoT resource discovery problem is based on a new logical network node called the *Resource Directory* (RD)^[6, 7]. The RD idea was originally conceived and validated in the *European Union* (EU)-funded *SENSEI* research program before coming to the IETF for standardization^[8]. The RD is defined in [6] to be applicable to a given *domain* and not the entire Web. The domain is a logical grouping of IoT devices that are related to an RD. An RD may support multiple domains. The details of defining the extent of a given domain boundary, however, are left to implementation and are not specified. Typically, the RD domains specified in IETF use cases are building-wide, campus-wide, or city-wide. The domain concept maps well into the expected deployment model of IoT devices in semi-closed networks.

In the simplest case, there would be a one-to-one mapping between each semi-closed network and a domain. The RD approach thus provides a distributed resource discovery mechanism for IoT scenarios. Figure 2 shows some typical RD domains.

Figure 2: Typical Resource Directory Domains

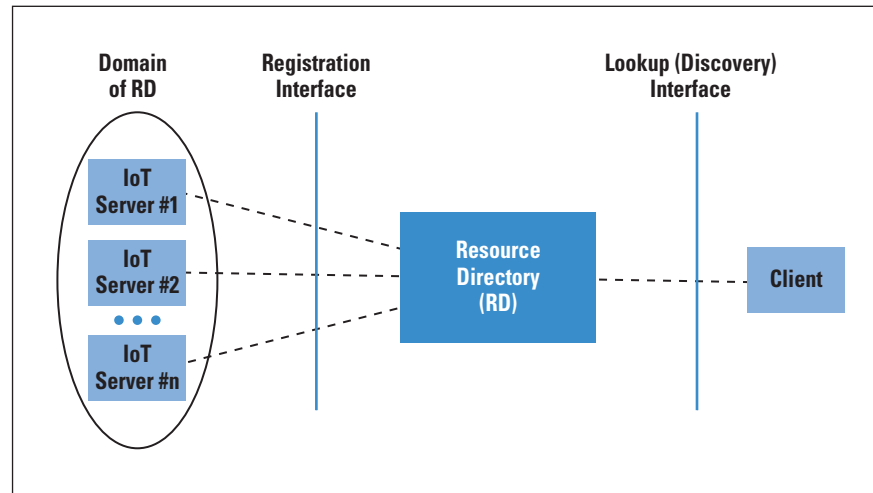

The resource registration step is done in a push fashion by IoT devices acting as mini Web servers pushing their resource information into the RD resource database. Figure 3 shows the architecture of a given RD. All the IoT devices acting as Web servers will first register their resources (URIs) via a registration interface.

Discovery can then be performed on the registered resources by an IoT client using the lookup interface. Mutual authentication, encryption, and access control are required for both the registration and lookup interfaces to ensure security and privacy of the entire resource discovery process.

A given device may use both the registration interface (as a Web server) and the lookup interface (as a client). The client may be located anywhere in the Web, but must have some knowledge regarding which specific RD to direct the resource discovery request to. For example, a newly installed home light controller may perform a lookup on its own home RD to find all the lights installed in the house.

Or, a national smart-grid controller may perform a lookup on a known RD in a remote city to find all the electric transformers located in that city.

Figure 3: IoT Resource Directory Architecture (adapted from [6])

IoT devices communicate with the RD using a *Representational State Transfer* (REST)-based protocol similar to HTTP but optimized for IoT. This protocol is referred to as the *Constrained Application Protocol* (CoAP)^[9]. The resource information pushed by the IoT servers into the RD uses CoAP messages with a specific payload format termed the *Link Format*^[7]. Only the URI, hyperlinks, and some meta-data are sent from the IoT device to the RD. Application content is not sent to the RD. Table 1 shows a comparison of the main resource discovery features of a traditional Web search engine and an IoT RD.

Resource Directory Protocol Considerations

As mentioned previously, CoAP is a Web transfer protocol, similar to HTTP, but optimized for IoT scenarios. CoAP provides a request/response interaction model between clients and servers. It supports key Web concepts such as URIs and Internet media types. CoAP messages are sent over *User Datagram Protocol* (UDP), and the CoAP header is encoded in a simple binary format. A CoAP request consists of a method (that is, GET, PUT, POST, and DELETE) that is applied to a resource identified by its URI, and a payload described by an Internet media type as well as other metadata.

CoAP messages may easily be interworked with HTTP in the forward or reverse directions via special cross-protocol proxies^[9]. In addition, CoAP uses *Datagram Transport Layer Security* (DTLS)^[10] to provide a secure session between the communicating parties.

In CoAP, every physical IoT device is assumed to have one or more resources, each identified by a URI. A resource may contain application information gathered by the IoT device (for example, temperature), or may be a method to control the device (for example, turn it ON/OFF). An example CoAP request and response pair is shown in Table 2.

Table 1: Comparison of Resource Discovery Features of Web Search Engine versus IoT Resource Directory

Characteristic	Traditional Web Search Engine (for example, Google)	IoT Resource Directory
(1) How is resource information initially received by node?	Mainly pulled from target website by Web crawlers after initial visit	Mainly pushed by target IoT devices directly to RD (usually after power-up)
(2) How is updated resource information transferred to node?	Pulled from target website by Web crawlers that revisit according to their search engine policy	Pushed by target IoT device directly to RD according to their own update policy
(3) What resource information is transferred to node?	The entire website (that is, URIs, hyperlinks, metadata, and most application content)	URIs, hyperlinks, and metadata (but no application content is transferred)
(4) What transfer protocols are supported?	HTTP	CoAP (Also some limited HTTP support exists. Further possible enhancements are discussed in [12].)
(5) What is the scope of a client discovery request for resources?	Global (that is, covers entire Internet)	Local within given RD domain (for example, city-wide)
(6) Typical end user that generates query for resources.	Human user (via a Web browser client) sends a search request	IoT device (that is, acting as both the client and end user) sends lookup request May also be used occasionally by human user (for example, via a CoAP-enabled Web browser client as part of management activities)
(7) Are resource discovery results ranked?	Yes	No (but being discussed as a future enhancement in [12])
(8) Are the resource discovery results machine readable?	No (but may support it in the future with further adoption of Semantic Web concept)	Yes (that is, results strictly follow Link Format ^[7])

Table 2: Example CoAP GET Request and Response

Request	GET coap://heater.net/temperature <u>Note:</u> Where Method = GET URI = coap://heater.net/temperature URI-Scheme component = coap:// URI-Host component = heater.net (or alternatively may be an IP address and Port Number) URI-Path component = /temperature
Response	2.05 Content "22.3 C" <u>Note:</u> Where Response code = 2.05 (indicating successful processing) Payload = 22.3 Celsius (C) temperature reading

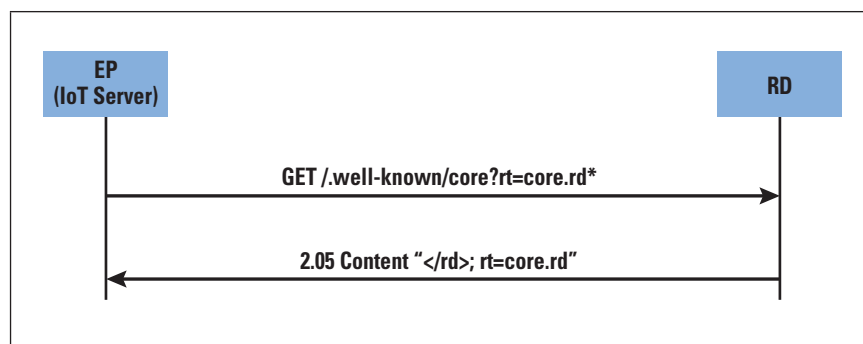

The following sections describe the key protocol steps and security characteristics related to RDs.

Finding the Resource Directory

The first step is for the IoT devices, or *End Points* (EPs) as they are called in [6], to find the appropriate RD. The most dynamic method for finding the RD is using IP multicast. Specifically, the device sends a CoAP multicast message to the CoAP IPv4 or IPv6 addresses reserved for this purpose^[11]. An alternative method would be, for example, factory preprovisioning of the RD information in the device.

Assuming the IP multicast method of finding the RD, each device (EP) sends a CoAP GET request to a specific URI-Path as shown in Figure 4. Specifically, the CoAP GET request is sent by multicast to the reserved “`/.well-known/core`” URI-Path. (Note that the URI-Scheme and URI-host components are not shown for simplicity in this and subsequent figures.) All the devices in the domain will then get this request because it is sent by IP multicast^[11]. However, only the RD will reply because the request URI has a query string for resource type (rt) added to the end (that is, `?rt=core.rd*`), indicating that the message is meant for the RD. The RD then responds indicating its URI-Path (that is, `/rd`) for subsequent registration or lookup requests^[6].

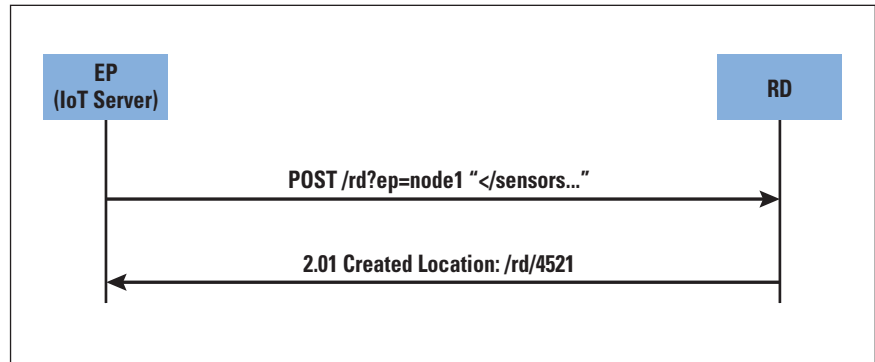

Figure 4: Finding a Resource Directory (adapted from [6])

Registering Resources

After finding the RD, each IoT device (EP) will register its own resources to the RD using the RD registration interface as shown in Figure 5. This registration is accomplished by each device sending a CoAP POST request directly to the RD with its list of URIs (that is, `/sensor...`) in the message payload, along with a query string identifying the registering device (that is, `?ep=node1`). The message payload containing the list of URIs being registered is formatted in the Link Format^[7]. The RD then responds with the resulting URI-Path (that is, `/rd/4521`) that it created to store the resources of the device^[6].

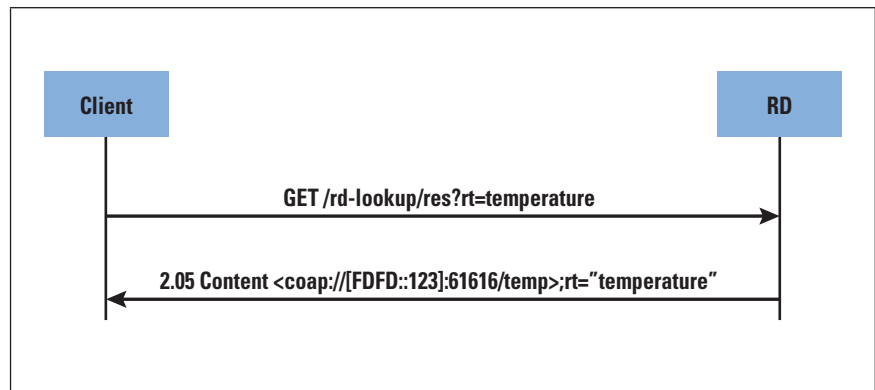

Figure 5: Registration of URIs to a Resource Directory (adapted from [6])

Resource Lookup (Discovery) by Client

The RD also supports a lookup interface for clients to make a discovery request on the RD database. The client may be located in the RD domain or may be outside of it. The client is aware of a given RD because it used the locating mechanism described previously, or it may have learned of the RD through other methods (for example, preprovisioning). Figure 6 shows a typical resource lookup request where a client is interested in finding all URIs related to “temperature.” Specifically, the client will send a GET request to the RD Lookup interface indicating that it is interested in the resource type of temperature in the query string (that is, `?rt=temperature`). The RD will then respond with a message containing the list of URIs of all the devices that it has in its registration database that match this criterion^[6]. The response message is formatted using the Link Format^[7].

Figure 6: Resource Lookup (Discovery) Request Sent to a Resource Directory (adapted from [6])

Other types of lookup requests may also be sent. For example, the RD may be queried to find out all the URIs supported by a given IoT device. Or, the RD may be queried to find out the identities of all the IoT devices in a given domain. The great majority of lookup requests to the RD will be sent by other IoT devices, without any human in the loop, for automated command and control. However, resource lookup requests may also be sent occasionally by humans via a CoAP-enabled Web browser interface for management activities.

Resource Directory Security Characteristics

Both the RD registration and lookup interfaces are protected by multiple layers of security to ensure that only authorized parties can access the RD. Specifically, mutual authentication is first required between the RD and any device attempting to access it. This authentication is accomplished using either preshared encryption keys, raw public keys, or X.509 security certificates as the security credentials^[9]. The appropriate credentials are used in the initial handshake of the DTLS session establishment to perform mutual authentication between the RD and the device or client accessing it. After the mutual authentication is completed, the cipher suite to be used for the DTLS session is negotiated. Then all subsequent messages exchanged between the RD and the device or client are securely encrypted via DTLS so that no unauthorized third party can decipher the communications^[6].

In addition to the DTLS security, the RD will also perform a fine-grained access control of any device attempting to communicate with it. Access control will be performed separately on the RD registration and lookup interfaces. Access control may be performed at the domain, device, or resource level^[6]. This control is especially important on the lookup interface for privacy and security reasons. For example, in a hospital setting many medical devices such as blood pressure monitoring devices may be registered to a RD, but only authorized medical staff should be able to discover a given device for privacy reasons. Or in a home setting, a visitor may be allowed to freely discover the television, but will be blocked from discovering the front door lock for security reasons.

Examples of Resource Directory Implementations

In parallel with the ongoing standardization efforts in the IETF for the RD protocol^[6, 12], there are several open source and commercial instances of RDs that have successfully interoperated with various IoT devices. Some examples are briefly described in the following paragraphs.

The *Californium* open source software project is a popular CoAP framework for IoT deployments. It is written in the *Java* programming language and specifically includes support for back-end infrastructure as part of its project scope. As such, it has released software loads that implement RD functionality that can be run on general-purpose servers^[13].

On the commercial front, ARM, the semiconductor and software company, has released several products for the IoT market. One of its products is a middleware offering called the “mbed Device Server.” This middleware includes support of RD functionality. This middleware software can run on various server hardware platforms^[14].

Another company that has done a lot of RD development work is Ericsson, the telecommunications equipment and service provider. Ericsson has done early prototyping and research^[15] in the RD concept starting from the initial EU SENSEI project days^[8]. The company has also participated in an open source software project for a cloud-based IoT gateway that includes RD functionality^[16].

Alternative Approaches to Discovery

The RD is not the only approach to the discovery problem for IoT networks. There are other methods such as *Domain Name Service – Service Discovery* (DNS-SD), which allows lookup of a given service via DNS^[17]. Another method is *Universal Plug and Play* (UPnP), which allows discovery of devices in home networks^[18].

The key difference between these other discovery methods and the RD approach is that the RD is geared towards resource discovery in the context of a REST-based Web model, meaning discovery of URIs and related metadata. The other existing discovery approaches are mainly oriented to discovering IP addresses, ports, and related parameters. So they are complementary to the URI discovery methods but cannot replace them. The only other widely used URI discovery scheme is the Web crawler approach described previously, which has the shortcomings in IoT deployments as described in Table 1.

Conclusion

The existing REST-based Web architecture and protocols have been extremely successful and a driving force behind the explosive growth of the Internet during the last 20 years. Search engines like *Google* and *Bing*, which use Web crawlers to discover resources (that is, URIs) efficiently, constitute a key part of the success of the Web. However, the existing model of resource discovery is expected to undergo radical changes with the addition in the future of an increasing number of IoT devices acting as both mini Web servers and clients. The IETF is currently standardizing protocol support for the Resource Directory, which will be optimized for distributed IoT resource discovery.

It is expected that an increasing number of discovery requests in the future will be handled by RDs for scenarios involving IoT devices. In parallel, human users will continue to heavily use traditional Web search engines like Google. There is also expected to be some cross-usage because traditional Web browsers may start to support CoAP software modules (plug-ins) and hence allow human users to make direct queries to RDs. However, a limiting feature of this interaction will be the security and privacy requirements of IoT deployments. Specifically, many IoT resources such as personal health-monitoring devices will have sensitive information that is not meant for public distribution, and they may also be located in semi-closed networks. Strong security and privacy is supported by the current RD model, which requires strict mutual authentication, encryption, and access control for both registration and discovery of IoT resources.

The IANA Transition

by Vint Cerf, Google

In this article I will explore the notable proposal sent in March 2016^[0] by the *Internet Corporation for Assigned Names and Numbers* (ICANN) to the U.S. Department of Commerce, *National Telecommunication and Information Agency* (NTIA) to end the long-standing contractual relationship between ICANN and NTIA for the conduct of the *Internet Assigned Numbers Authority* functions (“IANA functions”)^[1, 2]. ICANN was formed in late 1998 in response to a White House “White Paper” issued by Ira Magaziner, then a senior advisor for policy to President Bill Clinton. ICANN would undertake to form a private sector entity to carry out the coordinated assignment of Internet domain names, Internet addresses, and the maintenance of parameter registries needed for the operation of the suite of protocols used in the Internet.

These functions had been managed by Jonathan Postel acting as the IANA at University of Southern California’s Information Sciences Institute (and other earlier institutions where Postel had worked) under various government contracts. By 1996, the Internet was experiencing its so-called “dot boom” and the potential scale and liabilities of carrying out the IANA functions led to a serious effort to institutionalize the operation. For lack of space, I will leave out two years of community debate and fast-forward to the creation of ICANN to fulfill these functions. ICANN was conceived as a multi-stakeholder organization drawing on input from the private sector, civil society, governments of the world, and the technical community for the development of policy for the IANA functions and for the coordination of the multiple parties having a role in managing these unique identifiers and parameters.

In 1998, many organizations were involved in the evolution and operation of the Internet, its *Domain Name System* (DNS), Internet address allocation, and standards development. The *Internet Society*, founded in 1991, housed the standards-oriented *Internet Architecture Board* (IAB) and the *Internet Engineering Task Force* (IETF). There were then three *Regional Internet Registries* (RIRs)^[3] for Internet address allocation—RIPE-NCC, APNIC, and ARIN—and two more to follow later (LACNIC and AFRINIC). There were nominally 13 DNS *Root Server* operators providing top-level domain name resolution. Verisign generated and distributed the official domain name root zone based on input from IANA and, under the terms of the NTIA/ICANN contract, authorization from NTIA. Many domain name registries and registrars were created to support DNS operation.

The original plan was for ICANN to operate under NTIA oversight for a few years and then operate as an independent organization. In fact, the contractual obligations extended from 1998 to the present.

In March 2014, however, NTIA proposed that this contractual relationship for the IANA functions should be ended and ICANN be allowed to perform the IANA functions independently. In March 2016, ICANN delivered to NTIA its consolidated proposal from all the constituent parties for the transition from the present contractual relationship to independent operation. The two-year effort leading to this comprehensive proposal was not without considerable debate among all the parties. Many ideas were surfaced, analyzed, argued over, adopted, adapted, or discarded, leading to a consolidated result. The Department of Commerce and the U.S. Congress will be evaluating the proposed new *modus operandi* in the weeks ahead.

Some fears have been voiced that the complex proposal poses risks that authoritarian governments within the ICANN *Governmental Advisory Committee* (GAC) or through some external means might wrest control of ICANN from its multi-stakeholder constituencies. While the proposal should be evaluated on all its merits, I am persuaded the terms and conditions of the proposed operating practices are well protected against such an outcome. A great many conditions must be satisfied before the more extraordinary powers of the *sole designator* can be exercised. The headquarters of ICANN will remain in the U.S. The many entities that cooperate with ICANN to manage core Internet identifier administration have expressed full support for the proposal.

If I have any trepidation about the proposal, it is associated with its general complexity. As the former chairman of ICANN, I am no stranger to the evolution of ICANN's structure and processes and their relative intricacy. The new proposal adds its own unique aspects to this tendency, and it remains to be seen how well the system will work. However, ICANN has shown a remarkable ability to reform and adapt when necessary, and I believe that capacity is preserved under the new proposal. There is still a good deal of work ahead to actually implement what is ultimately approved, but I am confident this community is capable of achieving a successful outcome.

[Ed.: An earlier version of this article appeared in *Communications of the ACM*, Volume 59, No. 5, May 2016.]

VINTON G. CERF is Vice President and Chief Internet Evangelist for Google. He contributes to global policy development and continued spread of the Internet. Widely known as one of the “Fathers of the Internet,” Cerf is the co-designer of the TCP/IP protocols and the architecture of the Internet. He has served in executive positions at MCI, the Corporation for National Research Initiatives and the Defense Advanced Research Projects Agency (DARPA), and on the faculty of Stanford University.

Cerf served as Chairman of the Board of the Internet Corporation for Assigned Names and Numbers (ICANN) from 2000 to 2007 and has been a Visiting Scientist at the Jet Propulsion Laboratory since 1998. He served as founding President of the Internet Society (ISOC) from 1992 to 1995. Cerf is a Fellow of the IEEE, ACM, and American Association for the Advancement of Science, the American Academy of Arts and Sciences, the International Engineering Consortium, the Computer History Museum, the British Computer Society, the Worshipful Company of Information Technologists, and the Worshipful Company of Stationers, and he is a member of the National Academy of Engineering. He currently serves as Past President of the Association for Computing Machinery and Chairman of the American Registry for Internet Numbers (ARIN), and he has completed a term as Chairman of the Visiting Committee on Advanced Technology for the U.S. National Institute of Standards and Technology. President Obama appointed him to the National Science Board in 2012.

Cerf is a recipient of numerous awards and commendations in connection with his work on the Internet, including the U.S. Presidential Medal of Freedom, U.S. National Medal of Technology, the Queen Elizabeth Prize for Engineering, the Prince of Asturias Award, the Tunisian National Medal of Science, the Japan Prize, the Charles Stark Draper Award, the ACM Turing Award, Officer of the Legion d’Honneur, and 25 honorary degrees. In December 1994, *People* magazine identified Cerf as one of that year’s “25 Most Intriguing People.” His personal interests include fine wine, gourmet cooking, and science fiction. Cerf and his wife, Sigrid, were married in 1966 and have two sons, David and Bennett. vint@google.com

RACI

The *RIPE Academic Cooperation Initiative* (RACI) connects members of the academic community with the RIPE community by inviting students and researchers to present at meetings organized by the RIPE NCC. Successful applicants receive complimentary tickets, travel and accommodation to meetings and the opportunity to present their work to some of the leading technical figures in the Internet world. Examples of relevant topics include:

- Network Measurement and Analyses
- IPv6 Deployment
- BGP Routing
- Network Security
- Internet Governance
- Peering and Interconnectivity
- The Internet of Things

For more information about RACI, including the application process and deadlines, visit: <http://ripe.net/raci>

NTIA Issues IANA Transition Proposal Report

On 9 June 2016, *The National Telecommunications and Information Administration* (NTIA) issued its assessment report on the *IANA Stewardship Transition Proposal*. (Ed.: See article on page 26). In order to be accepted, the proposal needed to be shown to have broad community support and address the following four principles:

- Support and enhance the multistakeholder model
- Maintain the security, stability, and resiliency of the Internet DNS
- Meet the needs and expectations of the global customers and partners of the IANA services
- Maintain the openness of the Internet

The NTIA further stipulated that “it would not accept a proposal that replaces its role with a government-led or intergovernmental organization solution.” After thorough review the NTIA reports that it finds that “the IANA Stewardship Transition Proposal meets the criteria necessary to complete the long-promised privatization of the IANA functions.”

The full report is available at:

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

The Internet Protocol Journal is published under the “CC BY-NC-ND” Creative Commons Licence. Quotation with attribution encouraged.

FROM THE EDITOR

Publication of this journal is made possible by numerous individuals and organizations. Every year in late August we initiate a sponsorship renewal campaign. This year our funding fell short of our sponsorship target, so we delayed publication of the September issue until now. If you are a subscriber, you should have received an e-mail asking for a donation. I am happy to say that many subscribers responded to that request (see page 42), and with the help of these individuals and our corporate sponsors we are now ready to deliver to you this *November* issue. This will be the third and final issue in 2016, but we hope to return to our regular quarterly publication schedule in 2017. We still need more individual and corporate sponsors, so please ask your company to sign up for a sponsorship or make a donation at <http://tinyurl.com/IPJ-donate>

We are pleased to welcome two new members of our Editorial Advisory Board. David Conrad is the Chief Technical Officer at the *Internet Corporation for Assigned Names and Numbers* (ICANN), and Cullen Jennings is a Cisco Fellow at Cisco Systems, Inc. We are grateful to Fred Baker, who has left Cisco Systems and our Editorial Advisory Board, and we wish him every success in the future.

A large percentage of Internet traffic is electronic mail. In our first article, William Stallings gives an overview of the many enhancements that are designed to make e-mail communication more secure and reliable in the face of an increasing amount of spam and other attack vectors.

Previous articles in IPJ have covered various aspects of *Cloud Computing* and *Software-Defined Networks* (SDNs). In our second article, Russ White and Shawn Zandi take a critical look at the complexity of these technologies.

As always, we welcome your feedback, suggestions, book reviews, articles, and sponsorship support. You can contact us by sending an e-mail to ipj@protocoljournal.org and visit our website for subscription information, back issues, author guidelines, sponsor information, and much more.

Comprehensive Internet E-Mail Security

by William Stallings, Independent Consultant

For both organizations and individuals, e-mail is pervasive and vulnerable to a wide range of security threats. In general terms, e-mail security threats can be classified as follows:

- *Authenticity-related threats*: Could result in unauthorized access to an enterprise's e-mail system. Another threat in this category is deception, in which the purported author isn't the actual author.
- *Integrity-related threats*: Could result in unauthorized modification of e-mail content.
- *Confidentiality-related threats*: Could result in unauthorized disclosure of sensitive information.
- *Availability-related threats*: Could prevent end users from being able to send or receive e-mail messages.

To assist in addressing these threat categories, the *National Institute of Standards and Technology* (NIST) has issued SP 800-177^[1], which recommends guidelines for enhancing trust in e-mail. The document is both a survey of available standardized protocols and a set of recommendations for using these protocols to counter security threats to e-mail usage.

For an understanding of the topics in this article, it is useful to have a basic grasp of the Internet mail architecture, which is currently defined in RFC 5598^[2]. The discussion now provides an overview of the basic concepts.

At its most fundamental level, the Internet mail architecture consists of a user world in the form of *Message User Agents* (MUA), and the transfer world, in the form of the *Message Handling Service* (MHS), which is composed of *Message Transfer Agents* (MTA). The MHS accepts a message from one user and delivers it to one or more other users, creating a virtual MUA-to-MUA exchange environment. This architecture involves three types of interoperability. One is directly between users: messages must be formatted by the MUA on behalf of the message author so that the message can be displayed to the message recipient by the destination MUA. There are also interoperability requirements between the MUA and the MHS—first when a message is posted from an MUA to the MHS and later when it is delivered from the MHS to the destination MUA. Interoperability is required among the MTA components along the transfer path through the MHS.

Figure 1: Function Modules and Standardized Protocols Used Between Them in the Internet Mail Architecture

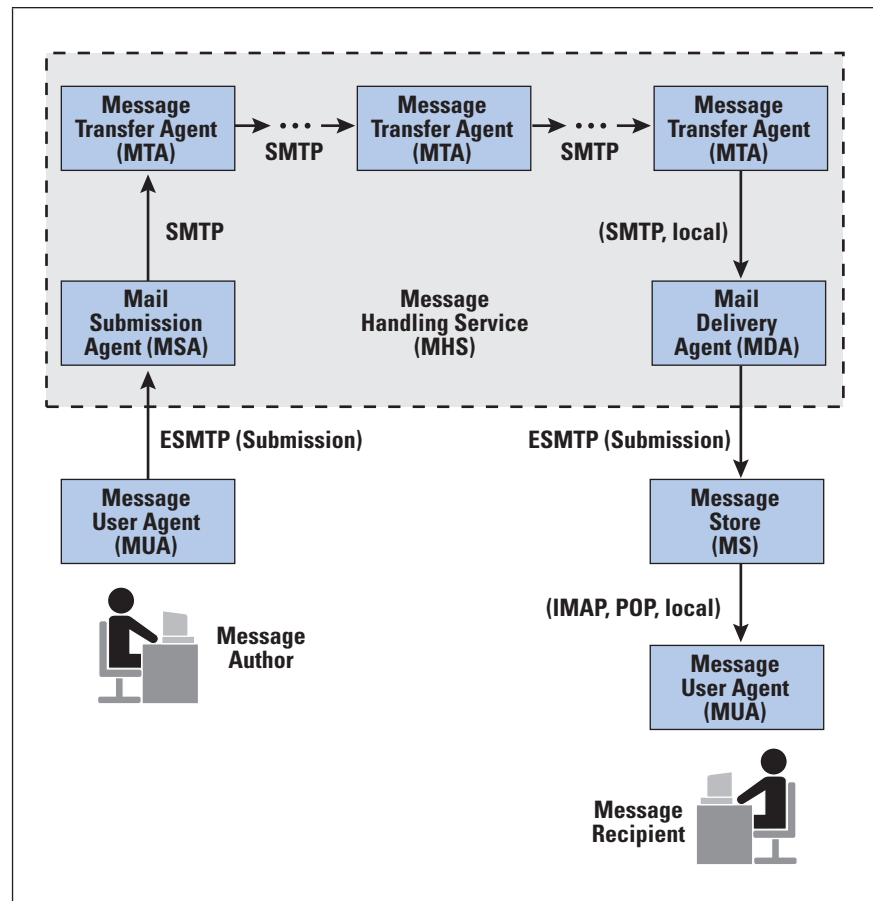

Figure 1 illustrates the key components of the Internet mail architecture, which include the following:

- **Message User Agent (MUA)**: Operates on behalf of user actors and user applications. It is their representative within the e-mail service. Typically, this function is housed in the user's computer and is referred to as a *client* e-mail program or a local network e-mail *server*. The author MUA formats a message and performs initial submission into the MHS via a *Mail Submission Agent* (MSA). The recipient MUA processes received mail for storage and/or display to the recipient user.
- **Mail Submission Agent (MSA)**: Accepts the message submitted by an MUA and enforces the policies of the hosting domain and the requirements of Internet standards. This function may be located together with the MUA or as a separate functional model. In the latter case, the *Simple Mail Transfer Protocol* (SMTP) is used between the MUA and the MSA.
- **Message Transfer Agent (MTA)**: Relays mail for one application-level hop. It is like a packet switch or IP router in that its job is to make routing assessments and move the message closer to the recipients. Relaying is performed by a sequence of MTAs until the message reaches a destination MDA. An MTA also adds trace information to the message header. SMTP is used between MTAs and between an MTA and an MSA or MDA.

- *Mail Delivery Agent* (MDA): The MDA is responsible for transferring the message from the MHS to the *Message Store* (MS).
- *Message Store* (MS): An MUA can employ a long-term MS. An MS can be located on a remote server or on the same machine as the MUA. Typically, an MUA retrieves messages from a remote server using the *Post Office Protocol* (POP) or the *Internet Message Access Protocol* (IMAP).

As will be seen subsequently, an important element in securing e-mail is the use of *public-key cryptography*. In turn, the use of public-key cryptography depends on the use of *Public-key Certificates*. In essence, a public-key certificate consists of a public key plus a user ID of the key owner, with the whole block signed by a trusted third party. A common scheme for the creation and use of public key certificates is by means of a third party known as a *Certificate Authority* (CA). A CA is an entity that is trusted by the user community, such as a government agency or a financial institution. The essential elements in the CA scheme include:

1. Client software creates a pair of keys, one public and one private. The client prepares an unsigned certificate that includes a user ID and the user's public key. The client then sends the unsigned certificate to a CA in a secure manner.
2. A CA creates a signature by calculating the hash code of the unsigned certificate and encrypting the hash code with the CA's private key; the encrypted hash code is the signature. The CA attaches the signature to the unsigned certificate and returns the now-signed certificate to the client.
3. The client may send its signed certificate to any other user. That user may verify that the certificate is valid by calculating the hash code of the certificate (not including the signature), decrypting the signature using the CA's public key, and comparing the hash code to the decrypted signature.

If all users subscribe to the same CA, then there is a common trust of that CA. All user certificates can be placed in the directory for access by all users. In addition, users can transmit their certificate directly to other users. In either case, when B is in possession of A's certificate, B has confidence that messages it encrypts with A's public key will be secure from eavesdropping and that messages signed with A's private key are unforgeable.

If there is a large community of users, it may not be practical for all users to subscribe to the same CA. Because it is the CA that signs certificates, each participating user must have a copy of the CA's own public key to verify signatures. This public key must be provided to each user in an absolutely secure (with respect to integrity and authenticity) way so that the user has confidence in the associated certificates.

Thus, with many users it may be more practical for there to be numerous CAs, each of which securely provides its public key to some fraction of the users. In practice, there is not a single CA but rather a hierarchy of CAs. This setup complicates the problems of key distribution and trust, but the basic principles are the same.

Several issues with the use of CAs should be mentioned. As can be deduced from the preceding paragraph, a hierarchical CA system can become cumbersome and not scale well. Nevertheless, this scheme is still the preferred one, and it is recommended by SP 800-177. A separate issue is one of security. The global CA ecosystem has become subject to attack in recent years, and has been successfully compromised more than once. One way to protect against CA compromises is to use the *Domain Name System* (DNS) to allow domains to specify their intended certificates or vendor CAs. Such uses of DNS require that the DNS itself be secured with *Domain Name System Security Extensions* (DNSSEC) as described subsequently.

For the reader who needs an introduction or refresher on concepts of public-key cryptography, authentication, and digital signatures, a *Crypto Portal* white paper^[3] provides a quick and easy overview. A useful overview of CA and public-key certificate concepts is NIST SP 800-32^[4].

Trustworthy E-Mail

The following protocols and standards are described in and recommended by SP 800-177:

- *STARTTLS*: An SMTP security extension that enables an SMTP client and server to negotiate the use of *Transport Layer Security* (TLS) to provide private, authenticated communication across the Internet.
- *Secure Multipurpose Internet Mail Extensions* (S/MIME): Provides authentication, integrity, nonrepudiation (via digital signatures) and confidentiality (via encryption) of the message body carried in SMTP messages.
- *DNS-Based Authentication of Named Entities* (DANE): Designed to overcome problems in the *Certificate Authority* (CA) system by providing an alternative channel for authenticating public keys based on DNSSEC, with the result that the same trust relationships used to certify IP addresses are used to certify servers operating on those addresses.
- *Sender Policy Framework* (SPF): Enables a domain owner to specify the IP addresses of MTAs that are authorized to send mail on its behalf. SPF uses the DNS to allow domain owners to create records that associate the domain name with a specific IP address range of authorized MTAs. It is a simple matter for receivers to check the *SPF text record* (TXT) in the DNS to confirm that the purported sender of a message is permitted to use that source address and reject mail that does not come from an authorized IP address.

- *DomainKeys Identified Mail* (DKIM): Enables e-mail actors (authors or operators) to affix their domain name to the message reliably, using cryptographic techniques, so that filtering engines can develop an accurate reputation for the domain. The MTA can sign selected headers and the body of a message. This signature validates the source domain of the mail and provides message body integrity.
- *Domain-based Message Authentication, Reporting, and Conformance* (DMARC): Publishes a requirement for the author domain name to be authenticated by DKIM and/or SPF, for that domain's owner to request recipient handling of nonauthenticated mail using that domain, and for a reporting mechanism to send reports from recipients back to domain owners. DMARC lets senders know the proportionate effectiveness of their SPF and DKIM policies, and signals to receivers what action should be taken in various individual and bulk attack scenarios.

Figure 2 shows how these components interact to provide message authenticity and integrity. Not shown, for simplicity, is that S/MIME also provides message confidentiality by encrypting messages. Together, these protocols provide a comprehensive Internet e-mail security strategy. This article provides an overview of each.

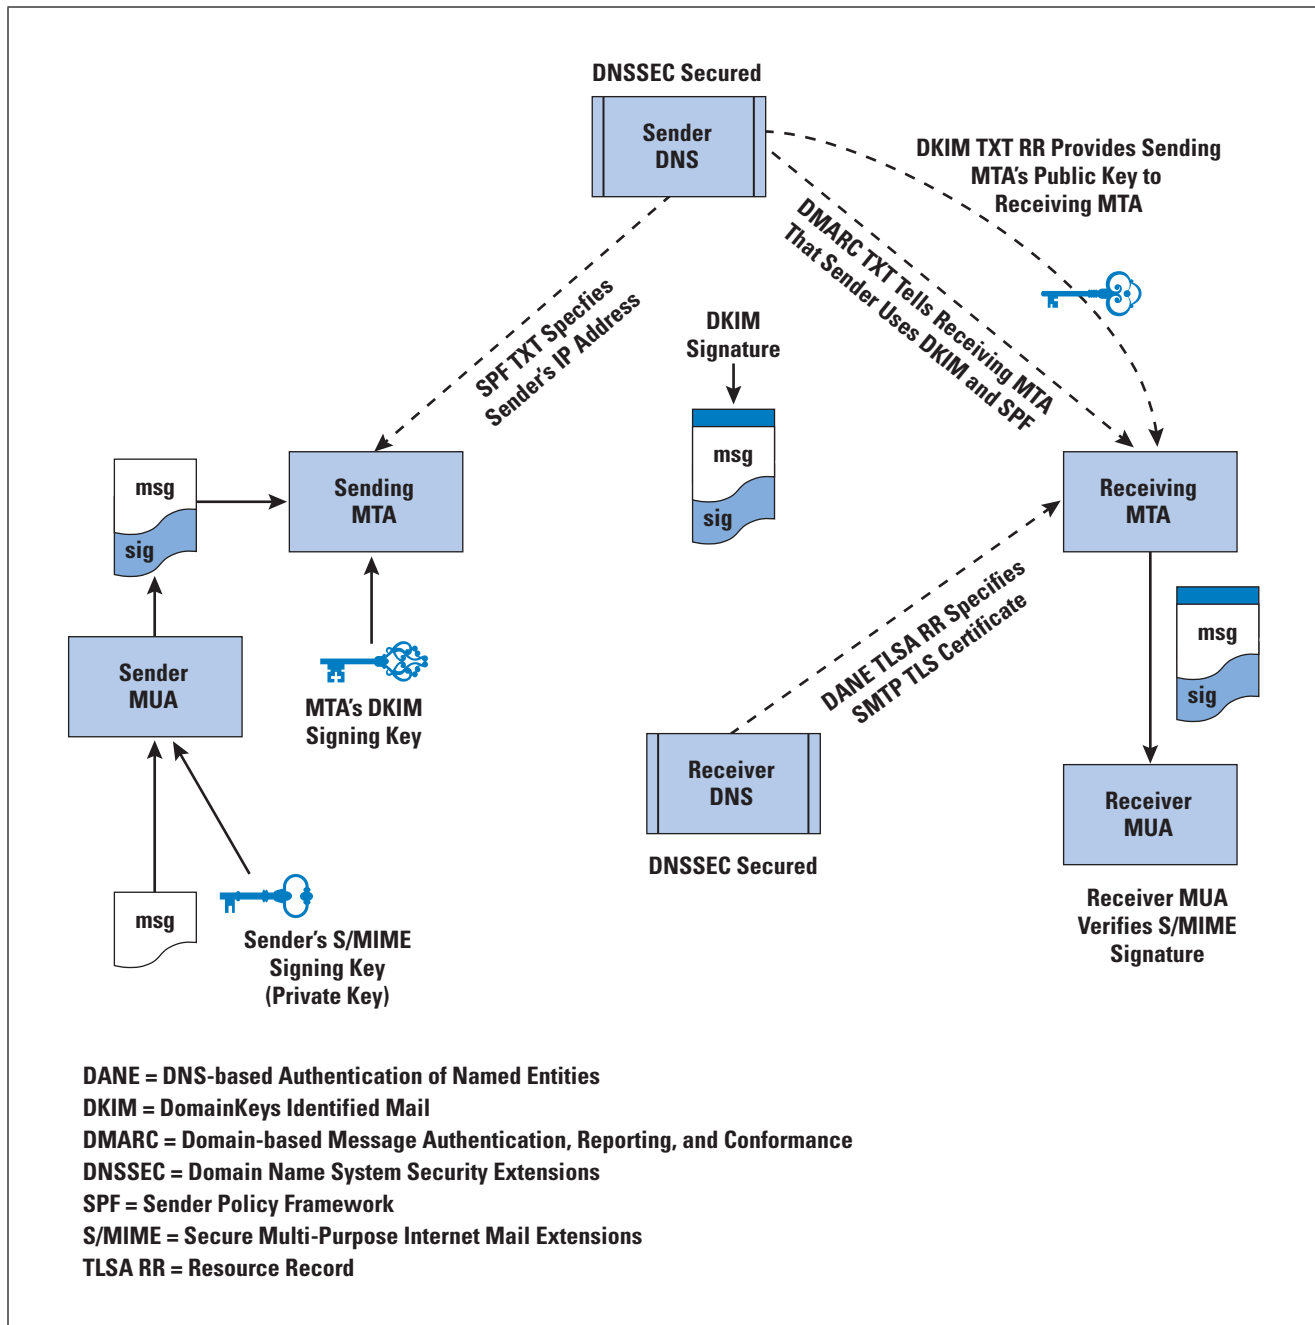

STARTTLS

A significant security-related extension for SMTP is STARTTLS, defined in RFC 3207^[5]. STARTTLS enables the addition of confidentiality and authentication in the exchange between SMTP agents. This addition enables SMTP agents to protect some or all of their communications from eavesdroppers and attackers by invoking a *Transport Layer Security* (TLS) session within the SMTP connection. STARTTLS has been widely deployed, and is supported by Amazon, Facebook, Google, Microsoft, Yahoo, and others^[6]. A 2014 study by Facebook, which sends several billions of e-mails daily, found that 76% of host names that receive Facebook e-mails support STARTTLS^[7].

TLS is a security layer implemented just above TCP. TLS is an Internet Standard that replaces *Secure Sockets Layer* (SSL) with essentially the same functionality^[8]. With TLS in place, an application has a TLS *socket address* and communicates to the TLS socket address at the remote application. These addresses are distinct from those used by the same application running directly over TCP. The security functions provided by TLS are transparent to the application and also to TCP. Thus, neither TCP nor the application needs to be modified to invoke the security features of SSL. TLS provides three categories of security, confidentiality, and authentication.

If the client does initiate the connection over a TLS-enabled port, the server may prompt with a message indicating that the STARTTLS option is available.

Figure 2: The Interrelationship of DNSSEC, SPF, DKIM, DMARC, DANE, and S/MIME for Assuring Message Authenticity and Integrity

The client can then issue the STARTTLS command in the SMTP command stream, and the two parties proceed to establish a secure TLS connection. Many e-mail providers and servers now have STARTTLS enabled^[9, 10], including Amazon, Comcast, Dropbox, Facebook, Google, Microsoft, and Yahoo.

As described in SP 800-177, STARTTLS may be vulnerable to a *Man-In-The-Middle* (MITM) attack when it is initiated as a request by the server. In this case, the MITM receives the STARTTLS request from the server reply to a connection request, and scrubs it out.

The initiating client sees no TLS upgrade request and proceeds with an unsecured connection. However, SP 800-177 takes the position that some security is better than no security and that until TLS is available everywhere and automatically invoked, TLS-capable servers must prompt clients to invoke the STARTTLS command. TLS clients should attempt to either use STARTTLS initially or issue the command when requested.

S/MIME

Secure/Multipurpose Internet Mail Extension (S/MIME) is a security enhancement to the MIME Internet e-mail format standard^[11]. S/MIME is a complex capability that is defined in many documents. The most important documents relevant to S/MIME include the following [12–19]:

- *RFC 5750, S/MIME Version 3.2 Certificate Handling*: Specifies conventions for X.509 certificate usage by S/MIME v3.2.
- *RFC 5751, S/MIME Version 3.2 Message Specification*: The principal defining document for S/MIME message creation and processing.
- *RFC 4134, Examples of S/MIME Messages*: Gives examples of message bodies formatted using S/MIME.
- *RFC 2634, Enhanced Security Services for S/MIME*: Describes four optional security service extensions for S/MIME.
- *RFC 5652, Cryptographic Message Syntax (CMS)*: Describes CMS. This syntax is used to digitally sign, digest, authenticate, or encrypt arbitrary message content.
- *RFC 3370, CMS Algorithms*: Describes the conventions for using several cryptographic algorithms with the CMS.
- *RFC 5752, Multiple Signatures in CMS*: Describes the use of multiple, parallel signatures for a message.
- *RFC 1847, Security Multiparts for MIME—Multipart/Signed and Multipart/Encrypted*: Defines a framework within which security services may be applied to MIME body parts. The use of a digital signature is relevant to S/MIME, as explained subsequently.

S/MIME functionality is built into most modern e-mail software and interoperates between them. S/MIME provides four message-related services: authentication, confidentiality, compression, and e-mail compatibility.

Authentication is provided by means of a digital signature. Most commonly RSA with SHA-256 is used. The sequence is as follows:

1. The sender creates a message.
2. SHA-256 is used to generate a 256-bit message digest of the message.
3. The message digest is encrypted with RSA using the sender's private key, and the result is appended to the message. Also appended is identifying information for the signer, which will enable the receiver to retrieve the signer's public key.
4. The receiver uses RSA with the sender's public key to decrypt and recover the message digest.
5. The receiver generates a new message digest for the message and compares it with the decrypted hash code. If the two match, the message is accepted as authentic.

The combination of SHA-256 and RSA provides an effective digital signature scheme. Because of the strength of RSA, the recipient is assured that only the possessor of the matching private key could have generated the signature. Because of the strength of SHA-256, the recipient is assured that no one else could generate a new message that matches the hash code and, hence, the signature of the original message.

Although signatures normally are found attached to the message or file that they sign, it is not always the case: Detached signatures are supported. A detached signature may be stored and transmitted separately from the message it signs. This option is useful in several contexts. A user may wish to maintain a separate signature log of all messages sent or received. A detached signature of an executable program can detect subsequent virus infection. Finally, detached signatures can be used when more than one party must sign a document, such as a legal contract. Each person's signature is independent and is therefore applied only to the document. Otherwise, signatures would have to be nested, with the second signer signing both the document and the first signature, and so on.

S/MIME provides *confidentiality* by encrypting messages using conventional encryption with a secret key, also known as a *symmetric key*. Most commonly, *Advanced Encryption Standard* (AES) with a 128-bit key is used, with the *Cipher Block Chaining* (CBC) mode. The key itself is also encrypted, typically with RSA, as explained subsequently.

As always, one must address the problem of key distribution. In S/MIME, each symmetric key, referred to as a *content-encryption key*, is used only once. That is, a new key is generated as a random number for each new message. Because it is to be used only once, the content-encryption key is bound to the message and transmitted with it. To protect the key, it is encrypted with the receiver's public key.

The sequence can be described as follows:

1. The sender generates a message and a random 128-bit number to be used as a content-encryption key for this message only.
2. The message is encrypted using the content-encryption key.
3. The content-encryption key is encrypted with RSA using the recipient's public key and is attached to the message.
4. The receiver uses RSA with its private key to decrypt and recover the content-encryption key.
5. The content-encryption key is used to decrypt the message.

As Figure 3 illustrates, both confidentiality and encryption may be used for the same message. The figure shows a sequence in which a signature is generated for the plaintext message and appended to the message. Then the plaintext message and signature are encrypted as a single block using symmetric encryption and the symmetric encryption key is encrypted using public-key encryption.

S/MIME allows the signing and message encryption operations to be performed in either order. If signing is done first, the identity of the signer is hidden by the encryption. Plus, it is generally more convenient to store a signature with a plaintext version of a message. Furthermore, for purposes of third-party verification, if the signature is performed first, a third party need not be concerned with the symmetric key when verifying the signature.

If encryption is done first, it is possible to verify a signature without exposing the message content. This option can be useful in a context in which automatic signature verification is desired, as no private-key material is required to verify a signature. However, in this case the recipient cannot determine any relationship between the signer and the unencrypted content of the message.

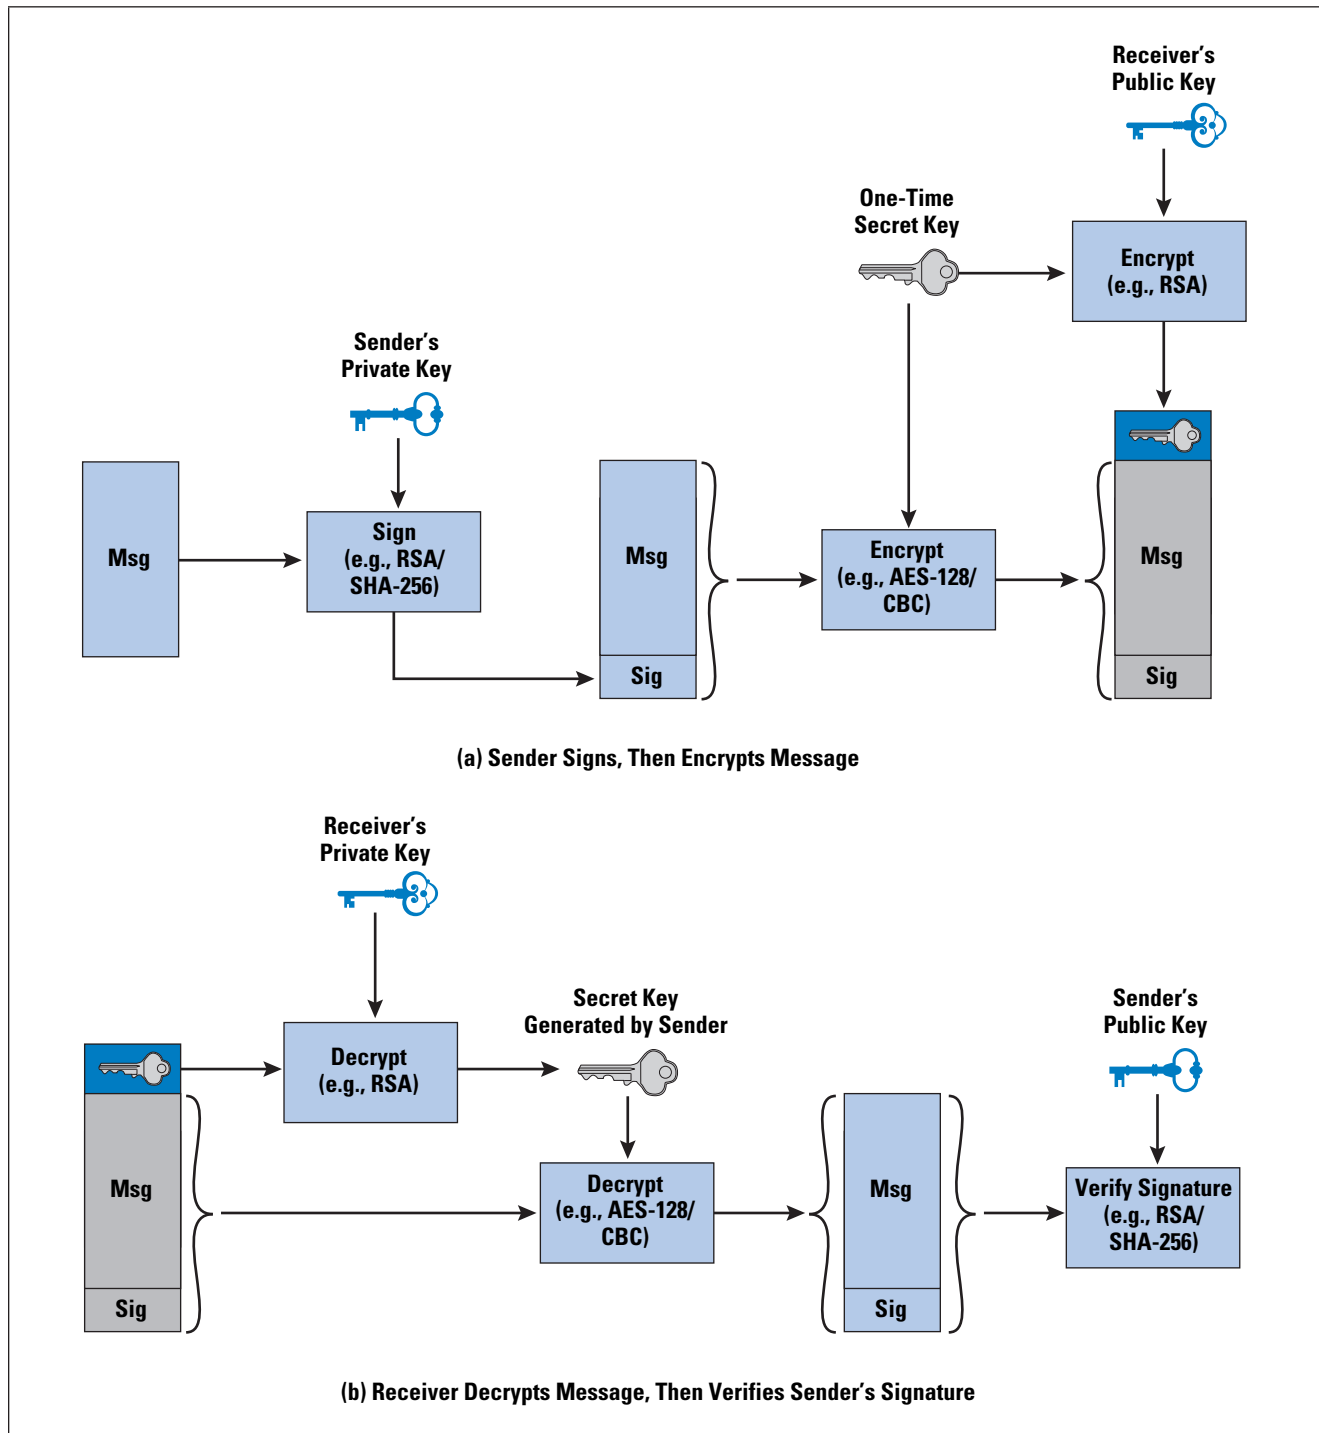

When S/MIME is used, at least part of the block to be transmitted is encrypted. If only the signature service is used, then the message digest is encrypted (with the sender's private key). If the confidentiality service is used, the message plus signature (if present) are encrypted (with a one-time symmetric key). Thus, part of or the entire resulting block consists of a stream of arbitrary 8-bit octets. However, many electronic mail systems only permit the use of blocks consisting of ASCII text. To accommodate this restriction and provide *compatibility*, S/MIME provides the service of converting the raw 8-bit binary stream to a stream of printable ASCII characters, a process referred to as 7-bit encoding. The scheme typically used for this purpose is Base64 conversion. Each group of three octets of binary data is mapped into four ASCII characters.

S/MIME also offers the ability to *compress* a message. Message compression has the benefit of saving space for both e-mail transmission and file storage. Compression can be applied in any order with respect to the signing and message encryption operations.

RFC 5751 provides the following guidelines:

- Compression of binary encoded encrypted data is discouraged, since it will not yield significant compression. Base64 encrypted data could very well benefit, however.
- If a lossy compression algorithm is used with signing, you will need to compress first, then sign.

Figure 3: Simplified S/MIME Functional Flow

SP 800-177 recommends the use of certificate chain authentication against a known certificate authority. Further, SP 800-177 indicates that users who want more assurance that the public key supplied is bound to the sender's domain may use a work-in-progress DANE-S/MIME mechanism^[20], in which the certificate and key can be independently retrieved from the DNS and authenticated per the DANE mechanism described subsequently.

In addition, SP 800-177 notes that MUAs typically use S/MIME private keys to decrypt the e-mail message each time it is displayed, but leave the message encrypted in the e-mail store. This mode of operation is not recommended, as it forces recipients of the encrypted e-mail to maintain their private key indefinitely. Instead, the e-mail should be decrypted prior to being stored in the mail store. The mail store, in turn, should be secured using an appropriate cryptographic technique (for example, disk encryption), extending protection to both encrypted and unencrypted e-mail.

OpenPGP

Pretty Good Privacy (PGP) was developed by Phil Zimmermann as a publicly-available freeware package to enable individuals to exchange secure e-mails without the need to rely on any institution. Efforts began early on to develop Internet standards for PGP^[21], culminating in *OpenPGP*. OpenPGP^[22, 23] is a proposed Internet Standard for providing authentication and confidentiality for e-mail messages. Although it is similar in purpose and functionality to S/MIME, OpenPGP uses different message and key formats and a different approach to establishing and using certificates. SP 800-177 cites many difficulties with OpenPGP, including lack of usability, scalability issues related to key distribution, and lack of authentication of key owners. Further discussion can be found in [24] and [25]. Accordingly, SP 800-177 recommends the use of only S/MIME and deprecates the use of OpenPGP.

DNS and DNSSEC

As background for the following sections, this section briefly reviews DNS and DNSSEC. The *Domain Name System* (DNS) is a directory lookup service that provides a mapping between the name of a host on the Internet and its numerical Internet address. Four elements comprise the DNS. The domain name space is a tree-structured name space to identify resources on the Internet. The DNS database is a collection of resource records organized into a distributed database; conceptually, each node and leaf in the name-space tree structure names a collection of information (for example, IP address, name server for this domain name) that is contained in *Resource Records* [RRs]). *Name Servers* are server programs that hold information about a portion of the domain-name tree structure and the associated RRs. *Resolvers* are programs that extract information from name servers in response to client requests. A typical client request is for an IP address corresponding to a given domain name.

The DNS database is divided into thousands of separately managed *zones*, which are managed by separate administrators. Using this database, DNS servers provide a name-to-address directory service for network applications that need to locate specific application servers.

Domain Name System Security Extensions (DNSSEC)^[26] is used by several protocols that provide e-mail security. DNSSEC provides end-to-end protection through the use of digital signatures that are created by responding zone administrators and verified by a recipient's resolver software. In particular, DNSSEC avoids the need to trust intermediate name servers and resolvers that cache or route the DNS records originating from the responding zone administrator before they reach the source of the query. DNSSEC consists of a set of new resource record types and modifications to the existing DNS protocol.

In essence, DNSSEC is designed to protect DNS clients from accepting forged or altered DNS resource records. It protects these clients by using digital signatures to provide: (1) data origin authentication to ensure that a RR has originated from the correct source; and (2) data integrity verification to ensure that the content of a RR has not been modified. The DNS zone administrator digitally signs every *Resource Record set* (RRset) in the zone, and publishes this collection of digital signatures, along with the zone administrator's public key, in the DNS itself.

In DNSSEC, trust in the public key (for signature verification) of the source is established not by going to a third party or a chain of third parties (as in *Public-Key Infrastructure* [PKI] chaining), but by starting from a trusted zone (such as the root zone) and establishing the chain of trust down to the current source of response through successive verifications of the signature of the public key of a child by its parent. The public key of the trusted zone is called the *trust anchor*.

DANE

DNS-Based Authentication of Named Entities (DANE)^[27, 28] is a protocol that provides mechanisms for domains to specify which X.509 certificates, which are commonly used for *Transport Layer Security* (TLS), should be trusted for the domain. DANE enables certificates to be bound to DNS names using DNSSEC. It is proposed in RFC 6698^[29] as a way to authenticate TLS client and server entities without a *Certificate Authority* (CA).

Briefly, DANE is an alternative mechanism for securely distributing information about domain names by using DNS. DANE defines a new type of DNS record that enables a domain to sign statements specifying which entities are authorized to represent it. Applications can use these records either to augment the existing system of CAs or to create a new chain of trust, rooted in the DNS.

The rationale for DANE is the vulnerability of the use of CAs in a global *Public-Key Infrastructure* (PKI) system. Every browser developer and operating system supplier maintains a list of CA root certificates as trust anchors. These certificates are called the *root certificates* of the software and are stored in its root certificate store. The PKI scheme allows a certificate recipient to trace a certificate back to the root. So long as the root certificate remains trustworthy and the authentication concludes successfully, the client can proceed with the connection. However, if any of the hundreds of CAs operating on the Internet is compromised, the effects can be widespread. The attacker can obtain the private key of the CA, be issued certificates under a false name, or introduce new bogus root certificates into a root certificate store. There is no limitation of scope for the global PKI, and a compromise of a single CA damages the integrity of the entire PKI system. In addition, some CAs have engaged in poor security practices. For example, some CAs have issued wildcard certificates that allow the holder to issue sub-certificates for any domain or entity, anywhere in the world.

The purpose of DANE is to replace reliance on the security of the CA system with reliance on the security provided by DNSSEC. This protocol is well expressed in RFC 6698:

“DNS-Based Authentication of Named Entities (DANE) offers the option to use the DNSSEC infrastructure to store and sign keys and certificates that are used by TLS. DANE is envisioned as a preferable basis for binding public keys to DNS names, because the entities that vouch for the binding of public key data to DNS names are the same entities responsible for managing the DNS names in question. While the resulting system still has residual security vulnerabilities, it restricts the scope of assertions that can be made by any entity, consistent with the naming scope imposed by the DNS hierarchy. As a result, DANE embodies the security “principle of least privilege” that is lacking in the current public CA model.”

DANE defines a new DNS record type, TLSA, which can be used for a secure method of authenticating *Secure Sockets Layer/Transport Layer Security* (SSL/TLS) certificates. The TLSA provides for:

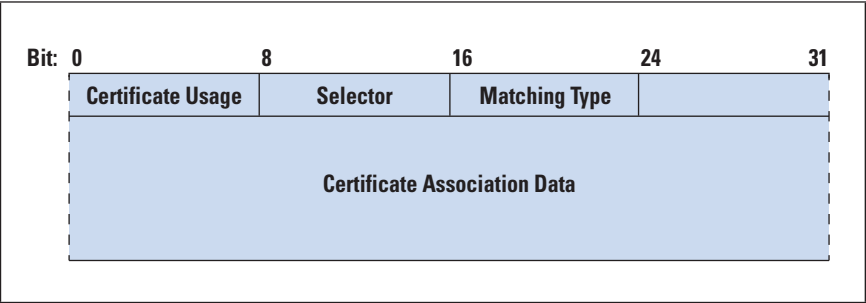

- Specifying constraints on which CA can vouch for a certificate, or which specific PKI end-entity certificate is valid.
- Specifying that a service certificate or a CA can be directly authenticated in the DNS itself.

The TLSA RR enables certificate issue and delivery to be tied to a given domain. A server domain owner creates a TLSA resource record that identifies the certificate and its public key. When a client receives an X.509 certificate in the TLS negotiation, it looks up the TLSA RR for that domain and matches the TLSA data against the certificate as part of the client’s certificate validation procedure.

Figure 4 shows the format of a TLSA RR as it is transmitted to a requesting entity. It contains four fields. The *Certificate Usage* field defines four different usage models, to accommodate users who require different forms of authentication. The usage models follow:

- *PKIX-TA (CA constraint)*: Specifies which CA should be trusted to authenticate the certificate for the service. This usage model limits which CA can be used to issue certificates for a given service on a host. The server certificate chain must pass PKIX validation that terminates with a trusted root certificate stored in the client.
- *PKIX-EE (service certificate constraint)*: Defines which specific end-entity service certificate should be trusted for the service. This usage model limits which end-entity certificate can be used by a given service on a host. The server certificate chain must pass PKIX validation that terminates with a trusted root certificate stored in the client.
- *DANE-TA (trust anchor assertion)*: Specifies a domain-operated CA to be used as a trust anchor. This usage model allows a domain-name administrator to specify a new trust anchor—for example, if the domain issues its own certificates under its own CA that is not expected to be in the end users’ collection of trust anchors. The server certificate chain is self-issued and does not need to verify against a trusted root stored in the client.
- *DANE-EE (domain-issued certificate)*: Specifies a domain-operated CA to be used as a trust anchor. This certificate usage allows for a domain-name administrator to issue certificates for a domain without involving a third-party CA. The server certificate chain is self-issued and does not need to verify against a trusted root stored in the client.

Figure 4: TLSA RR
Transmission Format

The first two usage models are designed to coexist with and strengthen the public CA system. The final two usage models operate without the use of public CAs.

The *Selector* field indicates whether the full certificate or just the value of the public key will be matched. The match is made between the certificate presented in TLS negotiation and the certificate in the TLSA RR. The *Matching Type* field indicates how the match of the certificate is made. The options are exact match, SHA-256 hash match, or SHA-512 hash match. The *Certificate Association Data* is the raw certificate data in hex format.

DANE can be used in conjunction with SMTP over TLS, as provided by STARTTLS, to more fully secure e-mail delivery. DANE can authenticate the certificate of the SMTP submission server that the user's mail client (MUA) communicates with. It can also authenticate the TLS connections between SMTP servers (MTAs). The use of DANE with SMTP is documented in RFC 7672^[30].

As discussed previously, SMTP can use the STARTTLS extension to run SMTP over TLS, so that the entire e-mail message plus SMTP envelope are encrypted. This option is used if both sides support STARTTLS. Even when TLS is used to provide confidentiality, it is vulnerable to attack in the following ways:

- Attackers can strip away the TLS capability advertisement and downgrade the connection to not use TLS.
- TLS connections are often unauthenticated (for example, the use of self-signed certificates as well as mismatched certificates is common).

DANE can address both these vulnerabilities. A domain can use the presence of the TLSA RR as an indicator that encryption must be performed, thus preventing malicious downgrade. A domain can authenticate the certificate used in the TLS connection setup using a DNSSEC-signed TLSA RR.

DNSSEC can be used in conjunction with S/MIME to more fully secure e-mail delivery, in a manner similar to the DANE functionality. This use is documented in an Internet Draft^[21], which proposes a new SMIMEA DNS RR. The purpose of the SMIMEA RR is to associate certificates with DNS domain names.

S/MIME messages often contain certificates that can assist in authenticating the message sender and can be used in encrypting messages sent in reply. This feature requires that the receiving MUA validate the certificate associated with the purported sender. SMIMEA RRs can provide a secure means of doing this validation.

In essence, the SMIMEA RR will have the same format and content as the TLSA RR, with the same functionality. The difference is that it is geared to the needs of MUAs in dealing with domain names as specified in e-mail addresses in the message body, rather than domain names specified in the outer SMTP envelope.

Sender Policy Framework

Sender Policy Framework (SPF) is the standardized way for a sending domain to specify a list of MTAs that are authorized to send on behalf of the domain. The problem that SPF addresses is the following: with the current e-mail infrastructure, any host can use any domain name for each of the various identifiers in the mail header, not just the domain name where the host is located.

Two major drawbacks of this freedom follow:

- It is a major obstacle to reducing *Unsolicited Bulk E-mail* (UBE), also known as *spam*. It makes it difficult for mail handlers to filter out e-mails on the basis of known UBE sources.
- *Administrative Management Domains* (ADMDs) are understandably concerned about the ease with which other entities can use their domain names, often with malicious intent.

However, a basic limitation of SPF is that it forces mail to follow a specific path and breaks when legitimate mail deviates from this path, such as a message that goes through a mailing list.

RFC 7208 defines the SPF^[31]. It provides a protocol by which ADMDs can authorize hosts to use their domain names in the **MAIL FROM** or **HELO** identities. (It is worth noting that this domain name is the return address for error messages, rather than being required to be the same as the author's address.) Compliant ADMDs publish SPF records in the DNS specifying which hosts are permitted to use their names, and compliant mail receivers use the published SPF records to test the authorization of sending MTAs using a given **HELO** or **MAIL FROM** identity during a mail transaction.

SPF works by checking a neighboring, upstream client MTA IP address against the policy encoded in any SPF record found at the sending domain. The sending domain is the domain used in the SMTP connection, not the domain indicated in the Author From field in the message header as displayed in the MUA. Thus SPF checks can be applied before the message content is received from the sender.

Figure 5 on the following page is an example in which SPF would come into play. Assume that the sender's IP address is **192.168.0.1**. The message arrives from the MTA with domain **mta.example.net**. The sender uses the envelope **MAIL FROM** tag of **alice@example.org**, indicating that the message originates in the **example.org** domain. But the message header specifies **alice.sender@example.net**. The receiver uses SPF to query for the SPF RR that corresponds to **example.org** to check if the IP address **192.168.0.1** is listed as a valid sender, and then takes appropriate action based on the results of checking the RR.

A sending domain needs to identify all the senders for a given domain and add that information into the DNS as a separate resource record. Next, the sending domain encodes the appropriate policy for each sender using the SPF syntax. The encoding is done in a TXT DNS resource record as a list of mechanisms and modifiers. Mechanisms are used to define an IP address or range of addresses to be matched, and modifiers indicate the policy for a given match. The SPF syntax is fairly complex and can express complex relationships between senders. For more details, see RFC 7208.

Figure 5: Example in Which SMTP
Envelope Header Does Not
Match Message Header

```

S: 220 foo.com Simple Mail Transfer Service Ready
C: HELO mta.example.net
S: 250 OK
C: MAIL FROM:<alice@example.org>
S: 250 OK
C: RCPT TO:<Jones@foo.com>
S: 250 OK
C: DATA
S: 354 Start mail input; end with <CRLF>.<CRLF>
C: To: bob@foo.com
C: From: alice.sender@example.net
C: Date: Today
C: Subject: Meeting Today
. . .

```

If SPF is implemented at a receiver, the SPF entity uses the SMTP envelope **MAIL FROM:** address domain and the IP address of the sender to query an SPF TXT RR. The SPF checks can be started before the body of the e-mail message is received, possibly resulting in blocking the transmission of the e-mail content. Alternatively, the entire message can be absorbed and buffered until all the checks are finished. In either case, checks must be completed before the mail message is sent to the end user's inbox.

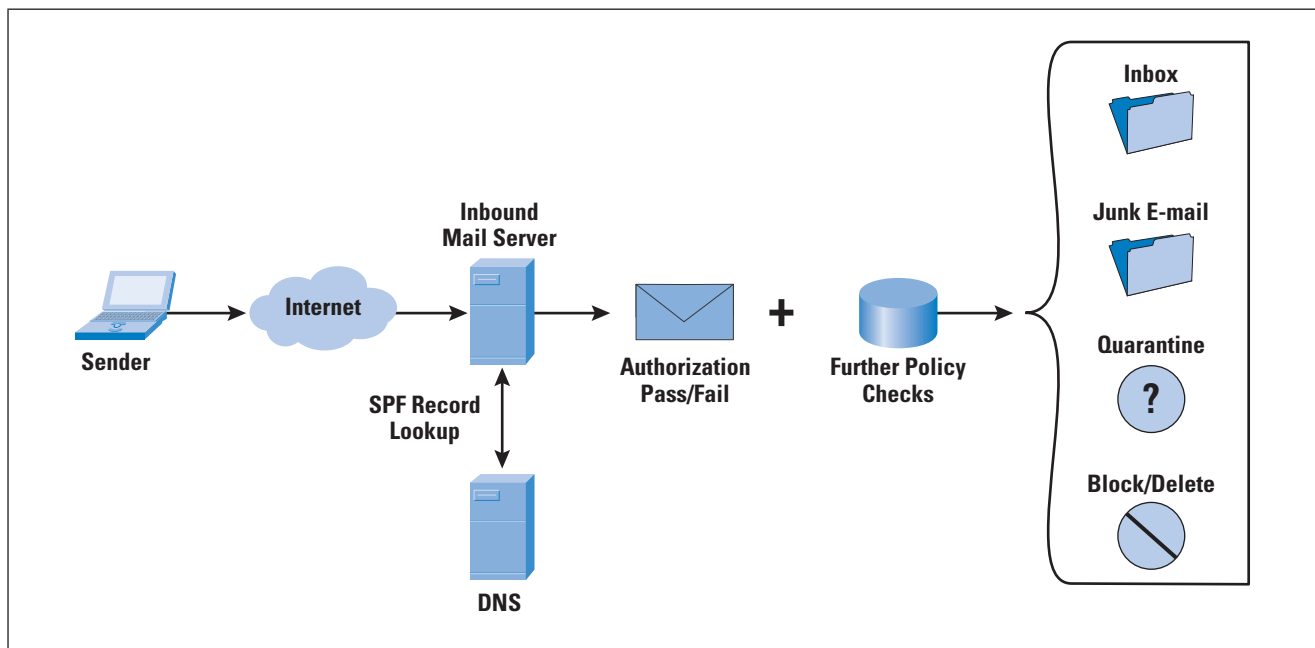

The checking involves the following rules:

1. If no SPF TXT RR is returned, the default behavior is to accept the message.
2. If the SPF TXT RR has formatting errors, the default behavior is to accept the message.
3. Otherwise the mechanisms and modifiers in the RR are used to determine disposition of the e-mail message.

With respect to SPF alone, to say in step 1, preceding, that the default behavior is to accept the message is correct. However, it should be noted that SPF is usually working within a mixture of anti-abuse tools and the aggregate filtering engine typically does not accept a message based on the results of only one of its tools, such as SPF.

Figure 6 illustrates SPF operation. As of 2016, more than 27% of all Internet domains implement SPF^[32].

Figure 6: Sender Policy Framework Operation

DKIM

DomainKeys Identified Mail (DKIM) permits a person, role, or organization that owns the signing domain to claim some responsibility for a message by associating the domain with the message^[33]. The domain can be an author's organization, an operational relay, or one of their agents. DKIM separates the question of the identity of the signer of the message from the purported author of the message. Assertion of responsibility is validated through a cryptographic signature and by querying the signer's domain directly to retrieve the appropriate public key.

The qualifier *some* in the first sentence of the preceding paragraph is important. In particular, the text directly "covered" by the signature is not vetted for authenticity.

Message recipients (or agents acting in their behalf) can verify the signature by querying the signer's domain directly to retrieve the appropriate public key and thereby can confirm that the message was attested to by a party in possession of the private key for the signing domain. DKIM is an Internet Standard defined in RFC 6376^[34]. DKIM has been widely adopted by a range of e-mail providers, including corporations, government agencies, Gmail, Yahoo, and many *Internet Service Providers* (ISPs). As of 2016, an estimated 40% of Internet sites deploy DKIM^[35].

An *Administrative Unit* (AU) is that portion of the path of an e-mail message that is under a single administration. DKIM focuses primarily on attackers located outside of the AUs of the claimed originator and the recipients, indirectly, by creating a verifiable signature of valid mail from the administrative unit.

It is with these external AUs that the trust relationships required for authenticated message submission may not exist and do not scale adequately to be practical. Conversely, within these AUs, there are other mechanisms (such as authenticated message submission) that are easier to deploy and more likely to be used than DKIM. External bad actors are usually attempting to exploit the “any-to-any” nature of e-mail that motivates most recipient MTAs to accept messages from anywhere for delivery to their local domain. They may generate messages without signatures, with incorrect signatures, or with correct signatures from domains with little traceability. They may also pose as mailing lists, greeting cards, or other agents that legitimately send or resend messages on behalf of others.

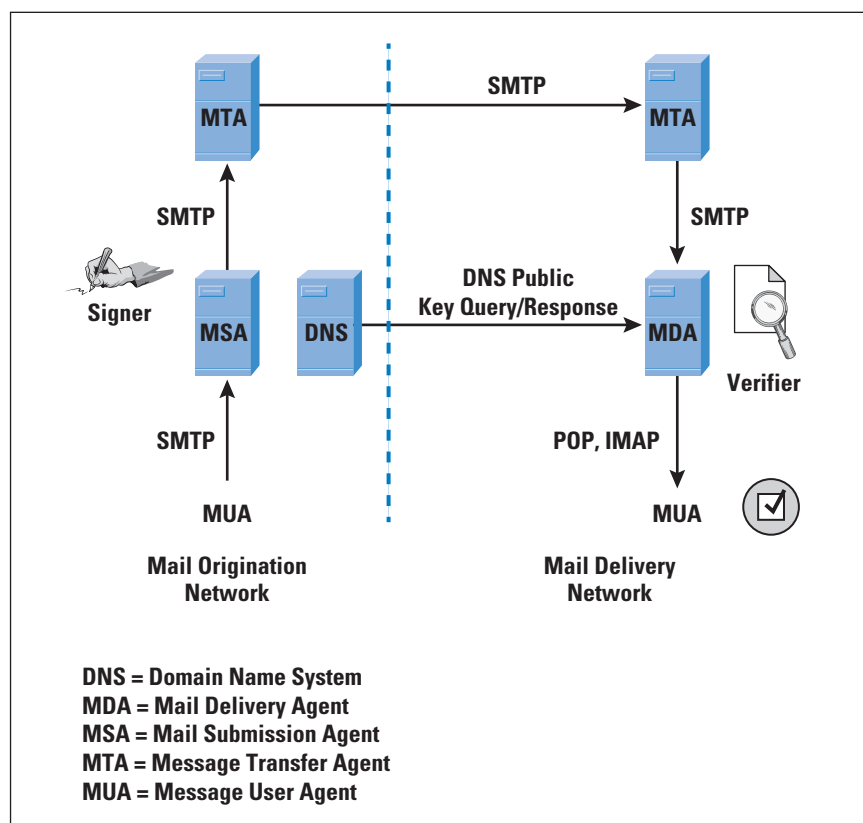

DKIM is designed to provide an e-mail authentication technique that is transparent to the end user. In essence, a user’s e-mail message is signed by a private key of the administrative domain from which the e-mail originates. The signature covers none, some, or all of the content of the message and some of the e-mail message headers.

Note that the signature is not validating any of what is signed, as digital signatures usually do. Rather, the choice of what to cover is meant as a means of gluing the **d=domain name** to the overall message in a way that is difficult to spoof. At the receiving end, the Message Delivery Agent can access the corresponding public key via a DNS and verify the signature, thus authenticating that the message comes from the claimed administrative domain. Thus, DKIM allows an enterprise to vouch for an e-mail message sent from a domain it does not control. This approach differs from that of S/MIME, which uses the originator’s private key to sign the content of the message. The motivation for DKIM is based on the following reasoning:

- S/MIME depends on both the sending and receiving users employing S/MIME. For almost all users, the bulk of incoming mail does not use S/MIME, and the bulk of the mail the user wants to send is to recipients not using S/MIME.
- S/MIME signs only the message content. Thus, RFC 5322^[36] header information concerning origin can be compromised.
- DKIM is not implemented in client programs (MUAs) and is therefore transparent to the user; the user doesn’t need to take any action.
- DKIM can be configured to apply to all mail from cooperating domains.
- DKIM allows good senders to prove that they did send a particular message and to prevent forgers from forging the DKIM signature.

Figure 7 is a simple example of the operation of DKIM. We begin with a message generated by a user and transmitted into the *Message Handling Service* (MHS) to an MSA that is within the user’s administrative domain. An e-mail message is generated by an e-mail client program.

Figure 7: Simple Example of DKIM Deployment

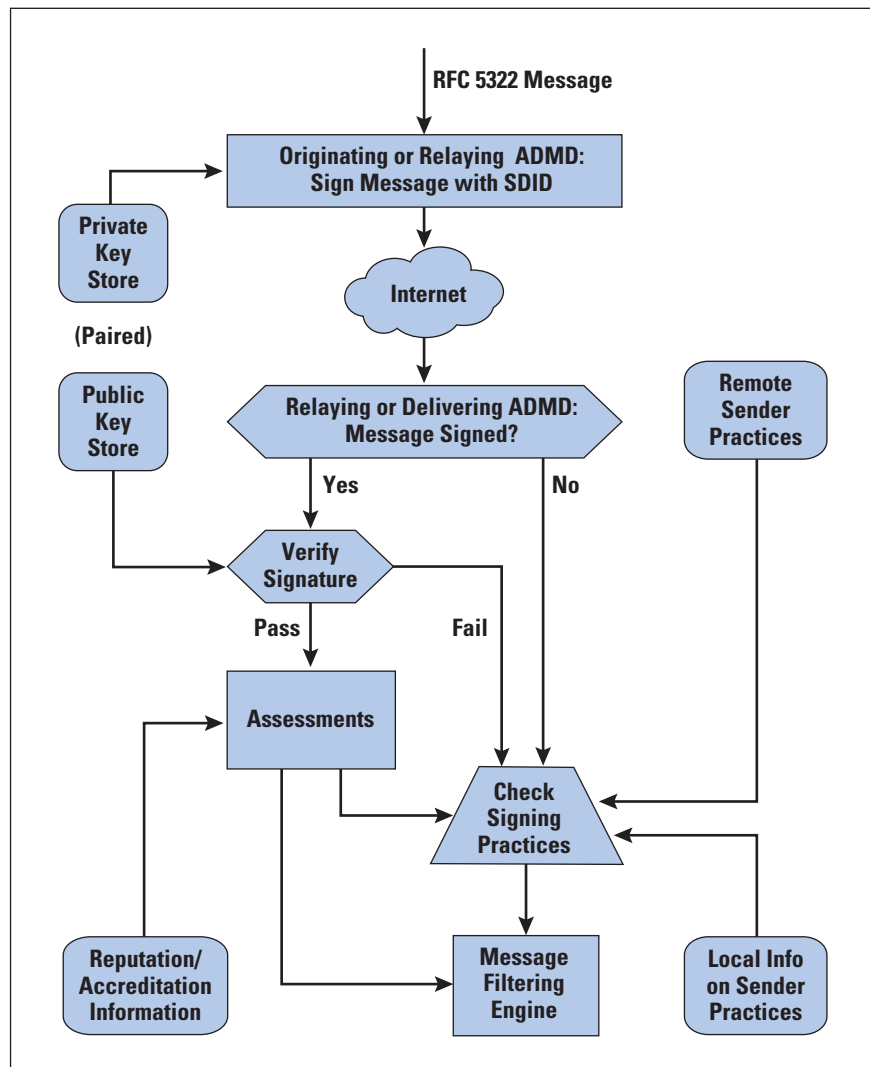

The content of the message, plus selected RFC 5322 headers, is signed by the e-mail provider using the provider's private key. The signer is associated with a domain, which could be a corporate local network, an ISP, or a public e-mail facility such as Gmail. The signed message then passes through the Internet via a sequence of MTAs. At the destination, the MDA retrieves the public key for the incoming signature and verifies the signature before passing the message on to the destination e-mail client. The default signing algorithm is RSA with SHA-256. RSA with SHA-1 also may be used.

Figure 8 on the following page, from RFC 5585^[37], provides a more detailed look at the elements of DKIM operation. Basic message processing is divided between a signing *Administrative Management Domain* (ADMD) and a verifying ADMD. At its simplest, this processing is between the originating ADMD and the delivering ADMD, but it can involve other ADMDs in the handling path.

Signing is performed by an authorized module within the signing ADMD and uses private information from a Key Store. Within the originating ADMD, this signing might be performed by the MUA, MSA, or an MTA. Verifying is performed by an authorized module within the verifying ADMD. Within a delivering ADMD, verifying might be performed by an MTA, MDA, or MUA. The module verifies the signature or determines whether a particular signature was required.

Verifying the signature uses public information from the Key Store. If the signature passes, reputation information is used to assess the signer and that information is passed to the message filtering system.

Figure 8: DKIM Functional Flow

If the signature fails or there is no signature using the author's domain, information about signing practices related to the author can be retrieved remotely and/or locally, and that information is passed to the message filtering system. For example, if the sender (for example, Gmail) uses DKIM but no DKIM signature is present, then the message may be considered fraudulent.

The signature is inserted into the RFC 5322 message as an additional header field, starting with the keyword `Dkim-Signature`. You can view examples from your own incoming mail by using the "View Long Headers (or similar wording) option for an incoming message.

Before a message is signed, a process known as *canonicalization* is performed on both the header and body of the RFC 5322 message. Canonicalization is necessary to deal with the possibility of minor changes in the message made en route, including character encoding, treatment of trailing white space in message lines, and the “folding” and “unfolding” of header lines. The intent of canonicalization is to make a minimal transformation of the message (for the purpose of signing; the message itself is not changed, so the canonicalization must be performed again by the verifier) that will give it its best chance of producing the same canonical value at the receiving end. DKIM defines two header canonicalization algorithms (“simple” and “relaxed”) and two for the body (with the same names). The simple algorithm tolerates almost no modification, while the relaxed tolerates common modifications.

DMARC

Domain-Based Message Authentication, Reporting, and Conformance (DMARC), defined in RFC 7489^[38], allows e-mail senders to specify policy on how their mail should be handled, the types of reports that receivers can send back, and the frequency of those reports.

DMARC works with SPF and DKIM. SPF enables senders to advise receivers, via DNS, whether mail purporting to come from the sender is valid, and whether it should be delivered, flagged, or discarded. However, neither SPF nor DKIM includes a mechanism to tell receivers if SPF or DKIM is in use, nor do they have a feedback mechanism to inform senders of the effectiveness of the anti-spam techniques. For example, if a message arrives at a receiver without a DKIM signature, DKIM provides no mechanism to allow the receiver to learn if the message is authentic but was sent from a sender that did not implement DKIM, or if the message is a spoof. In essence, DMARC addresses these issues by indicating whether SPF and/or DKIM will be used, what a receiver should do when they aren’t, and how receivers should report aggregate results for the domain.

DKIM, SPF, and DMARC authenticate various aspects of an individual message. DKIM authenticates the domain that affixed a signature to the message. SPF focuses on the SMTP envelope, defined in RFC 5321^[39]. It can authenticate either the domain that appears in the **MAIL FROM** portion of the SMTP envelope or the **HELO** domain, or both. These domains may be different, and they are typically not visible to the end user.

DMARC authentication deals with the From domain in the message header, as defined in RFC 5322. This field is used as the central identity of the DMARC mechanism because it is a required message header field and therefore guaranteed to be present in compliant messages, and most MUAs represent the RFC 5322 From field as the originator of the message and render some or all of this content of the header field to end users. The e-mail address in this field is the one used by end users to identify the source of the message and therefore is a prime target for abuse.

DMARC requires that the From address match (be aligned with) an Authenticated Identifier from DKIM or SPF. In the case of DKIM, the match is made between the DKIM signing domain and the From domain. In the case of SPF, the match is between the SPF-authenticated domain and the From domain.

A mail sender that uses DMARC must also use SPF or DKIM, or both. The sender posts a DMARC policy in the DNS that advises receivers on how to treat messages that purport to originate from the sender's domain. The policy is in the form of a DNS TXT resource record associated with the sender's domain name. The sender also needs to establish e-mail addresses to receive aggregate and forensic reports. Because these e-mail addresses are published unencrypted in the DNS TXT RR, they are easily discovered, leaving the poster subject to unsolicited bulk e-mail. Thus, the poster of the DNS TXT RR needs to employ some kind of abuse countermeasures.

Similar to SPF and DKIM, the DMARC policy in the TXT RR is encoded in a series of tag=value pairs separated by semicolons. Once the DMARC RR is posted, messages from the sender are typically processed as follows:

1. The domain owner constructs an SPF policy and publishes it in its DNS database. The domain owner also configures its system for DKIM signing. Finally, the domain owner publishes via the DNS a DMARC message-handling policy.
2. The author generates a message and hands the message to the domain owner's designated mail submission service.
3. The submission service passes relevant details to the DKIM signing module in order to generate a DKIM signature to be applied to the message.
4. The submission service relays the now-signed message to its designated transport service for routing to its intended recipient(s).

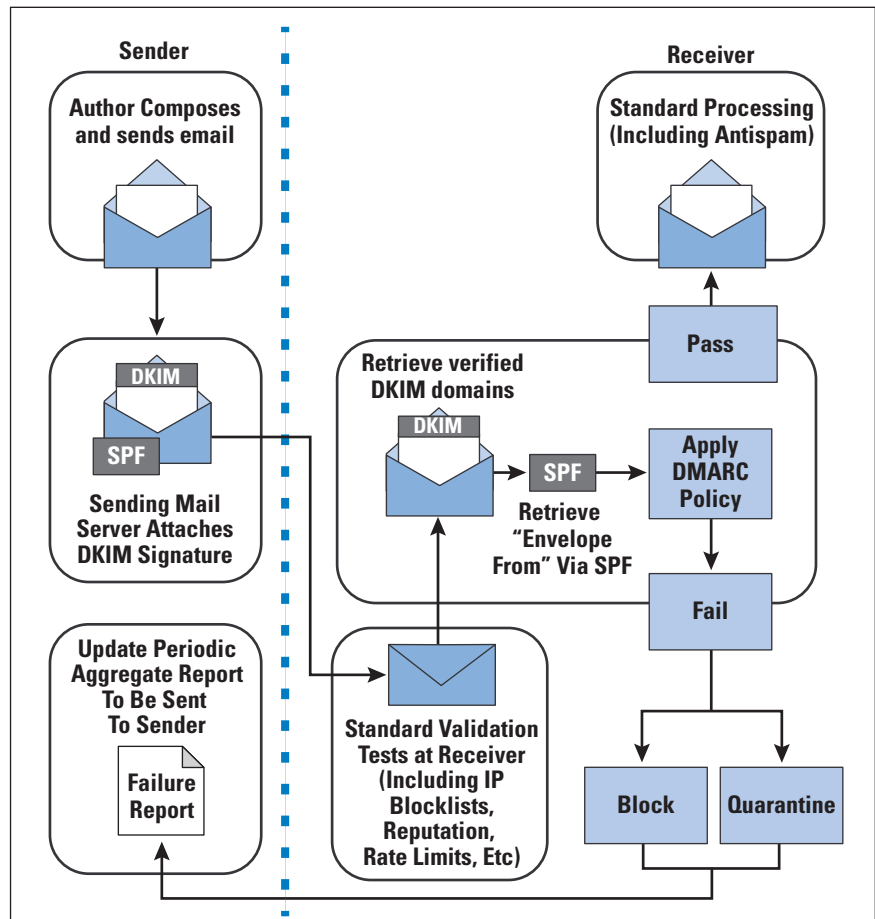

A message generated on the sender side may pass through other relays but eventually arrives at a receiver's transport service. The typical processing order for DMARC on the receiving side follows:

1. The receiver performs standard validation tests, such as checking against IP blocklists and domain reputation lists, as well as enforcing rate limits from a particular source.
2. The receiver extracts the RFC 5322 From address from the message. This address must be a single, valid address or else the mail is refused as an error.
3. The receiver queries for the DMARC DNS record based on the sending domain. If none exists, DMARC processing is terminated.
4. The receiver performs DKIM signature checks. If more than one DKIM signature exists in the message, one must verify.

5. The receiver queries for the SPF record of the sending domain and performs SPF validation checks.
6. The receiver conducts Identifier Alignment checks between the RFC 5321 From and the results of the SPF and DKIM records (if present).
7. The results of these steps are passed to the DMARC module along with the Author's domain. The DMARC module attempts to retrieve a policy from the DNS for that domain. If none is found, the DMARC module determines the organizational domain and repeats the attempt to retrieve a policy from the DNS.
8. If a policy is found, it is combined with the Author's domain and the SPF and DKIM results to produce a DMARC policy result (a "pass" or "fail") and can optionally cause one of two kinds of reports to be generated.
9. Recipient transport service either delivers the message to the recipient inbox or takes other local policy action based on the DMARC result.
10. When requested, Recipient transport service collects data from the message delivery session to be used in providing feedback.

Figure 9, based on one at [DMARC.org](https://dmarc.org), summarizes the sending and receiving functional flow.

Figure 9: DMARC Functional Flow

DMARC reporting provides the senders feedback on their SPF, DKIM, Identifier Alignment, and message disposition policies, which enables the sender to make these policies more effective. Two types of reports are sent: *Aggregate Reports* and *Forensic Reports*.

Aggregate Reports are sent by receivers periodically and include aggregate figures for successful and unsuccessful message authentications, including:

- The sender's DMARC policy for that interval
- The message disposition by the receiver (that is, delivered, quarantined, rejected)
- SPF result for a given SPF identifier
- DKIM result for a given DKIM identifier
- Whether identifiers are in alignment or not
- Results classified by sender subdomain
- The sending and receiving domain pair
- The policy applied, and whether it is different from the policy requested
- The number of successful authentications
- Totals for all messages received

This information enables the sender to identify gaps in e-mail infrastructure and policy. SP 800-177 recommends that a sending domain begin by setting a DMARC policy of **p=none**, so that the ultimate disposition of a message that fails some check is determined by the receiver's local policy. As DMARC aggregate reports are collected, the sender will have a quantitatively better assessment of the extent to which the sender's e-mail is authenticated by outside receivers, and will be able to set a policy of **p=reject**, indicating that any message that fails the SPF, DKIM, and alignment checks really should be rejected. From their own traffic analysis, receivers can determine whether a sender's **p=reject** policy is sufficiently trustworthy to act on.

A *Forensic Report* helps senders refine the component SPF and DKIM mechanisms as well as alerting them that their domain is being used as part of a phishing/spam campaign. Forensic reports are similar in format to aggregation reports, with these changes:

- Receivers include as much of the message and message header as is reasonable to allow the domain to investigate the failure. Add an *Identity-Alignment* field, with DKIM and SPF DMARC-method fields as appropriate.
- Optionally add a *Delivery-Result* field. Add DKIM Domain, DKIM Identity, and DKIM selector fields, if the message was DKIM signed. Optionally also add DKIM Canonical header and body fields.
- Add an additional DMARC authentication failure type, for use when some authentication mechanisms fail to produce aligned identifiers.

Since its introduction, DMARC has seen rapid acceptance. Thousands of companies use it to prevent billions of messages fraudulently using their Internet domains from reaching inboxes, thereby protecting their customers and employees from phishing and other abuse. Recently, two of the largest mailbox providers in the world—Google and Yahoo—have announced that they are extending that protection to cover more of their Internet domains^[40].

Summary

The IETF has developed a suite of protocols that provide comprehensive Internet e-mail security. Many of these protocols have been widely deployed, and the entire suite is recommended by NIST.

Acknowledgment

The author would like to express his gratitude to the reviewer for the many detailed and helpful comments.

Cloudy-Eyed: Complexity and Reality with Software-Defined Networks

by Russ White and Shawn Zandi, LinkedIn

Software-Defined Networks (SDN) are promoted as a way to eliminate the complexity of distributed control planes, increase network responsiveness to specific applications and business requirements, and reduce operational and equipment cost. If this description sounds like the classic “too good to be true” situation, that’s because it might just be. Just like you can’t build a database that has ideal consistency, accessibility, and partitionability, you can’t build a cheap network with optimal routing and minimal control-plane state. It’s just a reality of the complexity built into the physical shape of the universe that everything has a tradeoff—*cheap, fast, and high quality, choose two*.

When we reach the top of the SDN hype cycle, what will our options be? Perhaps the best place to start in answering this question is by considering why the “big promise” of SDN hasn’t been really successful in the real world.

Defining SDN: Then and Now

To really understand the hype and promise of SDNs, it’s important to go back to the beginning and consider what the original promise really was. There were originally three crucial elements to the SDN story.

First, SDNs were supposed to remove the intelligence from distributed control planes, replacing them with the centralized calculation of network paths in a controller. While an individual autonomous router has only a localized view of network conditions, a centralized controller can gain a more global view. A global view would allow the controller to more efficiently manage and direct traffic through the network in a way that improves both the efficiency of the network and the performance of applications running across the network.

Second, SDNs were supposed to provide a much more granular level of control—down to the flow level. This added level of control would enable much better policy control in various ways, including the discovery and direction of elephant flows, quality of service on a per-application/per-user basis, and other options.

Third, SDN would enable the network to be programmable, thereby reducing operational costs, enabling a more lean/agile view of the network, and allowing applications to interact directly with the network.

The definition of SDN has changed over the years, broadening so that it now includes just about any network technology that allows programmatic access to information about and control over the network.

An SDN, in more recent terms, seems to include everything from the ability of an application to schedule bandwidth (which is a rather more complicated problem than it seems) to gaining better telemetry data. The centralized controller, flow-based forwarding, and commoditization of hardware are still in scope, but they appear to be mixed in with a much more limited view of the “core components” of the SDN message. Why has the concept of the SDN changed across time?

It’s possible to argue that this definitional change is just a matter of the marketing departments at a wide array of vendors grabbing hold of the term, but there seems to be something deeper here. Perhaps the “something deeper” is the original ideals have proven more difficult to achieve than were first thought. A short overview of the challenges of deploying the original SDN ideal might be useful in understanding the historical flow of these changes. Three larger areas are considered in the following sections: centralizing the calculation of network paths, flow-based forwarding, and network programmability.

Centralizing the Calculation of Network Paths

Distributed control planes, such as *Intermediate System-to-Intermediate System* (IS-IS) and *Border Gateway Protocol* (BGP), are often (rightly) seen as one of the most complex components of a network. In fact, entire networks are designed around the operation of these routing protocols, including the consideration of topics like:

- Splitting up failure domains through information hiding
- Managing complex policies through communities, tags, and metrics
- Choosing topologies based on fast convergence characteristics
- The interaction of multiple distributed control planes running on a single network

Further, in order to support the complex processing and data handling of distributed control planes, network devices are typically large, expensive devices, with fast processors and large memory pools. In particular, as the need for policy-driven path selection (which generally means choosing a path through the network that is less optimal than the shortest path from a metrics perspective, but more optimal from a network usage or quality-of-service perspective) increased, the processing power and memory requirements of individual routers ramped up.

If distributed control planes could be eliminated and replaced by a controller (or set of controllers), the complexity of each forwarding device could be reduced dramatically, because the jobs of discovering the local topology and calculating the best path per destination would be offloaded from the individual boxes, and pushed onto the controller. By removing this processing from the routers, small, cheap, lightweight forwarding-only devices could be used instead of the traditional router.

Hence the world could move to *white-box* devices that would be available off the shelf and require little configuration.

Complexity, however, is not so easy to slay. The centralized controller approach presents numerous problems that will, most likely, forever limit it in scale and scope to something smaller than what was originally envisioned, such as two or three controllers providing forwarding information for tens of thousands of switches running at scale. Some of these problems include the relationship between centralized computation and reactive control planes, remote reactions to local topology and reachability changes, and what can fairly be described as the halo effect around software engineering.

Centralized Control and Reactive Forwarding

Distributed control planes, such as IS-IS, are proactive in their discovery of topology and reachability. Before the first packet is transmitted across the network, the routing protocol must discover a set of loop-free paths that can reach every destination in the network. Since this discovery and calculation process typically involves flooding, processing, and managing a lot of information, distributed control planes often rely on information hiding through aggregation to manage the amount and speed of state being carried in the protocol. For instance, in IS-IS intermediate systems in the level 2 flooding domain don't have any information about the topology of the outlying level 1 flooding domains. In a similar way, intermediate systems in a level 1 flooding domain know only about the topology within the flooding domain and which intermediate systems are connected to the level 2 flooding domain.

When the calculation of routes is centralized, there must still be some form of information hiding to scale the control plane. Instead of aggregation at specific topological points in the network, SDN control planes most often opt for moving to a reactive control plane, meaning the forwarding devices discover reachability information only when they receive the first packet in a flow. While this does reduce the amount of forwarding state in any particular device, it also has many drawbacks.

Specifically, reactive control planes disconnect the apparent state of the network from the perspective of any attached device from the actual state of the network. From the host's perspective, the network is up, and therefore there is a path to most destinations that begins with the first packet in a flow. In a reactive control plane, however, there is some amount of lag between the first packet in a flow being transmitted and the path actually being available. One objection to this observation is that the *Domain Name System* (DNS) is also reactive in much the same way. However, end devices generally participate in the DNS system, and hence know the state of their ability to forward in terms of name resolution.

Further, while it's always possible for the network to change state in the middle of a flow being transmitted, reactive control planes suffer from a wider set of causes for these changes. This situation is always true, of course, but while proactive control planes treat a disconnect between apparent and actual states as an error condition to be resolved, reactive control planes treat such a disconnect as a normal state of affairs. In a larger sense, disconnects between the actual and perceived states of the network are seen by attached devices as network instability; the stronger the disconnect, the more unstable the network appears to be. This condition can have an adverse effect on applications and host behavior. Local cache timeouts, cache failures, and other problems need to be included in the more general topology changes and problems common to distributed control planes for path failures.

Centralized Control and Fast Reaction to Changes in the Network

Centralized control planes disconnect local state from recalculation of the best path. If a local node or link fails, information about the state change must be transmitted to a remote device (the controller), which must recalculate a new set of paths, and then distribute those paths throughout the network. These operations can be made very quickly using techniques such as calculating and installing a backup route, but there is no simple way for a centralized controller to react more quickly, and with less chance of an unanticipated failure mode than with a distributed control plane.

The centralized/decentralized decision isn't necessarily a *better-versus-worse* decision, it's just a *different* decision with a *distinct set of tradeoffs*. Each path has its own complexities and problems to address; no set of problems seems to be much less complex to solve than any other set in this case.

The Halo of Software Development

Distributed control planes, as mentioned previously, are very complex, and they require a lot of configuration to deploy, design, troubleshoot, and manage. It seems simpler, in many ways, to just replace all the people who do this configuring, troubleshooting, and managing, with a small team of coders who can build and maintain a controller. The code would be simpler because it's all "in one place," and can be more customized to fit a particular business environment. The reality, however, is far different.

But a single controller simply won't do when it comes to scaling out a network. Even if you could run a network of thousands of routers with a single controller, it goes against every foundational concept of solid system design to do so. There must be at least two controllers, in topologically diverse locations within the network, to provide redundancy in support of overall system resilience. Moving from one controller to two inevitably means providing some way to distribute reachability and policy information between the controllers.

Ultimately, then, a distributed control plane must be built to allow communication between the controllers.^[1] Couldn't this distribution just be some standard distributed database? It could, but there's a difference between distributing a database and distributing the meaning contained in the database. To distribute the meaning, you must have an agreed-on format, encoding, and other things. If you examine existing distributed routing protocol specifications, you'll find they spend a lot of time describing not only how to carry information, but also how to specify what sort of information is being carried, and consistent ways to interpret and use that information. To make multiple controller configurations successful (especially across multiple controller vendors), either it all will need to be rebuilt in an inter-controller protocol, or—perhaps simpler—the controllers could just use an existing routing protocol. Regardless of the solution chosen, the problems involved in a distributed control plane haven't been removed from the network, they've just been moved to someplace else in the network.

Further, the distributed protocols the SDN controller is designed to replace are really just other software. The complexity in these protocols comes from the propensity of engineers to push functionality into them to address an ever-expanding array of use cases. As time passes and the larger (or perhaps more obvious) use cases are handled, protocol developers chase smaller problems, finally reaching into large amounts of code for what is really a set of corner cases. But moving the development of the control plane from one place in the network to another place in the network isn't going to solve this problem—the process of accretion of new features and an ever-larger code base and inter-controller protocol specifications to support an ever-increasing set of use cases is going to remain the same.

Flow-Based Forwarding

Standard IP headers contain at least five fields of interest to network devices:

- Source IP address
- Source port number
- Destination IP address
- Destination port number
- Protocol number (or identifier)

Some transport protocols also include more information that might be of interest, such as the *Transmission Control Protocol* (TCP) socket number, which can indicate a particular application, and information about the expected quality of service for this packet (and ultimately flow). Much of this information (and more) could be used to forward traffic into multiple paths through the network based on policy and available bandwidth. However, existing routing protocols are designed to provide reachability, and hence forwarding, information based on the destination address only.

There has long been a desire to forward traffic based on much more than the destination address, so that individual applications can be independently routed through the network, and information other than the destination address can be used to deny access to specific network resources. These requirements have led to a string of work in the area of accounting for the IP source, at the least, when making forwarding decisions.^[2]

Figure 1 provides an example.

Figure 1: Flow-Based Forwarding Control Example

In this example, Host A is sending a large file to Server F, while the user at Host B, a small handheld mobile device, is participating in a video conference through Server G. Assuming the two server addresses are shared among numerous different services, destination-based addresses cannot be used to differentiate between the large file transfer and the video conference. In this case, if the network administrator knows about the file transfer, the source addresses of A and B, along with the source and destination protocol information, can be used to differentiate the two traffic streams. This solution would allow the file-transfer traffic to be directed along the [C,D,E] link, while the video conferencing traffic would be directed along the [C,E] link. This traffic separation can be used to allow the video conference traffic to pass along links that aren't being heavily used by the file transfer.

Flow-based forwarding, however, presents many problems.

First, the amount of control-plane state required to forward every flow in a large network individually would be far beyond reasonable. The problem is not just the number of flows, but also the flow setup rate. To put this idea in real terms, if there are 10,000 hosts such as A and B in the illustration, and each attempts to open a different website, and each website requires 20 TCP connections, the network is required to calculate and install 2,000,000 flows in a matter of seconds. Few controllers could handle flow setup rates at this level.^[3]

Second, the hardware costs of implementing such a scheme would be very high. The amount of flow state required in each device would be incredibly large—larger than most commodity hardware can support.

In addition, the cost of examining the full header on each packet at each hop in the network to achieve correct routing would be very high as well. The cost includes not only the capital expenditures (CapEx) of acquiring hardware that can support full header examination at every hop, has the table space to hold per-flow tables across millions of flows, and can support the flow setup rate required in a large fabric, but also the operating expenses (OpEx) in terms of power use for such devices. Power drives much more of large-scale design than is often considered; however small the energy cost per packet to examine the entire header at each device, it can still add up, over billions of packets switched, to significant numbers.

Third, the use cases for such flow-based forwarding, in the real world, tend to be rather narrow. Replacing the control plane that manages millions of flows through a large-scale data center fabric to support custom routing for a few thousand flows at any given time doesn't appear to be a good tradeoff in terms of complexity and network manageability.

Of course, SDNs can operate in a mode where most traffic is forwarded based on the packet destination, and the small number of flows that need special routing are handled by examining the full packet header (the five tuples noted previously or deeper), but this solution is a compromise with reality, rather than the original ideal of SDNs. The concluding section of this article considers the more realistic option of compromising with reality, so it is not covered here.

Making the Network Programmable

Finally, SDNs have promised a great deal in terms of network programmability. The breakdown involves three different areas: dynamic provisioning, and dynamic interactions between applications and the network. These topics are considered in the sections that follow.

Dynamic Provisioning

If there's one point virtually every network engineer agrees on, it's that large-scale networks are difficult to provision, monitor, and troubleshoot. It would certainly be a boon to network operations, particularly in large networks, if there were a single, unified interface into every vendor's platform, and every control-plane implementation deployed across the network, to facilitate provisioning and management. While the idea of a single interface is noble, the reality of the market is probably going to intercede—as it has many times in the past—because vendors must be able to differentiate themselves somehow in order to actually sell hardware, software, and services. This reality isn't an indictment of vendor business models, it's just reality as it exists. There are two ways to express this problem.

First, vendors try to differentiate themselves with new features, architectures, and ideas their competitors don't have. New ideas, however, require new models that can be used to configure and manage newly designed and/or modified hardware and software.

If the vendor publishes standardized models for managing these things before they are completed, they lose competitive advantage.

Second, vendors tend to be able to command higher returns on vertically integrated solutions that are easy to deploy and manage *as a unit*. Building vertically integrated solutions, however, tends to thrive on well-integrated, single-vendor interfaces between the parts.

Both of these factors place vendors in the position of trying to balance openness with profit margins. The market demands openness, but it also demands simplicity and innovation, and these goals are sometimes (or even often) contradictory from the vendor's perspective.

The most likely result of these two factors is that SDN interfaces tend to be restricted in their scope and scale to the “lowest common denominator” of available features. Some level of configuration and trace information might be available through vendor-specific extensions, but not on the “common model.” Models such as *OpenFlow* tend to start with clean implementations, and then tend to fragment over time as vendors rush to build product. There is little incentive to consider additions to the base work, along with the rework such additions would require on a per-vendor basis, over time.

There is tension around automated provisioning from the network operator's side, as well. On the positive side, dynamic provisioning does take humans out of the repetitive action loop of quickly provisioning network devices and virtual topologies. Thus the speed and accuracy of configuration, provisioning, and fault isolation can be improved dramatically; in other words, automation can reduce the *Mean Time Between Mistakes* (MTBM). However, automating processes also introduce a level of brittleness into the operational cycle that can be undesirable.

Brittleness, in this context, can be seen as a set of systems that react to a wide array of situations with a small set of behaviors. Just as there can be monocultures in bacteria colonies, there can be monocultures in networks. To give a specific example, if every implementation of IS-IS in the network reacts the same way to a given situation, then it's possible for a single defect to cause every router in the network to fail under a single (though perhaps unusual) set of conditions.

The same sorts of situations can arise in provisioning or managing a network; an event that “slips through the cracks” of the automation system, or an attacker who can feel out the perimeters of defense, can take an entire system down very quickly. Another term for this situations is “robust yet fragile”:

At some point, any complex system becomes brittle—robust yet fragile is one phrase you can use to describe this condition. A system is robust yet fragile when it is able to react resiliently to an expected set of circumstances, but an unexpected set of circumstances will cause it to fail.^[4]

The best ways to counter are to intentionally avoid monocultures where possible, and intentionally inject human decision points in the process. Reducing repetitive human work is good, but removing humans from the entire decision process is bad. This brittleness can end up replacing a large number of smaller failures due to human error and replace them with large systemic failures.

Application Interaction

Combining dynamic provisioning and dynamic policy results in what can be called an *Application Programming Interface* (API) for the network itself. Treating the network as a programmable entity allows applications to directly interact with the network as a system. The general idea can look something like this:

- An application needs a certain amount of bandwidth with specific quality-of-service parameters at a particular time.
- The application uses an interface into a controller to reserve this bandwidth, providing the controller with the impacted endpoints, etc.
- The controller uses some means to build the right network conditions to accommodate the needs of the application.

Another example might be offloading the processing of packets for security reasons into the network. Applications and operating system security are becoming more widely deployed as encryption of data in motion becomes more common. For instance, LinkedIn currently deploys *Transport Layer Security* (TLS) on all external-facing connections, and is in the midst of deploying TLS across the data center fabric among internal applications. This type of encryption reduces the usefulness of firewalls as network appliances (or a “bump in the wire”) for blocking various types of attacks. The movement towards application and operating system security, however, means the host must perform all filtering, and must also forward traffic that needs to be forwarded to a honeypot or collection point for further processing. If the network has a policy interface, however, the host could instruct the controller to install policy at any point in the network that makes sense to either block or redirect attacker flows. This model would take security-related packet processing off the host and place it into the network, where specialized hardware can be deployed, and traffic can be optimally redirected or dropped more optimally.

The same objections that can be raised for dynamic provisioning can be raised for direct interaction between applications and the network, such as brittleness. To such interactions can be added the potential for feedback loops between various applications and network conditions (the main reason live measurement of network conditions was removed from the *Enhanced Interior Gateway Protocol* [EIGRP], soon after its first deployments, and replaced with relatively static metrics).

Summary of Network Programmability

Once a dynamic interface to the network as a network is in place, this abstraction can breed complexity beyond what the engineers responsible for maintaining and troubleshooting the network can readily understand. This complexity leads to several different problems, such as the “magic-button effect,” where no one really knows why “doing x” solves a particular problem, but since no one can figure it out (and no one has time to figure it out), someone writes a script that “pushes the button” every time “x” happens.

Overall, then, the promise of SDNs in the provisioning space is great—but parallel complexities must be managed. At this point, there is little sense that our understanding of SDN complexity has matured to the point of being able to use the full potential of the technology in the provisioning space.

Conclusion: Looking to the Future

While SDNs aren’t poised to “consume the world” in their original form because of issues surrounding centralized controllers, scale, and speed, the concepts involved are beginning to be applied to many different problem spaces. A hybrid-mode approach that allows a more standard distributed control plane to provide forwarding information for the bulk of the traffic based on the destination address, but allows overriding forwarding decisions based on other factors for a small percentage of the traffic, is gaining traction in data center fabrics of all sizes. Programmability is being used in long-haul networks, particularly in conjunction with optical transport, to handle customized forwarding as well. Essentially, the model that’s being adopted in the real world is splitting policy from base reachability, leaving the base reachability under the control of distributed control planes, while moving policy-based forwarding into a controller.

Leaving the the proven scalable distributed control plane in place and using SDN to take advantage of the perks such as traffic engineering, bandwidth optimizations, intelligent routing, special policies, and other uses seems to be the most practical path forward. Network operators may find themselves deploying different mixes of SDN-type controls and distributed control planes based on application support and business strategy, but there’s little doubt that both distributed control planes and what will be called SDN—programmability layered on top of the distributed control plane—will both continue to be used into the foreseeable future.

SDN is not a product. Rather, it’s a methodology or tool; not a destination, goal, or product to sell, or sometimes to market, and should not be considered a target to reach but a strategy to perform certain tasks depending on real needs and if certain requirements apply.

The *Regional Internet Registries* (RIRs) form an important part of the administrative ecosystem of the Internet. APNIC and RIPE are already sponsors of this journal, and we are pleased to announce that another RIR, the *Latin America and Caribbean Network Information Centre* (LACNIC), is now a sponsor of IPJ. LACNIC has additionally agreed to translate selective articles and provide article summaries from IPJ in Spanish.

Selective articles from IPJ are also available in Russian through the publication Интернет изнутри (*Internet Inside*), available at:
<http://www.ccni.ru/publications/>

Our individual donors and organizational sponsors make publication of this journal possible. We are especially thankful for the support of Rabbi Rob Thomas and Lauren Thomas who agreed to match individual donations from October 2016 until April 2017.

The *Border Gateway Protocol* (BGP) is a core component of the Internet routing system. Like most Internet protocols, BGP was developed in the *Internet Engineering Task Force* (IETF). The IETF has been criticized for its slow process, and in many cases for developing protocols without proper input from those who actually run networks, collectively referred to as the “operators.” Job Snijders describes how a group of dedicated operators were able to develop specifications for *BGP Large Communities* within the IETF process in record time.

Various aspects of *The Internet of Things* (IoT) have previously been covered in this journal. This time Bob Hinden looks at the problem of securing IoT devices in light of some large-scale attacks that exploited security weaknesses in common devices such as IP cameras.

In our final article, Geoff Huston and Joao Luis Silva Dama discuss *privacy* in the context of the *Domain Name System* (DNS). The *DNS PRIVate Exchange* (DPRIVE) Working Group of the IETF has been working on this topic, considering ways in which the interaction between a DNS client and a DNS resolver can be protected.

BGP Large Communities

by Job Snijders, NTT Communications

If the *Domain Name System* (DNS) is the phonebook of the Internet, used to translate names to numeric addresses, then the *Border Gateway Protocol* (BGP)^[1] is the map of the Internet: how to reach those addresses. This article focuses on a minute, but oh-so-critical aspect of BGP operations called *BGP Communities*. We will cover what BGP Communities are, why “done” is better than “perfect,” and how disaster was avoided.

A BGP crash course: The Internet is an assemblage of independent networks. The technical term for such a network is an *Autonomous System* (AS), and each is assigned a globally unique identifier called the *Autonomous System Number* (ASN). All these networks exchange routing information with other networks using BGP, a path vector protocol. This exchange of routing information is composed of announcements such as “this specific set of addresses can be reached through my network.” A set of addresses is called a *route*. Routes are often decorated with meta-information known as BGP Communities. These BGP Communities can be considered marker colors of sorts. Such marker colors are used as an additional input in the route evaluation process, which is a function of a network routing policy (Figure 1).

Figure 1: The Stamps on the List of Addresses Symbolize the Function of BGP Communities

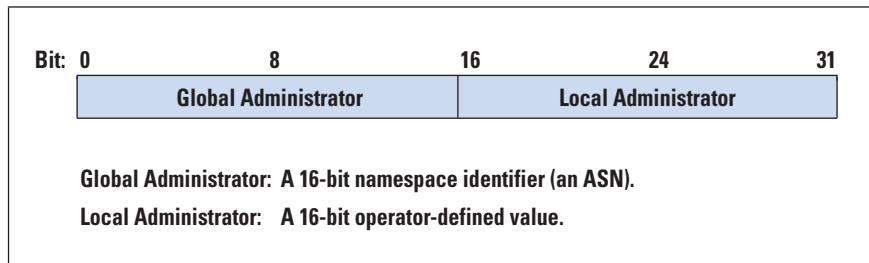

Over the last 20 years, BGP Communities have become the tool of choice to facilitate operations in all BGP networks. BGP Communities are used, for instance, to group routes together and ensure that only a specific group of routes is announced at a given interconnection point with another network.

However, along with the advent of a new type of network identifier in 2007, 32-bit ASNs (previously ASNs were 16 bits) came an operational problem: by embracing 32-bit ASNs, we had suddenly outgrown classic BGP Communities.

How Can BGP Communities Be Too Small?

Let's first explore what BGP Communities actually mean for operations. BGP Communities are defined in RFC 1997^[2]. Each BGP Community is a fixed-width 32-bit entity; you can attach multiple BGP Communities to a route. The convention is that the first 16 bits are the ASN in which the last 16 bits have a meaning. For human consumption, a BGP Community is usually represented as two 16-bit values separated by a colon (Figure 2).

Figure 2: A Classic BGP Community

An example BGP Community and its application would be **2914:664**; the first part, **2914**, is NTT Communications' ASN. The second part (called the *Local Administrator*), which carries the value **664**, is defined by NTT and has meaning only within NTT's network. According to NTT's documentation^[3], the value **664** within the **2914** namespace means "only blackhole outside the country the announcement originated." BGP Communities are the lingua franca of inter-domain routing; however, (oddly enough) its vocabulary is exchanged through out-of-band means such as published documentation. Thousands of networks have defined their own routing functions and associated BGP Communities.

In the early 2000s work began to extend the BGP protocol so that it could accommodate the ever-growing Internet. The exhaustion of the 16-bit ASN pool we are facing right now was already anticipated then. Through RFC 4893^[4] the range of possible ASNs was extended from 65,535 to 4,294,967,295 ($2^{32} - 1$). The observant reader will have noted the friction between the previously described application of a BGP Community and the existence of 32-bit ASNs: you simply cannot fit a 32-bit value in a 16-bit field!

Thus, operators of networks with a 32-bit ASN have been forced to work around this problem. Operators have used kludges ranging from using private 16-bit ASNs in the "ASN" field (those first 16 bits), to the ultimate rejection of the concept of 32-bit ASNs: returning the assigned 32-bit ASN to its respective *Regional Internet Registry* (RIR) and requesting a fresh 16-bit ASN. However, the *Internet Assigned Numbers Authority* (IANA) has been depleted of its supply of 16-bit ASNs. The RIRs are making impossible searches for 16-bit ASNs.

Rumor has it that some RIRs were considering reclamation strategies to increase their pool of 16-bit ASNs. A dire situation!

The Road to Perfection Is Always Under Construction

Surely the *Internet Engineering Task Force* (IETF) thought of this situation when updating the BGP-4 specification for 32-bit ASNs? Absolutely! But not in a way that would match operational practices. RFC 4893^[4] deferred the issue of BGP Communities as follows: “... the high-order two-octets of the community attribute [...] encode the Autonomous System number.” Quite clearly this would not work for BGP speakers that use 4-octets Autonomous System Numbers. Such BGP speakers should use the four-octet AS-Specific *Extended Communities* instead (see Figure 3).

Yes, Extended Communities, as defined in RFC 4360^[5], are bigger than regular BGP Communities: they contain a *Type* and *Subtype* field followed by 48 bits of data. However, the 48-bit length of the Extended Community value precludes the common operational practice of having the ability to encode ASNs in both the Global Administrator and the Local Administrator subfields. You can either encode a 16-bit value in the first part and a 32-bit value in the second part (Figure 3), or the other way around, but not a 32-bit value in both fields (Figure 4).

Figure 3: A BGP Extended Community Flavor #1

Figure 4: A BGP Extended Community Flavor #2

The *Type* and *Subtype* fields define the kind of Extended Community. The Value field can be split into either a two-octet *Global Administrator* subfield and a four-octet *Local Administrator* subfield, or a four-octet *Global Administrator* and a two-octet *Local Administrator*.

Even if your network does not have a 32-bit ASN, you might have to interact with 32-bit ASN networks. If we go back to the example of NTT’s routing policy^[3], one of the traffic engineering features is exposed through BGP Communities **65501:nnn**, where nnn is to be replaced with the Peer ASN and **65501** means “prepend AS 2914 once on outbound.” Ideally this works for 32-bit ASNs too!

The previous example highlights two issues: apparently AS 2914 ran out of BGP Community space and resorted to using a Private ASN in the first 16 bits: 65501; this situation is considered a form of namespace pollution. And secondly, had 2914 instead been a 32-bit ASN (such as AS 199036), you would not be able to encode a 32-bit ASN in the second field, even with Extended Communities. In other words, you cannot fit 64 bits worth of information into 48 bits of room. You can find many examples^[6] of networks offering traffic engineering features through the verbatim reference of a target Peer ASN in the BGP Community itself. Extended Communities have excellent use cases, but simply put, they aren't big enough for Internet routing operations.

So, if both Communities and Extended Communities weren't suitable, a third reimagination of the Communities *concept* was needed. Since these technologies tend to last for decades, and the previous two iterations had proven not to be usable if the technology changes, the bar was set pretty high.

Notable efforts in this problem space include *Flexible Communities* (started in 2003) and *Wide Communities* (started in 2010). These efforts have highlighted a disconnect between the IETF and operator communities. Not only were these two efforts moving forward on vastly different timescales than the operational community required (keep the impending doom of 16-bit ASN exhaustion in mind), but both efforts presented a tendency towards *feature creep*. The limitless extensibility was both a virtue and a curse: every possible use case would be consumed effortlessly in the specification, so the schedule overran, the specification complexity increased, and as a result no actual implementations had been produced. "A bird in the hand is worth two in the bush."

Another anti-pattern was at work in the IETF *Inter-Domain Routing* (IDR) Working Group. The anti-pattern is commonly called *Cookie Licking*. Cookie Licking is a reference to the metaphorical situation where someone takes a cookie, licks it, puts it back on the tray, and does not eat it! In volunteer communities this phenomenon can be noticed when a certain topic is discussed and someone says "I've already got this covered in my Internet-Draft." This statement might defer others from working on the topic, since you could easily assume the problem will be taken care of. But with the 32-bit ASN specification approaching the respectable age of 10 years, the pool of 16-bit ASNs running out, and no commonly acceptable successor available for BGP Communities, it became increasingly clear that a catastrophe was imminent. The issue had become a matter of extreme urgency: if we didn't start turning the tanker right now, it would crash into a wall two years down the road.

Origin Story: BGP Large Communities

In March 2016 in Sweden, Ignas Bagdonas (Equinix) presented his perspective on “some form of larger BGP communities.” In this presentation he iterated over challenges that 32-bit ASNs network operators face and provided an up-to-date overview of current and past attempts to mitigate those issues. After this presentation, I approached Bagdonas and proposed to team with him and jointly drive this effort forward.

In April 2016, I flew to the United States, where my friend Jared Mauch introduced me to Jakob Heitz (Cisco) over lunch. Heitz was intrigued by the effort and committed to providing running code for some form of “a simple, bigger BGP Community.” This agreement meant the first router vendor got on board, even if we didn’t know what the results would look like!

In May 2016 at the RIPE 72 meeting, Bagdonas presented again in the *Routing Working Group*. In the Q&A session, Ruediger Volk (Deutsche Telekom) made one of the most formative comments on the “larger communities” effort. Volk said: “The discussions in IETF about extending this [communities] have been around for many years, and no progress has been made. Any proposal that has an extended functionality comes with the problem that discussion of the additional functionality does not have a proof of termination.”

In other words, the IETF suffers from *bikeshedding*^[7]. Only something that was purposefully specified to be as narrow and as simple as possible would meet the network operator community’s immediate needs. Volk went on to say that something similar to the opaque approach of RFC 1997^[2] should be done, where the first bits indicate “Who owns the namespace” followed by some extra bits for the actual routing policy work.

It was this specific argument about namespace that led to defining Large BGP Communities as a 96-bit entity: All operators whether they have a 16-bit or a 32-bit ASN, would have 64 bits (8 bytes) of room to signal information or trigger actions in their network. With 64 bits available to the network operator, there even is enough to target a 32-bit ASN and still have space for an action such as “prepend” or “do not export.”

These conversations in the operational community led directly to Large Communities (by design) not being extendable. Extensibility comes at a cost. Also, knowing that the amount of noise generated by an idea is inversely proportional to the complexity of the idea, the IETF was asked to consider the simplicity of the Large Community a virtue, not a disadvantage. Of course, that request was ignored: over the span of just four months, almost 5% of all emails ever sent through the IDR mailing list in the last 20 years addressed the topic of Large Communities.

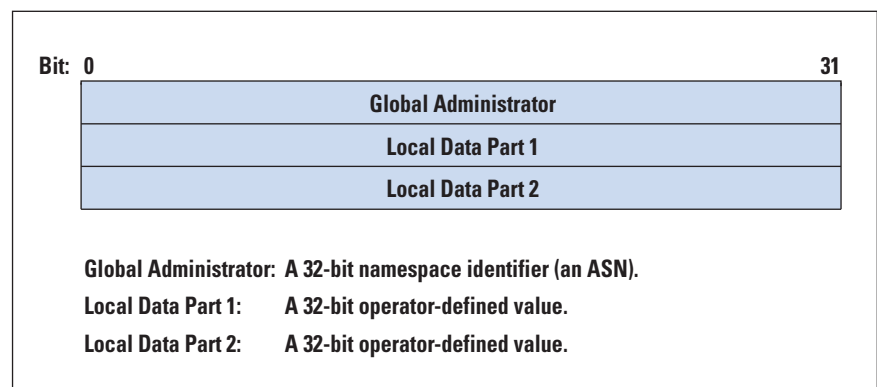

Aside from the fierce debate on the actual technology itself, the IANA *Early Allocation Procedure* uncovered very serious deployment issues. Initially Large Communities were assigned *BGP Path Attribute* value 30 by the IANA. Immediately following this allocation, BGP Beacons with the Large Community attached were brought online^[8] to test for problems of any kind. We expected the beacon prefix at least to propagate to all corners of the Internet, and optionally with its *Transitive Large BGP Communities* attribute still attached and intact. The beacon was launched from my home, but unfortunately the assigned codepoint did not pass the “Family Acceptance Factor.” My significant other noticed how certain websites that were reachable the day before could be reached no more. Collective sleuthing of the NLNOG^[9] operators brought to light that certain Huawei software was using BGP Path Attribute value 30 for something entirely different than Large Communities, and as such legitimate Large Communities were considered invalid and treated such prefixes with a withdraw. After this knowledge became public, Cisco and Juniper also emerged and a grand total of six squatted BGP Path Attribute values were uncovered^[10]. Squatting in this context means that the code point is used for a different purpose than the one designated by the IANA. In the end BGP Large Communities was assigned a new value: 32 — a very befitting number for the problem it solves.

To end this origin story: Ruediger Volk provided the effort with a challenge: “If we go really fast-track, we’ll be there in 5 years’ time, not before.” We all know that nothing motivates as much as a solid race against the clock: In exactly 6 months the Large Communities team produced 18 versions of the technical specification^[11], patched 2 packet analyzers, developed 7 implementations^[12], and obtained approval from the *Internet Engineering Steering Group* (IESG) to publish the document as an IETF Standards Track RFC.

So What Is This “BGP Large Community”?

An example of a Large Community is **2914:65400:38016**. Each BGP Large Community value is encoded as a 96-bit quantity: three unsigned 32-bit integers, separated by a colon. The **2914** part is called the *Global Administrator*, and the second and third fields (**65400** and **38016**, respectively) are called *Local Data Part 1* and *Local Data Part 2* (Figure 5).

Figure 5: A BGP Large Community

The Global Administrator is a 32-bit namespace identifier that allows different Autonomous Systems to define Large Communities without collision. The recommendation is to put your RIR-assigned ASN in the Global Administrator field. Using a 32-bit field allows full parity and fairness between 16-bit and 32-bit ASNs. Everyone can use their own ASN in Large Communities. The “Local Data Parts” are to be interpreted as defined by the owner of the ASN.

Special care was taken to define a canonical representation for Large Communities. Especially in our international community where we face communication challenges because of language barriers, it is important that Large Communities are easy to remember and easy to communicate by phone or email.

Use of BGP Large Communities

A design pattern promoted by the Internet Draft `draft-ietf-grow-large-communities-usage`^[13] specifies a **ASN:Function:Parameter** pattern to fill the three Large Community fields.

In existing deployments of Communities RFC 1997^[2] and preliminary deployments of Large Communities, two categories of Communities exist: *Informational Communities* and *Action Communities*.

Informational Communities serve as markers regarding, for instance, the origin of the route announcement, the relation with the *External Border Gateway Protocol* (EBGP) neighbor, or the intended propagation audience. Informational Communities also assist in network operations such as debugging. The Global Administrator field is set to the ASN that marks the routes with the Informational Communities. As an example: on a route that AS 64497 announces to AS 64498, AS 64497 might add Large BGP Community **64497:100:31** to signal to AS 64498 that the route was learned in the Netherlands. In this instance, the **100** value in *Local Data Part 1* is an indicator for the function “in which country a route originated” and the value **31**, as parameter, symbolises the Netherlands. In general, the intended audience of Informational Communities is downstream networks, but any Autonomous System could benefit from receiving these communities.

Action Communities are attached to routes to request nondefault behaviour in an Autonomous System. For instance, Action Communities are used to change the propagation characteristics of the route, or BGP Path attributes such as *LOCAL_PREFERENCE*, *AS_PATH*, and so forth. The Global Administrator field is set to the ASN value of the AS that has defined the meaning of the remaining fields and is expected to perform the action upon receiving the route. For instance, if AS 64499 wants to request AS 64497 to lower the *LOCAL_PREFERENCE* to **50** (below the default of **100**), AS 64499 could tag the route with **64497:20:50**. In general the intended audience of Action Communities is an upstream provider.

A real-life example of the application of Large BGP Communities can be found at the Route Servers operated by the *Internet Neutral Exchange Association* (INEX), Ireland. INEX^[14] extended its Route Server routing policy to support control over which Peer ASN receives what routing information through a trivial suppress/unsuppress mechanism. For instance, Large Community **43760:1:peer-as** means “Announce prefix to a peer-as,” whereas **43760:0:peer-as** means “Prevent announcement of a prefix to the ASN filled in as peer-as.” With BGP Communities such signaling was exclusively applicable to 16-bit ASNs.

Implementations

An IETF attitude from the past is “rough consensus and running code,” and especially for a technology like Large Communities (designed to be used in an inter-domain context), the more implementations, the more stable and commonly accepted the standard is. At the moment of writing there are nine confirmed implementations in various stages of general availability.

It is clear that the open source projects have taken a lead in implementing Large Communities. I attribute this situation in part to the fact that any contributor can dedicate time to create a patch. Secondly, the size of an ecosystem and the expected self-reliance (if any) of the user base affect the size of the effort. After all, most open source projects won’t need, or won’t have to train pre- and post-sales staff and technical assistance centers, update volumes of internal and external documentation, and, last but not least, figure out how to port the feature into the many concurrently supported releases.

These open source projects benefited from an open regression testing suite: *The Large Communities Playground*^[15]. This open source cross-vendor effort brought easy specification compliance, and functional testing to any Open Source Software project runnable inside Docker. The availability of this tool prevented duplicate efforts in establishing the appropriate environments, and ensured consistent interoperability of the implementations.

Considering the information available to me right now: *ExaBGP*, *GoBGP*, *OpenBGPD*, *rtbrick*, and *pmacct* are shipping Large Communities in their stable releases. *Quagga* and *frr* ship today or will do so shortly. *Arista EOS*, *Cisco IOS XR*, Juniper’s *Junos OS*, and Nokia *SR OS* are expected to publish software in the second half of 2017. Ancillary parts of the ecosystem such as *tcpdump*, *Wireshark*, *pbgpp*, *zebra-dump-parser*, *bpgdump*, and *mrtparse* have also been updated. Support for Large Communities in just the BGP Speakers simply wouldn’t be enough: to be a viable alternative to BGP Communities, every element in the ecosystem has to be updated, from packet analysers to research tools to statistics backends.

The future looks bright...2018 will be the year of Large Communities.

Conclusion

This challenging crusade through the IETF process has changed me from being an outside operator to a participant in the standardisation community. As much as Large Communities are a part of me, I am now a part of the IETF. Any criticism against the IETF institution displayed in this article applies equally to me as it does to others. We need to be vigilant to prevent another occurrence where operational reality and standardisation efforts grow apart so far that the only recourse left is to round up all the operators and show up with pitchforks and torches. In the end, it's just the results that matter; anything else is unimportant. Large Communities are here now, and will be so for the next decades.

Large Communities closed the final feature-parity gap between 16-bit and 32-bit ASNs. Now 32-bit ASNs are first-class citizens too.

The Internet of Insecure Things

by Bob Hinden, Check Point Software

We have a problem. As we have learned recently, most *Internet of Things* (IoT) devices are not secure. They have numerous security weaknesses, including default login/passwords and fixed firmware login/passwords (not easily changeable). In addition, the devices do not get regular software updates to fix security problems, and there is no one to call if problems arise. To make matters worse, these devices exist in large numbers. Gartner says that 6.4 billion IoT devices are deployed now, and forecasts 20.8 billion in 2020. The IoT contains billions of insecure things.

The security problem with these devices is not theoretical; the devices are used today to launch very large-scale *Distributed Denial of Service* (DDoS) attacks. Malware that takes advantage of the security weaknesses of these devices to create botnets exists.

IoT-Based DDoS Attacks

The first large IoT-based attack I am aware of was the DDoS attack on the popular online security publication *KrebsOnSecurity* blog^[1]. This attack happened on September 13, 2016. The blog had recently published a series of articles about an organization called *vDOS*, a DDoS-for-hire service. The blog stated that *vDOS* made approximately \$600k in 2 years by knocking sites offline. Two weeks after the articles were published, *KrebsOnSecurity* was attacked with 620 Gbps of traffic^[2]. Akamai was providing pro-bono DDoS protection to *KrebsOnSecurity*, but it couldn't continue to handle the traffic load^[3]. Fortunately, *Google Project Shield*^[4] is now protecting the website. Apparently, the source of the attack was IoT devices that included a myriad of technologies composed of IP cameras, *Digital Video Recorders* (DVRs), home routers, and other embedded computers.

The next large IoT-based DDoS attack occurred in early October of 2016. OVH^[5] is a large international web-hosting provider. The company was attacked by a botnet comprising more than 145,000 compromised IP cameras and digital video recorders. The attack peaked at 1 Tbps, and fortunately, OVH was able to withstand the attack. This attack was the largest DDoS attack at the time.

A very visible attack occurred on Friday, October 21, 2016. This attack was directed against DYN, a large provider of *Domain Name System* (DNS) services^[6]. The attack limited access to many of DYN's customers, including some of the biggest sites on the Internet, like Twitter, Amazon, Tumblr, Reddit, Spotify, and Netflix. For many Internet users, the Internet was down. Table 1 lists the major sites that were affected.

Table 1: Major Sites Affected in the Dyn Attack

Airbnb	Amazon.com	Ancestry.com	The A.V. Club	BBC
Boston Globe	Box	Business Insider	CNN	Comcast
CrunchBase	DirecTV	Elder Scrolls	Electronic Arts	Etsy
EQAO	FiveThirtyEight	Fox News	Guardian	GitHub
Grubhub	HBO	Heroku	HostGator	iHeartRadio
Imgur	Indiegogo	Mashable	NHL	Netflix
NYT	Overstock.com	PayPal	Pinterest	Pixlr
PlayStation	Qualtrics	Quora	Reddit	Roblox
Ruby Lane	RuneScape	SaneBox	Seamless	Second Life
Shopify	Slack	SoundCloud	Squarespace	Spotify
Starbucks	Storify	Swedish Civil Contingencies Agency	Swedish Government	Tumblr
Twilio	Twitter	Verizon	Visa	Vox Media
Walgreens	WSF	Wikia	Wired	Wix.com
WWE	Xbox Live	Yammer	Yelp	Zillow

We are still learning more about this attack, but it appears to be similar to the two earlier attacks. It's been reported that it peaked at 1.2 Tbps, another record. However, unlike the first two attacks, the effects of this one were visible to many Internet users, and it made the news cycle. We don't know for certain the motivations for this attack, but there is speculation that it was due to DYN's support of Brian Krebs, the man behind KrebsOnSecurity. It certainly got everyone's attention.

IoT Devices Involved in DDoS Attacks

The devices used in these attacks include a range of IP cameras, DVRs, and home routers. What these devices share is that they all ship with default login/passwords and can be enabled without changing these defaults. Some even have fixed firmware login/passwords that can't be changed. They are all widely available and fairly low-cost. For example, a search on Amazon for "IP camera" will result in several hundreds of pages of IoT devices for sale, most less than \$100 USD. While there clearly has been a lot of innovation to build so many different types and styles of IP cameras, innovation clearly hasn't addressed making them secure.

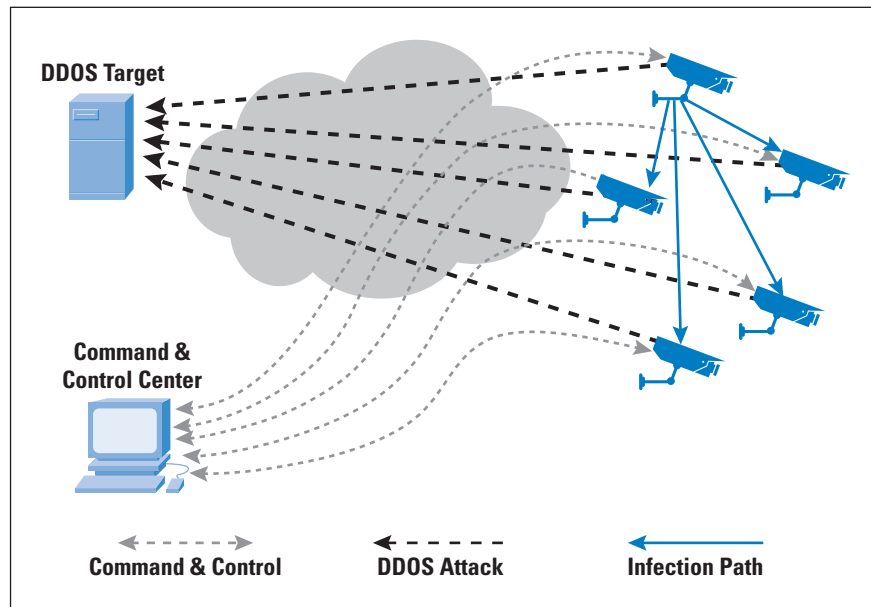

IoT Malware

The malware used in the KrebsOnSecurity attack was released recently. It is called *Mirai*^[7]. It works by scanning the Internet for vulnerable devices, looking for systems with factory default usernames and passwords. It installs itself in these IoT devices, turning devices into "bots" used to launch these DDoS attacks. *Bashlight* is another form of IoT botnet malware. It's similar to Mirai, as it infects IoT devices with default usernames and passwords.

According to research from Level3 Communications, Bashlight is responsible for infecting almost a million IoT devices and now competes with other botnets based on Mirai.

Mirai has two phases; in the first phase it infects IoT devices like IP cameras. In the second phase the attack is directed from a *Command and Control System*. These phases are illustrated in Figure 1.

Figure 1: Mirai Attack Mechanism

In the first phase, it scans broad ranges of IP addresses looking for devices that allow it to log in with a set of default login name and password combinations. These default login and password combinations are derived from the documentation of IoT devices. These attacks are very simple, not very sophisticated.

Examples of these login and password combinations follow:

```
admin/admin
root/admin
root/88888
root/root
ubnt/ubnt
```

The problem is that while these IoT devices allow the user to change the default, many users don't, and the setup of these IoT devices does not require it. Thus they are very vulnerable to being taken over by malware like Mirai.

One interesting part of the address scanning is that Mirai has a list of IP address ranges it does not scan. Some of these ranges belong to large companies like General Electric and Hewlett Packard, the U.S. Department of Defense, and the U.S. Postal Service. It's hardly the complete set of addresses for these organizations; I assume the Mirai authors had some reason to avoid these addresses. While the reason is unknown, they may have been trying to avoid detection.

A group named *Malware Must Die*^[8] has discovered new variants of IoT malware. This discovery isn't too surprising since the source code for Mirai was released and a lot of malware is a variant of earlier malware. One of these variants is called *Linux/IRCTelnet*^[9]. Its attacks are similar to those of Mirai, but it uses *Internet Relay Chat* (IRC) to communicate with compromised Linux-based IoT devices. It also has the capability to attack IoT devices running IPv6.

We Should Be Worried

We should be worried for three fundamental reasons. First, the sheer scale of these attacks is enormous. As shown in Table 2, they are growing:

Table 2: Growth of Attacks

Site	Number of Attackers	Traffic
KrebsOnSecurity	1.2 million	620 Gbps
OVH	145 thousands	1 Tbps
DYN	Millions	1.2 Tbps

At this level, every organization is vulnerable. The current number and the growth rate of new IoT devices show no evidence of slowing down. And finally, the nature of most IoT devices makes attacks on some of these new devices much more difficult to stop than attacks on conventional IT devices because they don't come with any kind of effective support.

Can We Fix These Problem?

Fixing these problems will be a challenge. Technically, some of the problems are straightforward to fix. For example:

- Do not allow default login/passwords, and require users to change them before the device is enabled.
- Do not have fixed unchangeable firmware login/passwords.
- Provide automatic updates of software.

Beyond that, matters get more difficult. How does the industry provide support for low-cost IoT devices? How long will they be supported? What happens when support ends; do the devices turn themselves off? How are attacks detected and contained? Harder still, how do we fix the currently very large deployed bases of IoT devices? Is anyone in the supply chain of the IoT devices concerned?

The economics of providing real security for IoT devices raises even more questions. Who is responsible when an IoT device is taken over by malware?

The user, the retail outlet where the device was purchased, the manufacturer, or the component vendors that the manufacturer used? How do you provide long-term support for a device that sells for less than \$100 USD? What happens when support ends?

Unfortunately, there are many more questions than answers.

What Can We Do?

While there isn't a simple single solution to these problems, there are some things we can do. Possibilities range from what IoT device owners, companies that sell the devices, companies that design and build the devices, and the IoT Industry need to do.

The first and simplest is that people who own IoT devices should not run them with default passwords. That precept applies to all Internet devices. You always should use unique and hard-to-guess login usernames and passwords. You should use different passwords for each device. This common sense advice will greatly reduce the likelihood that IoT malware will infect your devices.

Note that using a password manager is recommended for IoT devices and, of course, all places where you have accounts on the Internet. These password managers allow you to use impossible-to-guess passwords. This approach is clearly much better than using "admin/admin."

The next step after setting new login/password information is to reboot the devices. The IoT malware lives in memory and will be erased if the device is rebooted. Then check to determine if the new login/passwords are still there. This step won't help with default unchangeable firmware accounts, but is still worth doing.

Companies that sell IoT devices need to ensure that the devices they sell are reasonably secure. This can include things like requiring login/passwords to be set upon installation, not having fixed unchangeable firmware passwords, and allowing users to get updates that fix known security problems. Retail channels like Amazon, Best Buy, NewEgg, etc., and companies that specialize in these devices like FLIR Systems may have the most leverage over companies that design and build these devices because the device manufacturers don't sell directly themselves. They all sell through well-known retail channels. These channels may also be liable if they are selling insecure IoT devices. Will someone file a class action suit against one of these companies? Time will tell.

Companies that design, build, and manufacture IoT devices should make their products more secure. They need to require that login/passwords account information needs to be configured as part of the installation procedure. They should also provide automatic security updates.

I am not sure that without any other motivation these companies will do this procedure, given how far in the channel they are from the end user. I think with serious encouragement from the retail channel, for example, telling them “we will stop selling your products until their security is improved,” it will happen. There may even be a market for devices that are more secure than the others. On a positive note, it has been reported that the Chinese electronics firm Hangzhou Xiongmai Technology Co Ltd has initiated a recall of its IP cameras (webcams)^[11]. It is hard to tell how effective this effort will be, but it clearly will not be as good as pushing software updates.

The IoT industry needs to develop an approach to make the IoT secure. If it continues on the current path, IoT is going to be a disaster for this industry. I don’t think we are there yet, but the signs are not encouraging. We are not going to get the grand visions of IoT everywhere if people think the devices are insecure. The current IoT malware doesn’t attack the owners of these devices, and they may not even be aware their devices are compromised, but this is only the beginning.

The potential for the collection of data on the users of these devices is staggering. If the device is compromised, its camera and sensors can be used against the user. Who wouldn’t be susceptible to a ransom demand that threatened to share what you did in your house? While I am sure that most of us don’t have anything serious to hide, would you want the world to see everything you have done or said in your house? We already have DDoS for hire firms, so what happens when we get surveillance companies hiring IoT surveillance for hire firms? It would certainly make divorce court proceedings more interesting.

One bit of good news based on these recent attacks, a lot of work is going on to create security frameworks for IoT devices. Organizations doing this experimentation include parts of the U.S. Government like the *National Institute of Standards and Technology* (NIST)^[12] and the *Department of Homeland Security* (DHS)^[13], and a variety of organizations including the *Internet Architecture Board* (IAB)^[10], the *Broadband Internet Technical Advisory Group* (BITAG), the *GSM Alliance*, the *Industrial Internet Consortium*, and the *Open Web Application Security Project*. Bruce Schneier has compiled a good list of resources^[14]. While this is all good news, it’s not clear how these efforts will cause current and future IoT devices to change to be more secure. Some mix of consumer guidance, retail channel control, and/or government regulation may be needed.

Conclusion

The problem we have with the “Internet of Insecure Things” is only going to get worse for the immediate future. Many things need to happen to improve the situation, and it isn’t going to happen quickly. I believe there are a lot of benefits if we can start building the Internet of Secure Things, but we have a long way to go. It’s important that everyone involved take security more seriously. “Everyone” includes users, the retail channel, manufacturers of the devices, and the IoT industry. It will get better only if everyone gets involved.

BOB HINDEN is a Check Point Fellow at Check Point Software, and co-chairs the IPv6 working group in the IETF. Hinden was the Chair of the Internet Society Board of Trustees from 2013 to 2016, and a member of the Board of Trustees from 2010–2016. Previously at Nokia, he was a Nokia Fellow, Chief Internet Technologist at Nokia Networks, and Chief Technical Officer (CTO) at the Nokia IP Routing Group. He was one of the early employees of Ipsilon Networks, Inc. Nokia acquired Ipsilon on December 31, 1997. Bob was previously employed at Sun Microsystems, where he was responsible for the Internet Engineering group that implemented internet protocols for Sun’s operating systems. Prior to this position he worked at Bolt, Beranek, and Newman, Inc. on a variety of internetwork-related projects, including the first operational Internet router and one of the first TCP/IP implementations. Hinden was co-recipient of the 2008 *IEEE Internet Award* for pioneering work in the development of the first Internet routers. He has been active in the IETF since 1985 and is the author of 39 RFCs, including two April 1 RFCs. He served as the chair of the *IETF Administrative Oversight Committee* (IAOC) from 2009 through 2013. Before that he served on the *Internet Architecture Board* (IAB), was Area Director for Routing in the Internet Engineering Steering group from 1987 to 1994, and chaired the IPv6, Virtual Router Redundancy Protocol, Simple Internet Protocol Plus, IPAE, the IP over ATM, and the Open Routing working groups. He is also a member of the RFC Editorial Board and the RFC Series Oversight Committee. Hinden holds an B.S.E.E., and a M.S. in Computer Science from Union College, Schenectady, New York. DNS Privacy

by Geoff Huston and Joao Luis Silva Dama, APNIC

The *Domain Name System* (DNS) is normally a relatively open protocol that smears its data (which is your data and mine too!) far and wide. Little wonder that the DNS is used in many ways, not just as a mundane name resolution protocol, but as a data channel for surveillance and as a common means of implementing various forms of content access control.

But this situation is poised to change. The material released by Edward Snowden has sensitized us to the level of such activities that we have now become acutely aware that many of our Internet tools are just way too trusting, way too chatty, and way too easily subverted. First and foremost, in this collection of vulnerable Internet tools is the DNS.

A query made to the DNS is a precursor to almost every Internet transaction. Whether it's performing a search, downloading a web page, sending a mail message, opening a chat session, or even receiving an online advertisement, the DNS is often invoked as the first step. As users, we work in a symbolic world of readable names, such as **facebook.com** or **netflix.com**, whereas the underlying fabric of the Internet can send and receive packets only by using binary IP addresses rather than these symbolic names. So, we use the DNS to map from a name to an IP address. Thus, if you were able to look at a log of the DNS queries I've made in the last day or so, you may well be able to reconstruct my recent web browsing history, for example.

Obtaining a log of the DNS queries I make is perhaps the equivalent in terms of information content to obtaining a telephone log of called numbers from a previous generation of communications. A DNS transaction log may not provide information about the precise nature of the network transactions I've made, but it does record which sites I've been using. This information is often just good enough, as it's exactly what you would need to build a highly accurate profile of what I do on the Internet. It's not just national security bodies that have an interest in assembling such data logs. These days we see many systems that target individual users, and build a comprehensive profile of their needs and desires. The difference between an annoying advertisement and a timely helpful suggestion is just information about the user, and many companies assemble such profiles as part of their own commercial activities.

It's also true that the DNS is incredibly chatty. For example, to resolve a new name, such as **www.example.com**, a DNS resolver first asks the root name servers for the IP address of **www.example.com**. The root name servers would not be able to provide the answer, but they will respond with the authoritative name servers for the **.com** domain.

The resolver will then repeat this query relating to the IP address of the name `www.example.com`. to a `.com` name server, and once more the answer is an indirect one, indicating that while it does not know the answer, the list of name servers for the domain `example.com` should be queried. At this point the resolver can repeat the same query to a server that is authoritative for the `example.com` domain and probably receive an answer that contains the address of `www.example.com`.

But let's think about these DNS queries for a second. In this case, a root server, a `.com` server, and an `example.com` server are all now aware that I am "interested" in `www.example.com`, and they probably have stored a log of these queries. I have no idea if these logs are private or public. I have no idea how they are analyzed, and what inferences are drawn from this data.

It's possible that the data leakage is a little worse than described, because the application I am using, such as a browser, normally does not perform DNS name resolution itself. It passes the query to the platform operating system via a `gethostbyname()` call. The operating system platform also has an opportunity to log this query. The platform normally does not operate a standalone DNS resolver, and often is configured by the local network provider with DNS resolvers to use. So, my service provider may also be privy to all my DNS activity. But it need not stop there. My service provider might farm out its queries to a recursive forwarder, so that it can avoid the overheads of running a full DNS resolver.

Normally such forms of query indirection imply a loss of attribution, as such forwarded queries do not have any of my identifying details. Unless of course the resolver uses the *EDNS0 Client Subnet Option*^[1], in which case the forwarded queries still contain some critical details of my network, and, by inference, me as well.

All of these DNS queries can represent a lot of information, even in these days of data intensity. Back in April 2015 Google reported that its public DNS servers deliver some 400 billion responses per day^[2], and it appears that Google resolves some 12% of the total DNS load^[3], so there were some 3 trillion DNS queries per day at that time. It can only be larger today.

Not only is the DNS a chatty protocol that gratuitously sprays out information about user behaviours, it does so in an entirely open manner. DNS queries and their responses are unencrypted, and are sitting on port 53 in *User Datagram Protocol* (UDP) and *Transmission Control Protocol* (TCP). Because they are open and unencrypted, DNS queries can be easy to intercept, and, if *Domain Name System Security Extensions* (DNSSEC) is not used, false responses can be inserted back into the data stream, and the client may be none the wiser. In some countries, DNS substitution appears to be relatively commonplace^[4].

Other countries have turned to DNS interception and blocking in response to problems associated with overloading IP addresses with virtual web hosting^[5]. Little wonder that many users have tried to get around these local efforts to block access by using a third-party DNS resolver, and the use of Google's Public DNS resolver is a common response to such local efforts to interfere in the DNS. Indeed, so common is this response that now the local DNS blocking measures appear to include intercepting access to Google's DNS service as well!^[6]

DNS privacy has been a matter of some interest to the *Internet Engineering Task Force* (IETF), and changes are being proposed to the DNS protocol that would make it far harder to be used as a snooper's and censor's tool of choice.

What is going on to improve this situation and introduce aspects of privacy into the DNS?

QNAME Minimisation

The IETF *DNS Operations* Working Group has been performing what has been called query name minimisation in the DNS, resulting in a specification for *QNAME Minimisation*.^[7] To quote from this document: "QNAME minimisation follows the principle [that] the less data you send out, the fewer privacy problems you have."

In the previous example, the query to the root servers for the A record for **www.example.com** has two elements of gratuitous information: the fully qualified domain name and the query type. A more targeted query that does not gratuitously leak extraneous information is a query directed to the root name servers for the name server records for the **.com** domain. Similarly, the **.com** name servers would be queried simply for the name servers of **example.com** and so on (see Figure 1).

In general, this approach is no less efficient than using a full query name at every point, and is equally capable of using cached information. The technique has exposed some inconsistencies with the handling of so-called *empty nonterminal* domain names, but the approach can be implemented in a robust manner, and it is a solid step in plugging a gratuitous information leak. It appears that the recently announced Knot DNS resolver from the Czech domain provider CZ.NIC is one of the first DNS resolvers to implement QNAME Minimisation (<https://www.knot-resolver.cz>).

Figure 1: The Intended Operation of QNAME Minimisation

DNS and TLS

However, QNAME Minimisation is only part of the privacy story. The open nature of DNS queries makes third-party monitoring, interception, and substitution incredibly easy, it appears. The *DNS PRIVate Exchange* (DPRIVE) Working Group of the IETF has been working on this topic, looking at ways for the DNS query and response interaction between a DNS client and a DNS resolver to be protected in some manner.

There are two parts to this work. Firstly, to ensure that the response you receive is a response from the DNS resolver that you intended to ask, and secondly, to ensure that the query you pass to your DNS resolver is not readily readable by anyone other than the addressed DNS resolver.

One issue here is whether to try to secure the current UDP-based resolution protocol, or head to a TCP-based approach where solutions already abound, typically based on *Transport Layer Security* (TLS). TLS encrypts the conversation between a client and a server using session keys that are generated based on random seed values coupled with public/private key pairs. If you have a way of associating a service name (such as its DNS name) with a public key (as would be the case with a conventional DNS Name public key certificate), and a way of validating that key (using conventional name certificate validation), then you can achieve both of these objectives. The remote server has demonstrated to you that it has knowledge of the private key associated with the DNS name of the service, which is theoretically known only to the server and no one else.

By encrypting your session with a session key that is based in part on this private key, the content of the data exchange should be protected from onlookers and potential interceptors in a man-in-the-middle attack.

But there is a problem here in terms of the transport protocol of choice. TLS conventionally requires a reliable transport channel, such as provided by TCP, and as such cannot be used directly to secure datagram traffic as used by UDP. However, the DNS has been heavily reliant on the use of UDP as a means of supporting speed and scalability in the DNS. So, from some perspectives, DNS-over-TLS-over-TCP is not seen as the optimal response to the problem. TCP attempts to ensure sequenced delivery, and in a message-oriented application, the loss of a message in TCP holds up the delivery of all subsequent messages until TCP can correct the data loss and deliver the lost message. This TCP “head-of-line blocking” can pose unacceptable overheads when using TCP to carry the datagram-like message payloads of the DNS. DNS over *Internet Protocol Security* (IPsec) could be seen as offering a cleaner fit when looking at securing a UDP-based application, but IPsec is a kernel function rather than an application module, and its semantics apply at the IP layer rather than as an attribute of the transport protocol. This reality makes it challenging to incorporate IPsec into an application and operate the cryptographic functions in user space, as happens with DNS name resolution.

One of the consequent investigations has been to see if the functionality of TLS could be mapped into a datagram transport environment. Out of this consideration has come a new protocol, *Datagram Transport Layer Security* (DTLS), which is an adaptation of the TLS function that can present to the application a datagram-like delivery function that does not require reliable transport services. DTLS is intended to be able to recover from packet loss and reordering, but it would be intolerant of UDP packet fragmentation^[8]. Its design is modelled upon TLS 1.2 and intends to use some explicit additional features that allow TLS to function over a datagram transport as distinct from a reliable stream transport. DTLS intends to minimise the impact of the use of TLS on the DNS experience, particularly when compared to DNS-over-TLS-over-TCP. The major change envisaged would be to require an initial DTLS handshake to set up a shared encryption state, and the use of cookies to reuse that state across multiple individual response/query interactions.

One of the main features of the current DNS protocol when used over UDP is how little shared state overhead each individual transaction incurs, resulting in a highly responsive and capable service. DNS over DTLS attempts, as far as possible, to preserve this simple query/response datagram exchange model but does so in a manner where the client is using an encryption based on the validated credentials offered by the server. The current state of play of this specification is described in an Internet Draft working document.^[9]

DTLS is intolerant of IP fragmentation, so the operation of DNS over DTLS is similar in design to the use of the *Truncated* bit in DNS over UDP as a signal to the client to repeat the query using TCP. Here the intended operation is that if a DNS-over-DTLS server has a response that is greater than the local Path *Maximum Transmission Unit* (MTU) estimate, then the server should set the Truncated bit in its response, and this response is to be interpreted by the client as a signal that the client should repeat the query using DNS-over-TLS-over-TCP, in a manner analogous to the current use of the Truncated bit to signal to a client to repeat the query using TCP rather than UDP. However, it needs to be noted that at this point DTLS remains a design exercise, and it may be some time before implementations of this specification are available for general use by end-user DNS libraries, recursive resolvers, and servers.

The other option here is to absorb the TCP overheads into the solution and just use conventional TLS, which is a TCP service. Much has been said on the use of TCP as a mainstream transport protocol for DNS, as distinct from its current intended role as a backup to UDP for large responses. It has been argued that the TCP connection state overheads of the servers seriously impair their ability to handle large query loads, and the additional overhead of the protocol handshake would negatively affect the user experience. On the other hand, it is argued that already the web is being used overwhelmingly as a short transaction service, and web servers appear to withstand the imposed load. It is also noted that the use of TCP is an effective measure against various forms of abuse that rely upon the ability to perform source address spoofing in UDP.

The specification for *DNS over Transport Layer Security*^[10] is a relatively straightforward description, in that the transport service offered by TLS is effectively the same as that offered by TCP, but running the listener of the server at TCP port 853, rather than port 443. There is perhaps one change here, and that is a suggestion for TLS session reuse: “In order to minimize latency, clients SHOULD pipeline multiple queries over a [single] TLS session.” For transactions between a client and a recursive resolver, the suggestion for session reuse makes some sense. For transactions between a client and authoritative name servers where the client is itself performing DNS resolution, this choice may not be so readily achievable. The choice of a distinguished TCP port is also interesting. If you wanted the secure channel DNS traffic to merge into all other traffic and pose a challenge to attempts to block this service, the temptation to use port 443 for DNS over TLS would be overwhelming (at least for me!). More information on the current state of clients and servers that support DNS over TLS can be found at:

<https://portal.sinodun.com/wiki/display/TDNS>.

Secure DNS over JSON

Last, but not least, there is the option to use an entirely different data encoding protocol, and here a recently announced service from Google is relevant. The server at <https://dns.google.com> performs a resolution function over TLS using port 443 with the results passed back as a *JavaScript Object Notation* (JSON) data structure. This function can readily be transformed into an alternative form of *gethostbyname()* by the application's substituting a web object retrieval for a conventional DNS query. This substitution offers the caller some level of privacy from third-party inspection and potential intrusion and censorship, although it's unclear precisely what "privacy" means when you are sharing your DNS activity with Google!

Example script:

```
#!/usr/bin/env python
import json, requests

url = "https://dns.google.com/resolve"
params = dict(
    name='www.potaroo.net',
    type='A',
    dnssec='true'
)

resp = requests.get(url=url, params=params)
data = json.loads(resp.text)
print data[u'Answer'][0][u'data']
```

Application-Level DNS

Concerns about data leakage is not limited to external forms of surveillance and interception. An appropriately paranoid application would not use the DNS resolution service of the underlying host platform, because that would release the name queries of the application into an uncontrolled environment where it may be logged and accessed by the platform and other applications.

One response to this potential for uncontrolled leakage of information is for the application to assume a greater role in performing DNS resolution. The simple approach is for the application to outsource this role to a trusted agent, and do so over a secured channel, which is where secure DNS over JSON comes in. In this case, the application is not performing DNS resolution and validation itself, but in creating a secured channel to Google's resolution service across a TLS connection the application can obtain some level of assurance that it is not performing a local leak of DNS information, and that with DNSSEC validation enabled, the responses it receives have some level of assurance that they are genuine, assuming that the name being resolved is itself DNSSEC-signed.

But perhaps even that is too much outsourced trust. Another approach is being constructed by the *GetDNS* project.^[11] In this case, it's not a secure channel to a recursive resolver that will resolve the application queries. GetDNS provides the application with a local validating resolver as a set of library calls. This project currently supports DNS over TLS. The GetDNS project operates as an open source project, and the GetDNS project page contains pointers to the code. A web application is built into the API, and a portal to a resolver implemented in this manner can be found at:

`https://getdnsapi.net/query`

This approach of pulling the DNS resolution function potentially all the way back into the application has some interesting trade-offs. The queries being made now have a source address of the local host, so the data that is leaked through the DNS queries can identify the local host. If an authoritative name server does not support a secure channel for queries using DNS over TLS, then the API will necessarily use an open unencrypted channel (at this stage the DNS over DTLS is not included in the GetDNS code base, but if someone wants to submit code ...).

On the other hand, the DNSSEC validation function can be performed locally as well by a GetDNS instance, so that the application is not forced to trust the authenticity of a bit flag in the response from a remote resolver. This way the application has direct control of the validation function, and direct knowledge of its outcome.

Between these two approaches there are further apparent trade-offs.

Making queries via a secure channel to a busy recursive resolver—and Google's Public DNS is about as busy as a DNS resolver can be—means that it is possible, to some extent, to hide behind the cache of such busy resolvers. As long as you are comfortable with sharing your DNS queries with Google, then to some extent you can use secured access to a DNS recursive resolver that intends to operate with integrity, accuracy, and completeness. The secure channel is far harder to subvert and more resistant to efforts to eavesdrop on the query stream.

If you are uncomfortable with this approach, then another option is to pull the name resolution function back into your platform and even back into the application itself using a framework such as GetDNS. The extent to which your queries may be readily visible to third parties, and the extent to which your query stream may be subverted in various ways, now depends on the capabilities of the authoritative name servers. Without name server support for DNS over TLS and possibly also potential future support for DNS over DTLS, and without DNSSEC signed zones, the local DNS resolver may still be misled in ways that may not be readily detected.

In this case, the local resolver is powerless to fix this problem, because the privacy and protection mechanisms are now in the hands of the authoritative name servers and the zone admins that are queried by the local resolver.

With DNS privacy, there is no such thing as a free lunch! But maybe in QNAME Minimisation there is the possibility of a much cheaper lunch. The queries are much the same as before, but the impact is that the query name is only progressively revealed to the name servers that are authoritative for the domain being queried.

However, an equal cause for concern is that the queries and responses are open and susceptible to eavesdropping. Here the lunch is definitely more expensive! The measures to introduce a secure channel for DNS queries and responses take a simple open query/response stateless protocol and introduce state by way of session establishment and crypto state establishment. The overheads of such additional state can be many packets and the imposition of additional Round Trip Time intervals. It is also true that no DNS privacy solution is absolute in these frameworks. While it is possible to set up a secure and encrypted channel to a recursive resolver, the implication is that the recursive resolver is privy to the query stream, even if the local network infrastructure cannot directly eavesdrop on the queries.

Alternatively, the user application can operate as a resolver itself, and attempt to direct queries to authoritative servers over a secured channel, but the authoritative servers now have visibility on your identity, and they also have to cope with a dramatic change in the query load. The authoritative name server would no longer be able to rely on recursive resolvers to absorb many of the queries, so they would presumably be exposed to a far larger query load. In addition, they would need to maintain a significant state overhead to support secured channels to these end application-based name resolvers. This really does not look like a likely scenario. As a result, it appears, at least for the moment, that this work on secured transport channels is likely to be a measure used between end-user applications and recursive resolvers.

What Does All This Mean?

While today the open nature of DNS queries makes third-party monitoring, interception, and substitution incredibly easy, there are now some grounds to be optimistic and start to contemplate a DNS environment that preserves privacy and integrity.

By performing QNAME Minimisation it is possible to radically reduce the level of leaked information coming from the DNS, and by wrapping up DNS queries and responses in a secured channel it is no longer trivial for third parties to monitor and intercept DNS queries and their responses on the wire.

If applications made use of services that push local DNS query traffic into encrypted TLS sessions with recursive resolvers, such as the service Google offers, the result would be that much of today's visible DNS would disappear from view. Not only that, but it would make the existing practices of selective local inspection and intervention in the DNS resolution process far more challenging, if not infeasible. It may be even better if authoritative name servers were to also support queries over TLS and DTLS, allowing a local host to take over the resolution function and still use encrypted query traffic services.

If this scenario were to be coupled with widespread use of DNSSEC, then it would be a somewhat different Internet from the one we have today. It's pretty obvious that national online censorship efforts will continue, and online monitoring and surveillance will also continue. But the ability to coopt the DNS into the role of an exceptionally cheap and simple means to achieve these ends will cease at some time if we collectively choose to head down this path for adding privacy and security to the DNS.

GEOFF HUSTON, B.Sc., M.Sc., is the Chief Scientist at APNIC, the Regional Internet Registry serving the Asia Pacific region. He has been closely involved with the development of the Internet for many years, particularly within Australia, where he was responsible for building the Internet within the Australian academic and research sector in the early 1990s. He is author of numerous Internet-related books, and was a member of the Internet Architecture Board from 1999 until 2005. He served on the Board of Trustees of the Internet Society from 1992 until 2001. At various times Geoff has worked as an Internet researcher, an ISP systems architect, and a network operator. E-mail: **gih@apnic.net**

JOAO LUIS SILVA DAMAS is currently Senior Researcher at APNIC. Joao was also co-founder of Hivecast Inc, a DNS services company later sold to Dyn. Previously he worked at ISC (Internet Systems Consortium) as CTO overseeing technical developments. Earlier, he served as CTO at RIPE NCC and later founded Bond Internet Systems as a consulting and research company. For around 7 years he organised the RIPE plenary program and launched the current RIPE program committee. In 2008, together with colleagues, Joao launched ESN OG to bring together Spanish ISPs to interact with each other, an activity that continues to this day. E-mail: **joao@bondis.org**

ICANN Launches Testing Platform for the KSK Rollover

The *Internet Corporation for Assigned Names and Numbers* (ICANN) is offering a testing platform for network operators and other interested parties to confirm that their systems can handle the automated update process for the upcoming *Root Zone Domain Name Systems Security Extensions* (DNSSEC) *Key Signing Key* (KSK) rollover^[1, 2]. The KSK rollover is currently scheduled for October 11, 2017.

“Currently, seven hundred and fifty million people are using DNSSEC-validating resolvers that could be affected by the KSK rollover,” said ICANN’s Vice President of Research, Matt Larson. “The testing platform is an easy way for operators to confirm that their infrastructure supports the ability to handle the rollover without manual intervention.”

Internet service providers, network operators and others who have enabled DNSSEC validation must update their systems with the new KSK. This can be done in one of two ways:

- An operator can configure a new trust anchor *manually* by obtaining the new root zone KSK from the *Internet Assigned Numbers Authority* (IANA) website at:
<https://www.iana.org/dnssec/files>
- An operator can enable a feature available in many validating resolvers that *automatically* detects and configures a new root zone KSK as a trust anchor, in which case they need take no action.

Check to see if your systems are ready by visiting:
go.icann.org/KSKtest

The KSK has been widely distributed and configured by every operator performing DNSSEC validation. If the validating resolvers using DNSSEC do not have the new key when the KSK is rolled, end users relying on those resolvers will encounter errors and be unable to access the Internet. A careful and coordinated effort is required to ensure that the update does not interfere with normal operations.

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

Every day we seem to read another news story about some form of *cyber attack*, be that Denial of Service incidents, ransom ware, malware, website intrusions, compromised databases, so-called *phishing*, leaked e-mails, election hacking, and much more. The underlying opportunities for such attacks are varied, ranging from human factors like easy-to-guess passwords to poorly designed and insecure technologies, as we have discussed many times in this journal. As you might expect, making the Internet more secure and robust involves numerous efforts at every layer of the protocol stack.

Encryption is a time-tested method for securing end-to-end communication as well as for storing information in a manner that prevents unauthorized access. Encryption is also used in the generation of trusted *certificates* for secure web communication. In our first article, Daniel McCarney presents an overview of the *Automatic Certificate Management Environment* (ACME).

The *Domain Name System* (DNS) is one of the core components of the Internet. We have covered many aspects of the DNS over the years, but not looked closely at the *root server system* until now. Geoff Huston describes the history and evolution of the DNS and its root servers.

As announced in the previous edition of IPJ, the *Latin America and Caribbean Network Information Centre* (LACNIC) has agreed to translate selective articles from IPJ and provide summaries in Spanish. This service is now available at: <http://lacnic.net/ipjournal>

If you have a print subscription to this journal, you will find an expiration date printed on the back cover. For the last couple of years, we have “auto-renewed” your subscription, but starting with this issue, we ask you to log in to our subscription system and perform this simple task yourself. You should receive an e-mail with instructions for how to access this system. When logged in, you can update your mail and e-mail address and change your delivery options. For any questions, e-mail us at ipj@protocoljournal.org

A Tour of the Automatic Certificate Management Environment (ACME)

by Daniel McCarney, Internet Security Research Group

The introduction of *Let's Encrypt* has helped bolster *HyperText Transport Protocol Secure* (HTTPS) adoption by providing an easy-to-use and fully automated process for getting a trusted certificate for a domain name, all free of cost. Let's Encrypt is a service provided by the *Internet Security Research Group* (ISRG), a nonprofit organization with a mission to reduce financial, technological, and education barriers to secure communication over the Internet. To date, Let's Encrypt has issued certificates for more than 30 million websites.

Prior to Let's Encrypt, acquiring a certificate for a website was a difficult and error-prone process requiring frequent Google searches for obscure command-line incantations. Worse yet, this process typically had to be repeated manually with large periods of time elapsed between attempts—a recipe for disaster. One solution to both the usability and reliability issues created by placing this manual burden on a human is to augment the process with automation. A computer program will dutifully repeat complicated series of instructions at fixed intervals without missing a beat.

Frequently the methods of domain validation used by a certificate authority were difficult to automate at all (for example, e-mail-based validation) or required locking yourself in to a specific provider's *Application Program Interface* (API). Unlocking interoperable automation is critical to alleviating the burden on system administrators, promoting greater ease of use and helping create a fully encrypted web. Acknowledging this need for automation has been a core focus of Let's Encrypt from the very earliest days. The progress that Let's Encrypt has made in this area helps validate the premise that automation helps scale usage and has been reflected in the overall increase in HTTPS adoption observed by Mozilla Firefox telemetry, see Figure 1^[0].

Figure 1: Let's Encrypt Statistics

While much has been said about Let's Encrypt and the choice to provide the service free of cost, less attention has been directed at the work underpinning the automation aspect. Underneath the service provided by Let's Encrypt is hidden a larger effort to bring a secure, automated *Internet Engineering Task Force* (IETF) standardized protocol for certificate issuance. This protocol, called the *Automatic Certificate Management Environment* (ACME) protocol, is a multi-organizational standards effort currently in IETF Working Group *Last Call*. This article briefly describes the core aspects of ACME and some of the ecosystem that surrounds it.

ACME

In the context of IETF *Request for Comments* (RFC) documents, ACME is unfinished. To date the ACME Working Group has published six drafts as the standard has received external feedback, and lessons from Let's Encrypt have been folded back into the overall design. It is currently in a phase of development where no new major changes are expected and the primary work remaining is editorial and interoperability-related.

This article focuses on ACME as defined in **draft-07**^[1], the most current draft at the time of writing. As outlined in the next section, this focus means that our discussion of ACME will not perfectly match the Let's Encrypt service, which most closely resembles Version 3 (**draft-03**) of the draft specification for the moment while updates to the newer drafts are implemented.

The ACME Ecosystem

While ACME is a new protocol that is not yet standardized as an RFC, it already exists within an ecosystem of client and server implementations.

On the server side, Let's Encrypt has contributed an open source ACME implementation called *Boulder*^[2]. It's written in Go and as the production backend for the service provided by Let's Encrypt it is the most "battle-tested" ACME server codebase to date. At peak so far Let's Encrypt and the Boulder codebase have issued more than 1.2 million certificates in a single day. Internally Boulder is divided into subcomponents, each responsible for a portion of the responsibilities of a *Certificate Authority* (CA). Notable components include the CA, the *Validation Authority*, the *Registration Authority*, and the *Web Front End*. Components "talk" to each other using a universal *Remote Procedure Call* (RPC) framework called gRPC.

Boulder has evolved alongside the draft ACME protocol and so necessarily has some divergences where specification moved faster than implementation or vice versa. The Boulder developers document these divergences in the Boulder repository^[3] and adjust the codebase as the bounds of backwards compatibility with existing ACME clients allow. Since many ACME clients specifically target compatibility with Let's Encrypt and the Boulder implementation of ACME, most existing ACME clients will share these protocol divergences.

Our work to implement **draft-07**^[1] fully is not yet complete at the time of writing, but is expected to be available by the end of 2017 as a separate API endpoint to ease migration from older clients using the existing (largely **draft-03**-based) API.

One of the benefits of an open standard is the ease with which clients can be written to interact with Let's Encrypt and issue certificates. Better yet, if other CAs adopt ACME, these clients will be able to interact with those CAs with minimal modification. A plethora of clients have been written since the launch of Let's Encrypt targeting a variety of platforms, programming languages, and use cases. Whether you're looking to issue a single certificate from an embedded device or thousands of certificates on-demand for a large platform integration, an ACME client is available for your needs.

Most well-known of these clients is *Certbot*^[4]. Formerly known as the *letsencrypt* client, Certbot development has since been taken over by the *Electronic Frontier Foundation* (EFF) under its new name. As the first ACME client built for use with Let's Encrypt and the Boulder ACME server, it is still thought of as a reference client for Let's Encrypt. Certbot is an end-to-end solution capable of performing as much of the complicated administrative work as possible that is required to request, issue, and install a certificate for an HTTPS webserver.

Domain Validation

Let's Encrypt and the ACME protocol are both focused on *Domain Validated* (DV) certificates. *Organization Validated* (OV) and *Extended Validation* (EV) certificates are outside of the current scope of both the protocol and this article. OV and EV certificates require verification procedures that would be difficult if not impossible to automate programmatically. Unlike OV and EV certificates, a DV certificate does not attest identity but that the possessor of the private key corresponding to the public key in the certificate has demonstrated control of the domain names the certificate includes. The attestation from the CA that validated the domain control means you can be sure that your authenticated and encrypted *Transport Layer Security* (TLS) connection to the remote server is to a party in control of the domain name and not a *Man in the Middle* (MITM). It is important to know that this attestation does not vet anything about the trustworthiness of the domain owner.

Historically the technical method of domain validation that a CA employed was largely left to its own discretion and fairly ad-hoc. One method was to e-mail a token or activation link to an e-mail address believed to be authoritative for a given domain to prove ownership for an issuance request. The question of which addresses should be authoritative is the crux of this validation method, and mistakes in this decision process have led to certificates being issued to unauthorized parties in the past^[5].

Other popular methods involved generating a token to be placed in a well-known location in the HTTP webroot of the domain, or in a *Domain Name System* (DNS) record for the domain. Recent changes in the baseline requirements^[6] that CAs must meet have standardized the acceptable methods for domain validation and added some guardrails against mis-issuance.

Much of ACME directly addresses the domain validation process. This fact might be surprising if you were expecting to find a great deal of complicated cryptography related to the issuance of certificates themselves. Automating the act of issuing a certificate for a set of names is not the true challenge to scaling the web *Public Key Infrastructure* (PKI). The task of turning certificate signing requests into certificates with a software pipeline is well-understood. The larger challenge that must be addressed is how to scale the determination of whether the party requesting the certificate is authorized to act on behalf of all of the names the certificate includes. This contribution is one of the crucial ones of the ACME protocol: the introduction of clearly specified and peer-reviewed domain validation methods.

ACME Requests

All ACME requests are made over HTTPS. Protocol messages are primarily POSTed to HTTPS endpoints as *JavaScript Object Notation* (JSON) data. The JSON request data is authenticated and provided integrity through the application of *JSON Web Signatures* (JWS), as described in RFC 7515^[10]. GET requests do not have a JWS body and are not authenticated by the ACME account key; therefore only public resources are available via GET.

To provide anti-replay protection, all ACME server responses provide a *nonce* header. The value of this header must be provided in the next request to the server. A dedicated *new-nonce* endpoint also exists to request a fresh nonce without performing a throw-away request only to look at the nonce reply header.

Since JWS will not cover the *Uniform Resource Identifier* (URI) of an HTTPS request, the URI is also contained in all request bodies and must be verified by the server to ensure that an entity terminating the ACME HTTPS request (for example, a *Content Distribution Network* (CDN) or *Load Balancer*) did not modify the request URI from the one intended to be used by the client contained in the authenticated request body. The ACME draft threat model section covers these considerations with more detail.

Components of ACME

ACME was designed to be a *Representational State Transfer* (REST)ful protocol, so one way to approach understanding it is by examining the resources the protocol specifies. At its core ACME is made up of *Accounts*, *Orders*, *Authorizations*, and *Challenges*.

At a high level, issuing a certificate is a matter of creating an ACME account, submitting an order for a certificate containing a set of DNS identifiers, satisfying authorizations for each of the identifiers by solving challenges, and finally, polling the ACME server until a signed certificate satisfying the order is produced.

A special directory resource serves as the entry point for the account creation and certificate issuance flows of the ACME protocol. ACME clients identify servers by their directory URI and make an initial request to this resource in order to learn the URIs used for other resources and to get a first nonce value. The directory also contains metadata related to the ACME server (for example, terms of service requirements, *Certification Authority Authorization* (CAA) identifiers, etc.).

An example of Let's Encrypt's current `/directory` endpoint, as generated by Boulder, follows:

```
curl https://acme-v01.api.letsencrypt.org/directory
{
  "key-change": "https://acme-v01.api.letsencrypt.org/acme/key-change",
  "new-authz": "https://acme-v01.api.letsencrypt.org/acme/new-authz",
  "new-cert": "https://acme-v01.api.letsencrypt.org/acme/new-cert",
  "new-reg": "https://acme-v01.api.letsencrypt.org/acme/new-reg",
  "revoke-cert": "https://acme-v01.api.letsencrypt.org/acme/revoke-cert"
}
```

Accounts

The account resource is a container for information about a user and that user's account with the ACME server. Most importantly, an account contains a public key encoded as a *JSON Web Key* (JWK)^[11]. This public key is associated with the account at the time of account creation and is used to authenticate future requests. Like the other resources we'll see, an account is identified by its URI per usual REST practice. Account resources also contain additional metadata such as an e-mail address to contact for the account and whether a required Terms of Service Agreement has been acknowledged. In the earlier stages of the ACME draft accounts were called *registrations*, and you may still see references using this term in older material.

Accounts are created by POSTing an account resource to the new-account resource of the ACME server. Future updates (for example, to update contact information) are handled in a similar fashion. Notably you cannot view your current account information by sending a GET request to the account URI; instead you must use a POST request with an empty body. The rationale for this decision is rooted in the security model of the protocol. Only POST requests carry the required JWS to authenticate the request as coming from the account owner. If you use a JWS signed empty body in a POST request to retrieve account information, only the authorized account can view contact information.

An example POST body for a new account follows:

```
{
  "terms-of-service-agreed": true,
  "key": "...",
  "contact": [
    "mailto:example@example.com",
  ]
}
```

Orders

Orders encapsulate the request of an account for a certificate to be issued by the ACME server. The most important field of an order object is the *Certificate Signing Request* (CSR). You might be familiar with non-ACME CAs; the ACME CSR is a standard RFC 2986^[12] CSR, meaning existing tools (for example, *openssl*) can generate CSRs for use with ACME. For use within an Order the CSR is base64url-encoded, a practice used elsewhere in the protocol when binary data needs to be represented in a request.

The other important field of an Order object is the Authorizations field, containing an array of Authorization URIs. The ACME server is responsible for populating this field in the Order object returned to the client when a new order is created. Completing an order to obtain a certificate requires first completing each of the authorizations the order links to.

An example of a request body to create a new order for two DNS identifiers would resemble the following:

```
{
  "csr": "MIICmTCCAYECAQAw....cUc5i8XK-OBEMe",
}
```

Resulting in:

```
{
  "status": "pending",
  "expires": "2017-03-14T12:41:37-04:00",
  "csr": "MIICmTCCAYECAQAw....cUc5i8XK-OBEMe",
  "authorizations": [
    "/authZ/k4jO5648Y-qqrQ_F-bD6JLgtrfV4TJb6vef9GrlybvQ",
    "/authZ/c71yuTUHsuwIVeCk9B4DrsFA1MlCZMLtt4FDZ71KI20"
  ]
}
```

Presently, as described in the Boulder divergences document, Let's Encrypt does not implement the order resource. Instead clients must explicitly create authorization objects for each of the domains they wish to issue for themselves using the *new-authz* endpoint, as opposed to creating an order and receiving the URI of authorizations required from the server.

Authorizations

Authorizations are the core of the domain validation process in ACME. For an account to receive a certificate valid for an identifier, the CA needs to verify control of that identifier. If control is established, then the account is said to be authorized to request a certificate valid for the domain. In ACME an authorization starts its life in a *pending* status, indicating that the account has not yet completed the authorization process. In order to progress from the pending state to a *valid* state, the account holder must complete a set of required challenges. Authorizations also contain an expiry date, and both pending and valid authorizations fall out of usefulness after their expiry date. In the case of pending authorizations, this requirement keeps the challenges fresh. In the case of valid authorizations, it means that control must be reestablished through a fresh authorization and new challenges if the expiry has passed.

An example authorization follows:

```
{
  "status": "pending",
  "identifier": {
    "type": "dns",
    "value": "www.example.com"
  },
  "challenges": [
    {
      "type": "dns-01",
      "token": "T50nPYe3YNdKeqlqaelegDVftLpqG5D8klP_K7inCHY",
      "status": "pending",
      "error": {}
    }
  ],
  "expires": "2017-03-14T12:41:37-04:00"
}
```

Challenges

One or more challenges are embedded directly into authorizations and are identified by a type and a URI. Solving a challenge of an authorization will demonstrate the ACME account key holder's control over the identifier the authorization refers to, allowing issuance for that identifier. Each challenge type has its own method for demonstrating control, but all share the use of a random *token* and a key authorization.

The token is a random value used to identify the challenge. The token is always expressed in the *base64url* alphabet used throughout ACME, and to facilitate the usage in various challenge types it must not contain any padding characters.

The challenge key authorization is used to concretely link a specified ACME account key with the challenge for the purpose of validating an identifier. It is created by concatenating the random token present in the challenge and the Base64 URL encoding of the JWK thumbprint of the ACME account. The key authorization is provided in the subsequent JWS signed request from the ACME client to update a challenge, asking the server to attempt to verify control by performing the challenge verification process as required by the challenge type.

An example challenge follows:

```
{
  "type": "dns-01",
  "token": "T50nPYe3YNdKeqlgaelegDVftLpqG5D8klP_K7inCHY",
  "status": "pending",
  "error": {}
}
```

Getting a Certificate

After challenges have been completed successfully for each of the authorizations embedded in an order resource, the order is considered valid and the certificate can be issued. The ACME server proactively monitors order resources, and when an order is ready to be issued, it is responsible for issuing a certificate matching the domains from the CSR/authorizations. The order resource is then updated with a URI at which the client can download the issued certificate. After a client completes all of the authorizations the order requires, a polling state can be entered so the certificate URI can be added to the order to allow fetching the produced certificate.

Presently, as described in the Boulder divergences document, Let's Encrypt does not implement the order resource, so the issuance process is slightly different. Instead, clients must explicitly create authorization objects for each of the domains they wish to issue for themselves using the *new-authz* endpoint. After the authorizations are validated by completing challenges, the client can submit a CSR to the *new-cert* endpoint and will receive a certificate as a response provided the server is able to validate that the correct unexpired authorizations are in place.

Challenge Types

The ACME standard defines four distinct challenge types, each identified by the draft that it was introduced in: HTTP-01, DNS-01, TLS-SNI-01, and TLS-SNI-02. An additional *Out-of-Band* (OOB) challenge exists for integration with existing CAs. Let's Encrypt and Boulder presently do not implement TLS-SNI-02 or the OOB challenges.

HTTP-01 Challenges

The HTTP-01 challenge allows authenticating a domain by making an externally visible change to the domain website. The primary idea is that the ACME client must sign the requested key authorization and place the result in a pre-specified location in the domain webroot. The name of the file is the token value from the challenge, and the contents of the file will be the same computed key authorization that is included in the JWS signed POST body asking the server to validate the challenge.

For ACME, the pre-specified location for the challenge file is in `/.well-known/acme-challenge/`, a prefix registered with the *Internet Assigned Numbers Authority* (IANA) for the purpose of ACME domain validation. When the challenge is POSTed by the ACME client with the correct key authorization, the ACME server will make a GET request to this location on the domain referenced in the challenge authorization. Using the HTTP response, the server can validate the contents of the HTTP challenge file. If the correct key authorization was present at the correct location and signed by the correct ACME account key, then the challenge is completed and the account is considered to possess a valid authorization for this domain until the point at which it expires. Both the challenge and authorization objects are updated server side with a valid status and an expiry date.

The HTTP-01 challenge is a great fit if you are already running a world-accessible webserver on port 80 of your domains. Since the challenge requests are standard HTTP requests and will always be directed to a well-known path prefix, it is possible to implement more complex validation systems with ease. For instance, you could use the URL rewriting capabilities of a webserver to divert HTTP-01 challenge requests to a centralized server responsible for Let's Encrypt challenge validation. Many ACME clients (Certbot included) can start up a standalone HTTP server explicitly for the purpose of solving HTTP-01 challenges; this feature may be beneficial for issuing certificates for non-HTTPS services like the *Extensible Messaging and Presence Protocol* (XMPP) without needing to configure a heavyweight HTTP server.

DNS-01 Challenges

The DNS-01 challenge is conceptually similar to the HTTP-01 challenge but instead of provisioning a file at a well-known location the challenge responder provisions a TXT record at a well-known label.

For ACME, the required record is a TXT record for the label `_acme-challenge.` concatenated onto the domain being authorized. Rather than placing the entire key authorization as the value of this TXT record, the DNS-01 challenge asks that a SHA256 digest of the computed key authorization be used as the TXT record value.

When the ACME client POSTs the challenge with the JWS signed key authorization, the ACME server will verify the details of the key authorization and token match, and proceed to validate the TXT record by issuing a DNS query against one of the authoritative DNS servers for the domain being authorized. If the contents of that TXT record match the expectation of the server of the SHA256 of the challenge key authorization, then the account is considered to possess a valid authorization for this domain.

The DNS-01 challenge is often used in situations where ports 80 and 443 are not globally accessible (for example, because of corporate firewall policies), ruling out the use of HTTP-01 and TLS-SNI-02 challenges. Since the DNS-01 challenge requires only that a TXT record be updated, there's no requirement for a direct connection to the domain name that a certificate is to be issued for. Instead the challenge is validated through a query to the authoritative nameservers. The DNS-01 challenge is also well-suited to centralized management of certificate issuance. Many DNS providers support programmatic updates through an API, or with more traditional dynamic DNS updates through *nsupdate*-like tools. Using an ACME client that exposes hooks for adding and removing the required TXT records makes it easy to centrally issue certificates by automatically adjusting DNS as required by the challenges. Certbot presently supports DNS-01 in a manual-only mode, but some other ACME clients have fully automatic support with a variety of DNS providers.

TLS-SNI-02 Challenges

The TLS-SNI-02 challenge is perhaps the most unfamiliar of the ACME challenge types. For this challenge type the requester must configure a TLS server accessible at the domain to be authorized such that it will use a special self-signed certificate when processing TLS requests with a specific *Server Name Indication* (SNI)^[14] value.

The ACME client creates the self-signed certificate when it wishes to use a TLS-SNI-02 challenge to authorize a domain. The contents of the certificate are unimportant except for one crucial detail: the certificate must have two special *Subject Alternate Name* (SAN) values.

The first SAN value is a domain of the form `x.y.token.acme.invalid`, where `x` and `y` are computed as the SHA256 digest of the challenge token value, split into two labels. The second SAN value is a domain `x.y.ka.acme.invalid`, where `x` and `y` are computed as the SHA256 digest of the key authorization, split into two labels.

The TLS server used for responding to the TLS-SNI-02 challenge should be configured such that it returns the crafted challenge certificate whenever a TLS request arrives with the SNI value of the first SAN (for example, `x.y.token.acme.invalid`).

When the ACME client POSTs the challenge to begin the validation process, the ACME server will compute both SAN entries the same way the client did, and will send a TLS request to the domain using a SNI value of the first computed SAN. The ACME server can then validate that the challenge server presents a self-signed certificate with the two required SAN values verifying the challenge token and the key authorization.

The TLS-SNI-02 challenge is a good fit for environments where a webserver is already configured for HTTPS and you do not want to accept HTTP requests for HTTP-01 challenges or place files in the webroot of the domains. Similar to HTTP-01, Certbot and some other ACME clients can run a standalone TLS server for the purpose of solving TLS-SNI-02 challenges in place without requiring a heavier-weight server. The TLS-SNI-02 challenge uniquely employs the mechanics of certificates and TLS in order to provide authorization for the issuance of certificates; this symmetry of process and result is unique and satisfying from the perspective of an interested engineer.

The astute reader will note that unlike HTTP-01 and DNS-01, the TLS-SNI-02 challenge is on its second revision. Let's Encrypt and the Boulder codebase still use the original TLS-SNI-01 challenge from earlier drafts, but it suffers from one design flaw whereby all of the information required to complete the challenge was present in the request. This situation allows for a broken design where a TLS-SNI-01 challenge response server could be built that automatically replies to a challenge request without *a priori* knowledge of the challenges. To combat this design and its unintended security implications, the TLS-SNI-02 challenge requires that the key authorization, which isn't part of the challenge request, be returned as part of the challenge response.

What's Next?

We've covered the core of the ACME protocol, but the existing drafts have a great deal more information. Readers are encouraged to investigate the key rollover and revocation features of ACME from the standard since they were not covered in this article. Similarly the draft content offers more in-depth coverage of security considerations that may be of interest to readers with the hacker mindset.

The ACME standardization process is still underway. The IETF Working Group has most recently published **draft-07** and is undergoing a last-call process for interoperability testing. Sometime after this point we can expect the ACME draft will proceed to full RFC standard status.

Plenty of work remains to upgrade existing ACME servers and clients to support the latest iterations of the draft since most of the ecosystem is presently implementing ACME closer to the **draft-03** standard. Let's Encrypt intends to support the newer draft and final RFC version as independent directory endpoints alongside the current legacy **draft-03** era endpoint. This support will allow clients to gradually adopt support for the newest protocol features while continuing to renew legacy certificates produced with the **draft-03** endpoint.

The ACME protocol itself has left room for future improvements. Work is underway to develop a companion document^[7] describing additions to the CAA standard, RFC 6844^[13], that would allow domain owners to specify policy related to acceptable ACME account keys or challenge types. This work could allow for, as an example, adoption of a policy whereby only DNS-01 challenges could be used to issue certificates for a given domain name using ACME.

Standardization on challenges for non-DNS identifiers—such as IP addresses—is also an avenue for future ACME work. ACME was designed to handle additional identifier types and new challenges, and it will be interesting to see how the protocol evolves to handle use cases beyond domain validation of DNS identifiers.

Development of an open standard helps move the Web towards a world where HTTPS encryption is the norm. Certificates from Let's Encrypt are one avenue available to system administrators looking to increase the security of their websites. Adoption of ACME by other CAs and tools ensures that the decision to use HTTPS doesn't induce vendor lock-in and allows users the chance to change providers without abandoning automation. The future of ACME is still being written, and it's not too late to participate in the IETF Working Group^[8]. Readers are encouraged to subscribe to the mailing list^[9] and provide feedback as they envision integrating ACME into their own software and environments.

DANIEL MCCARNEY is a developer for the *Internet Security Research Group* (ISRG), where he works full-time on *Boulder*, the server-side software powering the Let’s Encrypt certificate authority. Prior to the ISRG Daniel was a security architect for a large content delivery network and focused on TLS and application security. He has a Masters in Computer Science from Carleton University, where his research touched both Android system security and password managers. Daniel resides in Montréal, Canada, where he enjoys long snowy walks with his dog Bart. Daniel can be reached at: cpu@letsencrypt.org

The Root of the Domain Name System

by Geoff Huston, APNIC

Few parts of the *Domain Name System* (DNS) are filled with such levels of mythology as its *root server system*. In this article I will explain what it is all about and ask the question whether the system we have is still adequate, or if it's time to think about some further changes.

The namespace of the DNS is a hierarchically structured label space. Each label can have an arbitrary number of immediately descendant labels and only one immediate parent label. Domain names are expressed as an ordered sequence of labels in left-to-right order starting at the terminal label and then enumerating each successive parent label until the root label is reached. In domain name expressions, the ASCII period character denotes a label delimiter. *Fully Qualified Domain Names* (FQDNs) are names that express a label sequence from the terminal label through to the apex (or *root*) label. In FQDNs this root is expressed as a trailing period character at the end of the label sequence. But there is a little more than that, and that's where the hierarchal structure comes in. The sequence of labels, as read from right to left, describes a series of name delegations in the DNS. If we take an example DNS name, such as `www.example.com`, then `com` is the label of a delegated zone in the root. Here we will call a *zone* the collection of all defined labels at a particular delegation point in the name hierarchy. The label "`example`" is the label of a delegated zone in the `com.` zone. And `www` is a terminal label in the `www.example.com.` zone.

But that is not all there is to the DNS. There are many more subtleties and possibilities for variation, but as we want to look specifically at the root zone, we're going to conveniently ignore all these other matters here. If you are interested, RFC 1034^[1] from November 1987 is still a good description of the way the DNS was intended to operate, and the recently published RFC 7719^[2] provides a good compendium of DNS jargon.

The most common operation performed on DNS names is to *resolve* the name; resolving is an operation to translate a DNS name to a different form that is related to the name. This most common form of name resolution is to translate a name to an associated *IP address*, although many other forms of resolution are also possible. The resolution function is performed by agents termed *resolvers*, and they function by passing queries to, and receiving results from, so-called *name servers*. In its simplest form, a name server can answer queries about a particular zone. The name itself defines a search algorithm that mirrors the same right-to-left delegation hierarchy.

Continuing with our simple example, to resolve the name `www.example.com.`, we may not know the IP addresses of the authoritative name servers for `example.com.`, or even `com.` for that matter. To resolve this name, a resolver would start by asking one of the *root zone name servers* to tell it the resolution outcome of the name `www.example.com.` The root name server will be unable to answer this query, but it will refer the resolver to the `com.` zone, and the root server will list the servers for this delegated zone, as this delegation information is part of the DNS root zone file for all delegated zones. The resolver will repeat this query to one of the servers for the `com.` zone, and the response is likely to be the list of servers for `example.com.` Assuming `www` is a terminal label in the `example.com.` zone, the third query, this time to a server for the `example.com.` zone, will provide the response we are seeking.

In theory, as per our example, every resolution function starts with a query to one of the servers for the root zone. But how does a resolver know where to start? What are the IP addresses of the servers for the root zone?

Common DNS resolver packages include a local configuration fragment that provides the DNS names and IP addresses of the authoritative name servers for the root zone. Another way is to pull down the current root hints file from <https://www.internic.net/domain/named.root>.

But it may have been some time between the generation of this list and the reality of the IP addresses of the authoritative root servers today, so the first actions of a resolver on startup will be to query one of these addresses for the name servers of the root zone, and use these name servers instead. This query is the so-called *priming query*^[3].

This priming implies that the set of root server functions includes supporting the initial bootstrap of recursive DNS resolvers into the DNS framework by responding to priming queries of the resolver, as well as anchoring the process of top-name name resolution by responding to specific name queries with the name server details of the next-level delegated zone. This role is critical in so far as if none of the root servers can respond to resolver queries, then at some point thereafter, as local caches of the resolvers expire, resolvers will be unable to respond to any DNS queries for public names. So, these root servers are important in that you may not know that they exist, or where they may be located in the net, but their absence, if that ever could occur, would definitely be noticed by all of us!

Moderating all considerations of the DNS is the issue of local caching of responses. For example, once a local resolver has queried a root server for the name `www.example.com.`, it will have received a response listing the delegated name servers for the `com.` zone.

If this resolver were to subsequently attempt to resolve a different name in the `com.` zone, then for as long as the `com.` name servers are still held in the resolver cache, the resolver will use the cached information and not query any root server. Given that the number of delegated zones in the root zone is relatively small (1,528 zones as of the start of 2017), then a busy recursive resolver is likely to assemble in its local cache the name servers of many of the top-level domain names. Then one would expect that it would have no further need to query the root name servers, except as required occasionally to refresh its local cache, assuming that it is answering queries about DNS names that exist in the DNS.

In that respect, the root servers would not appear to be that critically important in terms of the resolution of names, and certainly not so for large recursive name servers that have a large client population and therefore have a well-populated local cache. But this conclusion would not be a good one. If cached information of a recursive resolver for a zone has expired, it will need to refresh the cache with a query to a root server. At some point, all of the locally cached information will time out of the cache, and then the resolver will no longer be able to respond to any DNS query. To keep the DNS operating, recursive resolvers need to be able to query the root zone, so there is a requirement that collectively the root servers always need to be available.

In this respect, the root servers “anchor” the entire DNS system. They do not participate in every name resolution query, but without their feed of root zone information into the caches of recursive resolvers the DNS would stop. So these servers are important to the Internet, and it might be reasonable to expect a role of such importance to be performed by hundreds or thousands of such servers. But there are just 13 such root server systems.

Why 13?

The primary reason to have more than a single root server, and use multiple root servers, was diversity and availability. The root servers are intentionally located in different parts of the network, within different service provider networks. The intended objective is that in the case where a DNS resolver is incapable of contacting a root name server, then unless the resolver was itself completely isolated from the Internet, then the desired number of root servers was such that the likelihood that it could not reach any of the root name servers was considered to be acceptably low. By this reasoning, two is probably not enough, and three could well be insufficient as well, but perhaps hundreds of thousands of such root servers may well be a case of overkill!

This line of thought assumes that each named root server has a unique name, a unique IP address, and a single location. But perhaps we are assuming too much. There is a technique that places identically named and addressed servers at various locations across the Internet, called *anycast*^[5,6].

Using anycast, a user attempting to send an IP packet to an anycast service would be directed to the “closest” instance of the family of servers that share a common anycast IP address. Why not just use anycast for a collection of root servers and put as many root servers as we want behind a single IP address?

For a considerable time, anycast was viewed with some caution and trepidation, particularly in the days before *Domain Name System Security Extensions* (DNSSEC) of a signed root zone. What would stop a hostile actor from setting up a fake root server and publishing incorrect DNS information if the IP addresses the root servers used could be announced multiple times from any arbitrary location? There was also some doubt that the *Transmission Control Protocol* (TCP) would be adequately robust in such anycast scenarios. The original conservative line of thinking was that we needed multiple unitary DNS root zone servers, each with its own unique IP address announced from known points in the network fabric.

But needing “multiple” DNS root zone servers and coming up with the number 13 appears to be somewhat curious. It seems such an odd limitation in the number of root servers given that a common general rule in computer software design is Willem van der Poel’s *Zero, One, or Infinity Rule*, which states a principle in computer science that either an action or resource should not be permitted (zero), should happen uniquely (one), or should have no arbitrary limit at all (infinity). For root servers, it appears that we would like more than one root server. But why set the limit to 13?

The reason may not be immediately obvious these days, but when the DNS system was designed, the size limit of DNS responses using the *User Datagram Protocol* (UDP) was set to 512 bytes (Section 2.3.4 of RFC 1035). It seems a ludicrously small limit these days, but you have to also account for the fact that the requirement for IPv4 hosts was (and still is) that it accepts IPv4 packets up to 576 bytes long^[4]. Working backwards, that would imply that if you account for a 20-octet IPv4 packet header and an 8-byte UDP header, then the UDP payload could be up to 548 octets long, but no longer if you wanted some degree of assurance that the remote host would accept the packet. If you also allow for up to 40 bytes of IP options, then in order to ensure UDP packet acceptance under all circumstances the maximal UDP payload size should be 508 octets. The DNS use of a maximum payload of 512 bytes is not completely inconsistent with this assumption, but it is off by 4 bytes in this corner case!

This 512-byte size limit of DNS packets still holds, in that a query without any additional signal—that is, in today’s terms, a query that contains no DNS extension mechanisms that signal a capability to use a larger UDP response size—is supposed to be answered by a response with a DNS payload no greater than 512 octets long. If the actual response would be greater than 512 octets, then the DNS server is supposed to truncate the response to fit within 512 octets, and mark this partial response as *truncated*.

If a client receives a truncated response, then the client may repeat the query to the server, but use TCP instead of UDP, so that it could be assured of receiving the larger response.

The desire in the design of the DNS priming query and response was to provide the longest possible list of root name servers and addresses in the priming response, but at the same time ensure that the response was capable of being passed in the DNS using UDP, and not rely on the use of any form of optional DNS extension mechanism. The largest possible set of names that could be packed in a 512-octet DNS response in this manner was 13 such names and their IPv4 addresses—so there are at most 13 distinct root name servers in order to comply with this limit.

These days every root name server has an IPv6 address as well as an IPv4 address, so the DNS priming response that lists all these root servers and their IPv4 and IPv6 addresses is now 811 octets. If the resolver also requests that the response should include the DNSSEC signatures, then the size of the response would expand to 1,097 bytes. But if you pass a simple priming query to a root server without a UDP buffer size extension in the query, then you will still receive no more than 512 octets in response. The size-limited response will still list the names of all 13 root name servers, but will not list all of their IPv4 and IPv6 addresses in the additional section of the response.

The partial set of these additional records of root server names and their IPv4 and IPv6 addresses is passed back without any particular indication of what is missing. The decision as to which records to include and which to omit to meet the size restriction also varies between root name servers. Some root name servers provide the IPv6 addresses of root servers A through J in a 508-byte response, while others give all 13 IPv4 addresses and add the IPv6 addresses of A and B in a 492-byte response. The remainder provide the IPv4 and IPv6 addresses for A through F and the IPv4 address of G in a 508-byte response. I suppose that the message here is that recursive resolvers should support the *Extension Mechanisms for DNS* (EDNS(0)) as specified in RFC 6891^[14], and offer a UDP buffer size that is no less than 1,097 bytes if they want a complete DNSSEC-signed response to a root zone priming query.

However, even then the story is incomplete. These additional records are not DNSSEC-signed in the priming response, so if a resolver wants to assure itself that the IP addresses that are provided in this response are the actual IP addresses of the root servers, it needs to separately query these names and request DNSSEC credentials in the response. However, as of the time of writing of this article the zone **root-servers.net** is not DNSSEC-signed, so right at the heart of the DNS there is still a leap of faith that all resolvers need to make in order to link into the DNS through the priming process.

We are also entirely comfortable with anycast these days, and the root server system has enthusiastically adopted anycast, where most of the root servers are replicated in many locations. The overall result is that hundreds of locations host at least one instance of one of the root server anycast constellations, and often more. Part of the reason that our comfort level with anycast has increased is the use of a DNSSEC-signed zone, and recursive resolvers should be protecting their clients by validating the response they receive to ensure that they are using the genuine root zone data, to the extent that this data has been signed in the first place.

Should we do more?

It would certainly make some sense to sign the **root-servers.net** zone to further protect recursive resolvers from being led astray.

But what about the specification of 13 unique root server names and their associated anycast constellations? If we had more root servers, would it make everything else better? Should we contemplate further expanding these anycast constellations into thousands or even tens of thousands of root servers? Should we open up the root server letter set to more letters? Is there a limit to “more” or “many”? Where might that limit be, and why?

These days the response that recursive resolvers receive in 512 bytes or less is a partial view of the root name server system. From that perspective, 13 is not a practical protocol-derived ceiling on the number of distinct root server letters. Whether the partial response in 512 bytes reflects 6, 10, or 13 root name servers out of a pool of 13 or 14 or any larger number is largely no longer relevant. The topic has moved beyond a conversation about any numeric ceiling on the letter count into a consideration of whether more root server letters would offer any incremental benefit to the Internet, as distinct from the current practice of enlarging the root server anycast constellations. Indeed, rather than more root name servers, whether by adding more letters or enlarging anycast constellations, should we consider alternative approaches to the DNS that can scale and improve resilience under attack through answering root queries but not directly involving these root name servers at all? In other words, can we look at DNS structures that use the root servers as a distribution mechanism for the root zone data and use the existing recursive resolver infrastructure to directly answer all queries that relate to data in the root zone?

The reason to contemplate this question is that it is not clear that more root server letters or more root server anycast instances, or even both measures, make everything else better. Reducing the latency in querying a root name server has only a minimal impact for end users.

The design objective of the DNS system is to push the data as close to the user as possible in the first place, so that every effort is made to provide an answer from a local resolver cache.

It is only when there is a cache miss that the resolver query will head back into the authoritative DNS server infrastructure, a situation that would normally affect only a very small proportion of queries over time. The DNS derives its performance and efficiency through resolver caches, so the overall intention is to limit the extent to which resolvers query these root name servers to the minimal level possible.

Secondly, a local root name server may not necessarily provide any additional name resolution resilience in the case of local network isolation. Secondary root name servers also have an expiry time on the data they serve, and in the case of extended isolation the server will also time out a case to be able to respond. This timeout is as true for the root zone as it is for any other zone.

In many ways, the net effect of a local root name server on local users' Internet experience is minimal, and could well pass completely unnoticed in many cases.

In terms of the primary objectives of the root name server system, diversity and availability, there is little to be gained by adding additional root name letters. A significant expansion of the number of uniquely named root servers would ultimately make a complete priming response exceed 512 bytes, meaning either forcing all priming queries into TCP by signalling that the UDP response was truncated, or dropping some named root servers from a non-EDNS(0) priming query response.

But rather than resisting the hard limits imposed by protocol specifications in some early RFCs, perhaps we are asking the wrong question. Rather than trying to figure out how to field even more instances of root servers and keep them all current, there is perhaps a different question: Why do we need these special dedicated root zone servers at all?

If the only distinguishing feature of these root servers is the proposition that any response with a source address of any of these 26 distinguished IP addresses is by simple unfounded assertion the absolute truth, then it is laughably implausible. Anyone who has experienced DNS interceptors would have to agree that DNS lies are commonplace, and nation states as well as service providers across the entire Internet practice lying.

Enter DNSSEC

The DNSSEC-signing of the root zone of the DNS introduced further possibilities to the root zone service to resolvers. If a resolver has a validated local copy of the current *Key Signing Key* (KSK), then it can independently validate any response provided to it from any signed zone that has a chain of signing back to this KSK, including of course any signed response about the root zone itself.

A validating resolver no longer needs to obsess that it is querying a genuine root name server, and no longer needs to place a certain level of blind faith in the belief that its DNS queries are not being intercepted and that faked responses are not being substituted for the actual response. With DNSSEC it simply does not matter in the slightest how you get the response. What matters is that you can validate responses with your local copy of the root zone key. If you can perform this validation successfully, then the answer is much more likely to be genuine!

The ubiquitous use of DNSSEC casts the root server system in an entirely different light, and the relationship between recursive resolvers and the root servers can change significantly.

A relevant observation here is that some 75% of responses from the root zone are “no such domain” NXDOMAIN responses (for example,^[7]). Recursive resolvers could absorb much of the root server query load and answer these queries directly with NXDOMAIN responses if they used this form of response synthesis. The way resolvers could answer the queries is to use so called “aggressive NSEC caching^[11].” This approach uses the *Next Secure* (NSEC) records provided in the responses relating to the nonexistence of a name in the root zone to allow recursive resolvers to synthesise an authoritative NXDOMAIN response for queries relating to any name in the range specified in the NSEC data. Rather than caching a root zone NXDOMAIN answer for each individual nonexistent domain name, caching the NSEC response allows the recursive resolver to cache a common signed response for the entire span of query names as described in each NSEC response. With a cache of 1,528 defined top-level domains and another 1,528 NSEC records, a recursive resolver would be able to provide authoritative responses for any query that would otherwise be passed through to a root server.

Another approach is to use *local secondaries* for the root zone. This approach is not an architectural change to the DNS, or at least not intentionally so. For recursive resolvers that implement this approach, this change is a form of change in query behaviour in so far as a recursive resolver configured in this manner will no longer query the root servers for queries it would normally direct to an instance of the root. Instead, it directs these queries to a local instance of a slave server that is listening on the loopback address of the recursive resolver. This slave server is serving a locally held instance of the root zone, and the recursive resolver would perform DNSSEC validation of responses from this local slave to ensure the integrity of responses received in this manner. In effect, this technique loads a recursive resolver with the entire root zone into what is functionally similar to a local secondary root zone server cache. For users of this recursive resolver there is no apparent change to the DNS or to their local configurations. Obviously, there is no change to the root zone either.

This proposal provides integrity in the local root server through the mechanism of having the recursive resolver perform DNSSEC validation against the responses received from the local root slave. If the recursive resolver is configured as a DNSSEC-validating resolver, then this mechanism is configurable on current implementations of DNS recursive resolvers.

The advantage here is that the decision to set up a local slave root server or to use aggressive NSEC caching is a decision that is entirely local to the recursive resolver, and the impacts of this decision affect only the clients of this recursive resolver. No coordination with the root server operators is required, nor is any explicit notification. The outcomes are only indirectly visible to the clients of this recursive resolver, and no other.

Where does this leave the root server system?

In the light of increasing use of DNSSEC, the root server system is declining in relevance as a unique source of authoritative responses for the root zone, and we can forecast a time when their role in resolving queries would be largely anachronistic. A validated response can be considered a genuine response regarding the contents of the root zone, regardless of how the recursive resolver learned this response. It is no longer necessary to have a dedicated set of name servers running on a known set of IP addresses as the only means to protect the integrity of the root zone.

It is also true that the root servers are no longer being used as cache refresh for recursive resolvers for delegated domains. Today we see much of the time, effort and energy, and cost of root server operation being spent to ensure that NXDOMAIN answers are provided promptly and reliably. This use of time really does not make any sense these days. The use of local secondary root servers and the use of NSEC caching can remove all of these specific queries relating to undefined names to the root servers, and what would be left is the cache priming queries. If all recursive resolvers were able to use either of these measures, then the residual true role of the root server system would not be to respond to individual queries, but simply to distribute current root zone data into the resolver infrastructure.

If the functional intention of the root server system is to distribute signed root zone data to recursive resolvers, then perhaps we could look more widely for potential approaches. Regularising the times that changes are made to the root zone would help reduce opportunistic polling of the root servers to detect when a change might have occurred. Or using an approach based on *Incremental Zone Transfer* (IXFR) that would allow recursive resolvers to request incremental changes to the root zone based on differences between zone *Start of Authority* (SOA) numbers may be more efficient.

Maybe we can look further afield for additional ways to distribute the root zone contents. Social networks appear to be remarkably adept in their ability to distribute updates, and a thought is that the small set of incremental changes to the signed root zone would be highly amenable to similar techniques or even using the same social networks. One can readily imagine a feed of incremental root zone updates on media such as Twitter, for example!

I also can't help but wonder about the wisdom of the root zone servers being promiscuous with respect to whom they answer. Root zone query data points to some 75% of queries seen at the root zone servers generating NXDOMAIN responses, meaning that three-quarters of the responses from root servers are nonsensical questions in the context of the root zone. It's not clear to what extent the other 25% of queries reflect actual user activity. In an APNIC measurement exercise using synthetic domain names that included a time component, it was evident that more than 30% of the queries seen at the authoritative servers of the measurement reflected "old" queries, generated by query log replay or other DNS forms of stalking activities.

One way to respond to this situation is to farm out the query volume currently seen at the root servers into the existing recursive resolver infrastructure, so that all root zone responses are generated by these recursive resolvers, rather than passing queries onward to the root servers. If the root servers exclusively served some form of incremental zone transfer and did not answer any other query type directly, then we would see a shift in query traffic away from the root servers as a crucial DNS query attractor, leaving only a lower profile role as a server to recursive resolvers.

There is much to learn about the DNS, and there is still much we can do in trying to optimise the DNS infrastructure to continue to be robust, scalable, and accurate—all essential attributes to underpin the continued growth pressures of the Internet.

ISOC Issues Paper on Content Blocking

The *Internet Society* (ISOC) recently voiced its commitment to keeping the Internet on for everyone, in response to the increasing number of government orders to temporarily shut down or restrict access to Internet services. Speaking out at *RightsCon 2017*, the world's leading conference on Internet and human rights that took place in late March in Brussels, the organization underscored that any deliberate attempt to interrupt Internet communications or control the flow of information over the Internet puts society at risk.

Internet shutdowns, including those that impact social media sites or entire networks, occur when governments intentionally disrupt the Internet or mobile apps, often used in the context of elections, demonstrations or other tense social contexts. According to *Access Now*, there were 56 Internet shutdowns recorded worldwide in 2016, an upward trend from previous years.

A paper entitled “Internet Society Perspectives on Internet Content Blocking,”^[1] explores the most common Internet restriction techniques and highlights the shortcomings and collateral damage from the use of such measures. “From censorship to SMEs going out of business, the human, economic and technical costs of Internet shutdowns are just too high,” explains Nicolas Seidler, Senior Policy advisor at the Internet Society.

The paper describes and evaluates the most common content blocking techniques used by governments to restrict access to information (or related services) that is either illegal in a particular jurisdiction, is considered a threat to public order, or is objectionable for a particular audience.

According to Freedom House's *Freedom on the Net report 2016*, governments in 24 of the 65 countries assessed impeded access to social media and communication tools, up from 15 the previous year.

“Before they take action, we are calling policymakers to think twice: Internet shutdowns and content filtering are not the answer,” said Constance Bommelaer, Senior Director for Global Internet Policy at the Internet Society. “We are at a crossroads, and the actions we take today will determine whether the Internet will continue to be a driver of empowerment, or whether it will threaten personal freedoms and rights online,” added Bommelaer.

The Content Blocking paper can be downloaded in various forms and languages from ISOC's website^[1]. Quoting from the Foreword: “The use of Internet blocking by governments to prevent access to illegal content is a worldwide and growing trend. There are many reasons why policy makers choose to block access to some content, such as online gambling, intellectual property, child protection, and national security.

However, apart from issues relating to child pornography, there is little international consensus on what constitutes appropriate content from a public policy perspective.

The goal of this paper is to provide a technical assessment of different methods of blocking Internet content, including how well each method works and what are the pitfalls and problems associated with each. We make no attempt to assess the legality or policy motivations of blocking Internet content.

Our conclusion, based on technical analyses, is that using Internet blocking to address illegal content or activities is generally inefficient, often ineffective and generally causes unintended damages to Internet users.

From a technical point of view, we recommend that policy makers think twice when considering the use of Internet blocking tools to solve public policy issues. If they do and choose to pursue alternative approaches, this will be an important win for a global, open, interoperable and trusted Internet.”

IAB Issues RFC on Protocol Adoption and Transition

The *Internet Architecture Board* (IAB) has recently published a *Request for Comments* (RFC) on Protocol Adoption and Transition^[1]. The abstract states: “Over the many years since the introduction of the Internet Protocol, we have seen a number of transitions throughout the protocol stack, such as deploying a new protocol, or updating or replacing an existing protocol. Many protocols and technologies were not designed to enable smooth transition to alternatives or to easily deploy extensions; thus, some transitions, such as the introduction of IPv6, have been difficult. This document attempts to summarize some basic principles to enable future transitions, and it also summarizes what makes for a good transition plan.”

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

Publication of this journal is made possible by numerous individuals and organizations. Every year in late August we initiate a sponsorship renewal campaign, and the total funding determines our publication frequency for the following year. This *November* edition will be the third and final issue in 2017, but we hope to return to our regular quarterly publication schedule in 2018. We still need more individual and corporate sponsors, so please make a donation at <http://tinyurl.com/IPJ-donate> or ask your company to sign up for a sponsorship.

In our series of articles on emerging technologies we turn to *Blockchain*, a term that is now found in mainstream news outlets. We asked Bill Stallings to give us an introduction to this technology and consider some of its applications, such as *Bitcoin*.

Network Address Translation (NAT) has been widely deployed in both home and corporate networks for many years. Since the IPv4 address space is largely depleted, NATs provide an easy option for creating local networks that use private address space as defined in RFC 1918, and communicate with the public Internet through a single IP address. There are many technical problems associated with NATs, some of which have been described in other articles in this journal. This time, Geoff Huston provides an opinion piece “In Defence of NATs.”

After many years on the ICANN Board, Steve Crocker has finished his term, but has agreed to continue serving on our Editorial Advisory Board. Thank you, Steve! In other news, the *Internet Society* recently celebrated its 25th anniversary, while the *Internet Engineering Task Force* (IETF) celebrated its 100th meeting. For more information on these events, visit <http://isoc.org> and <http://ietf.org>

As mentioned in our previous issue, if you have a print subscription to this journal, you will find an expiration date printed on the back cover. For the last couple of years, we have “auto-renewed” your subscription, but now we ask you to log in to our subscription system and perform this simple task yourself. This process will ensure that we have your current contact information, as well as delivery preference (print edition or PDF download). For any questions, e-mail us at: ipj@protocoljournal.org

You can download IPJ
back issues and find
subscription information at:

A Blockchain Tutorial

by William Stallings, Independent Consultant

Blockchain is a recently-developed distributed digital implementation of the hardcopy transaction *ledger* that has been used throughout the world for centuries. Businesses and other organizations use ledgers in a variety of applications, such as to determine ownership, establish valuations, and document liabilities. The most common ledger applications are for tracking and chronologically recording transactions that involve an exchange of value between parties. Another common use of ledgers is to record birth and death certificates.

Blockchain first came to public notice as the technology that supports the virtual currency *Bitcoin*. And while the interest in Bitcoin has tended to wax and wane, the interest in blockchain continues to grow^[1].

Distributed Ledgers

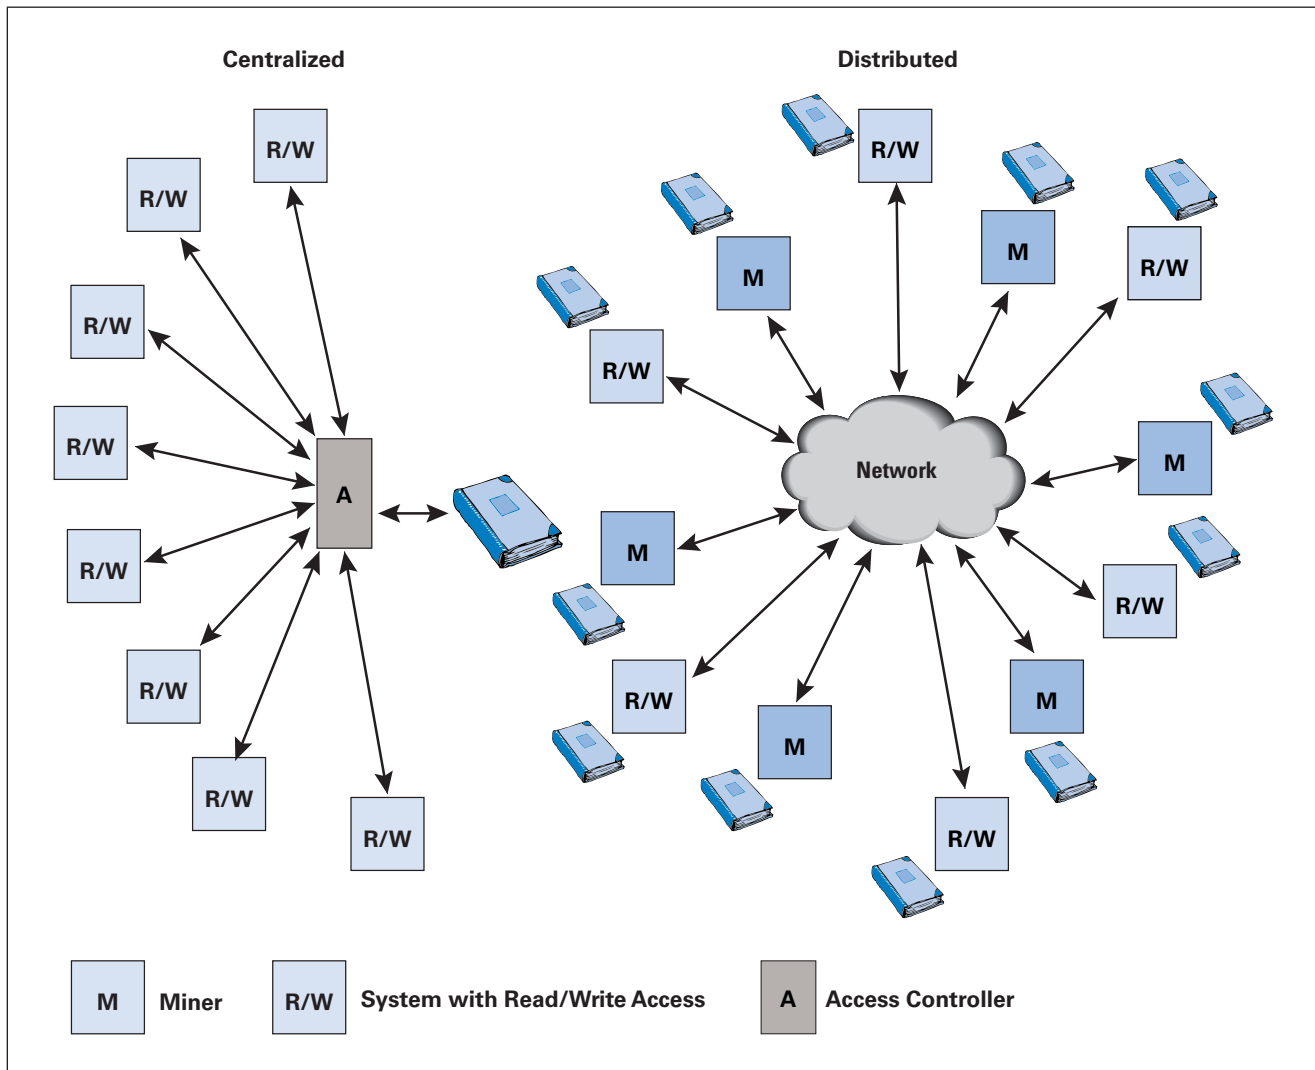

In the business context, a ledger, or *general ledger*, is defined as a central repository of the accounting information of an organization in which the summaries of all financial transactions during an accounting period are recorded. Also called the *book of final entry*, it provides all the data for preparing financial statements for the organization. As mentioned, the ledger can be used to record other types of transactions as well.

In the common business environment, a digital ledger is stored in a central server, and distributed access is provided with read and/or read/write privileges (Figure 1). To assure security, there is some sort of access control mechanism that authenticates users, enables secure access, and enforces access restrictions (for example, read-only). For a system with ongoing transactions and a heavy volume of read and write access, the central server model can be inefficient.

An alternative is a *secure distributed ledger*, which consists of an expandable list of cryptographically signed, irrevocable records of transactions that is shared by a distributed network of computers. Subject to network time delays, every participant has the same copy of the ledger. Each participant may propose a new transaction to be added to the ledger and when consensus that the transaction is valid is reached, it is added to the register.

Trust in a distributed ledger involves two concepts. First, security protocols and mechanisms, generally based on *Public-Key Cryptography*, ensure that the creator of each transaction is authenticated and validated. Transaction creators prove they are entitled to make a transaction by satisfying the particular conditions associated with this application. Meeting these conditions almost always involves the use of a secure digital signature.

Figure 1: Centralized and Distributed Ledgers

Second, a consensus mechanism is used in which computers on the network check each other to ensure records are consistent. In blockchain, this latter mechanism is implemented by systems called *miners*. Their job it is to determine that each new addition to the ledger is valid and consistent with previous entries. When the miners achieve consensus on a new entry, it is permanently added to the ledger.

Consider the use of a distributed ledger to record financial transactions or some other type of transaction that involves the exchange of value. Each transaction is a signed message that creates new outputs (transfer of value to another) while consuming old inputs (transfer of value from the transaction maker). For financial applications, each transaction is the digital equivalent of a paper check, and represents a promise by the payer to transfer control of a given amount of value to another party. The same funds or other value can be sent to only one party. An attempt at double spending, by creating two transactions that consume the same inputs, is prevented by the use of digital signatures and the trust mechanisms of the distributed ledger.

The Gartner Research document “What CIOs Should Tell the Board of Directors About Blockchain”^[2] lists the following benefits of using secure distributed ledgers:

- Civilians and computerized agents govern the economic and transaction infrastructure, which is global in scale, peer-to-peer, self-regulating, secure, and reliable.
- A decentralized, shared history of activity, obligations, rights, and records ensures transparency and certainty.
- Fine-grained and diverse (not just monetary) value exchange occurs directly between participants on a network, at lower cost and higher speed compared to legacy systems.
- The system is open to everyone, both public and private, but control and openness can be customized.
- Ownership and rights are recognized broadly. Value can be natively created and exchanged with no double spending or repudiation of transactions. The system guarantees proof of existence, process, and asset provenance.
- Embedded business logic enables dynamically self-executing smart contracts linked to diverse assets.
- Distributed autonomous organizations acting as full-fledged legal entities can execute transactions with no human intervention.

General Concept

In essence, blockchain is a data structure that makes it possible to create a digital ledger of transactions and share it among a distributed network of computers. After a block of data is recorded on the blockchain ledger, it is computationally infeasible to change or remove it. When someone wants to add to the ledger, participants in the network, all of which have copies of the existing blockchain, run algorithms to validate the proposed transaction. If a majority of nodes agree that the transaction looks valid—that is, identifying information matches the history of a blockchain—then the new transaction will be approved and a new block added to the chain. The transaction is fulfilled or executed only when it has been approved for addition to the blockchain. In contrast, in a typical computerized ledger scheme, transactions are submitted to a trusted central party that is responsible for validating the transactions and posting them in the ledger.

Blockchain provides a distributed public ledger containing transactions that are governed and maintained by specific protocols through consensus of the nodes participating in its network. The ledger consists of a linear time-sequenced chain of blocks, with each block containing one or more transactions. Each block is connected to the previous block via a hash (tamper-proof digital fingerprint). On the blockchain, users can observe transactions that have occurred, so they know which outputs are available for spending and which ones have been consumed.

Each block in the blockchain represents, in effect, the claim by someone on the network that the transactions contained inside the block are the first ones to spend the inputs involved, and therefore any transaction in the future that attempts to spend the same inputs should be rejected as invalid.

The term “blockchain” is used interchangeably to describe both the blockchain network (network of nodes) and the distributed ledger (chain of blocks). It offers a way for users who may not know or trust each other to create a record of *who* transacts *what* that will compel the assent of everyone concerned.

The blockchain ledger is not housed on a single privileged server. Rather, it is a shared data structure in which every node (user) on the network has the same copy of all other nodes (subject to propagation time delays) and can read any transaction in the ledger.

Blockchain Structure

A blockchain is a linear sequence of blocks used to store transactions. Each block contains one or more related transactions, and the blocks are ordered in increasing time sequence. Thus, each block represents a set of events that have occurred over a given time frame that is subsequent to the preceding block in the chain and prior to the following block in the chain. Users with application access to the chain can read any transaction in the sequence and can add a new block at the end of the sequence.

As shown in Figure 2, each block has a unique predecessor and successor. A block is added only at the newer, or higher end of the chain. As will be shown, there may temporarily be a branching structure as the chain grows. An essential element of blockchain is that each block is linked to its preceding block using a cryptographic algorithm. The scheme is designed such that it is computationally feasible to add a new block to the end of the chain but computationally infeasible to replace a block interior to the chain or to insert a new block between two existing blocks in the chain. After a block is added to the chain, it is read-only. Figure 3 shows the blockchain operation in general terms.

Figure 2: Block Chaining Concepts

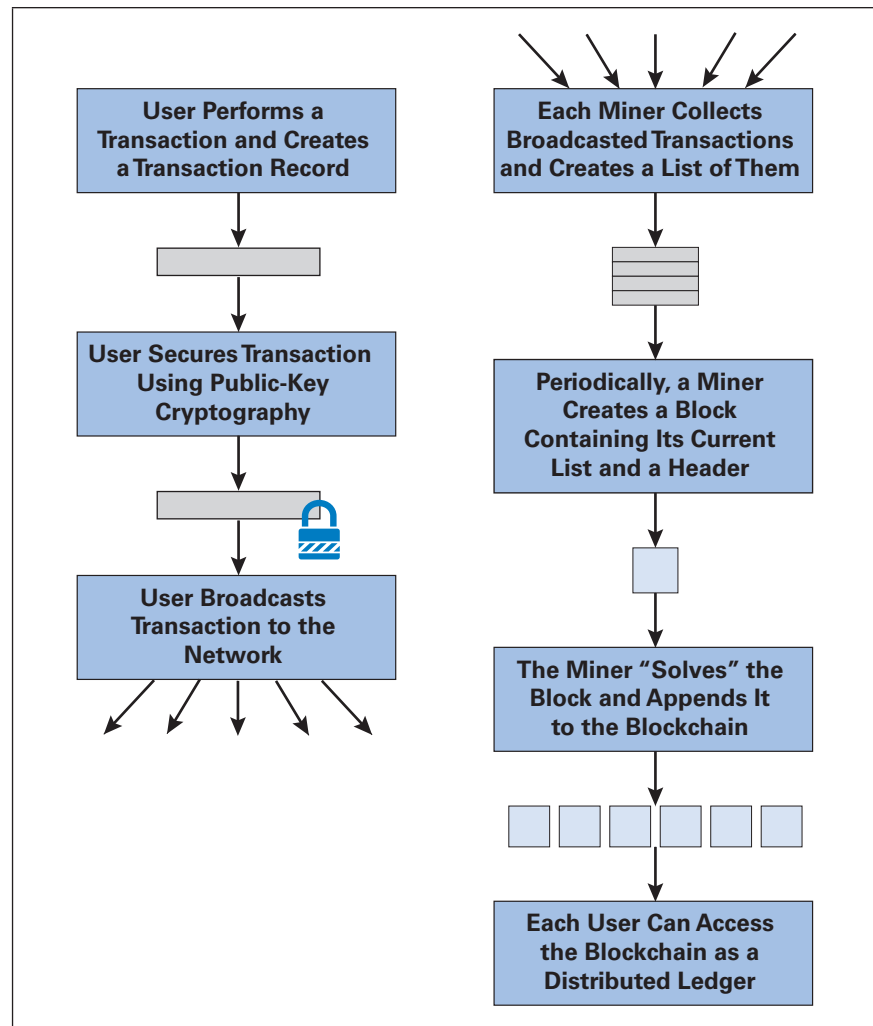

Figure 3: Basic Blockchain Logic

The exact structure of a block may vary from one application to another. Table 1 shows the typical block format. Each block begins with a “magic number” that uniquely identifies this chain. For Bitcoin, the magic number is 0xD9B4BEF9. This number is followed by a *blocksize* field that specifies the total number of bytes in the remainder of the block. Next comes the header, consisting of multiple fields. Finally, the block contains a transaction counter (≥ 1) followed by one or more transactions. The internal format of each transaction is application-dependent.

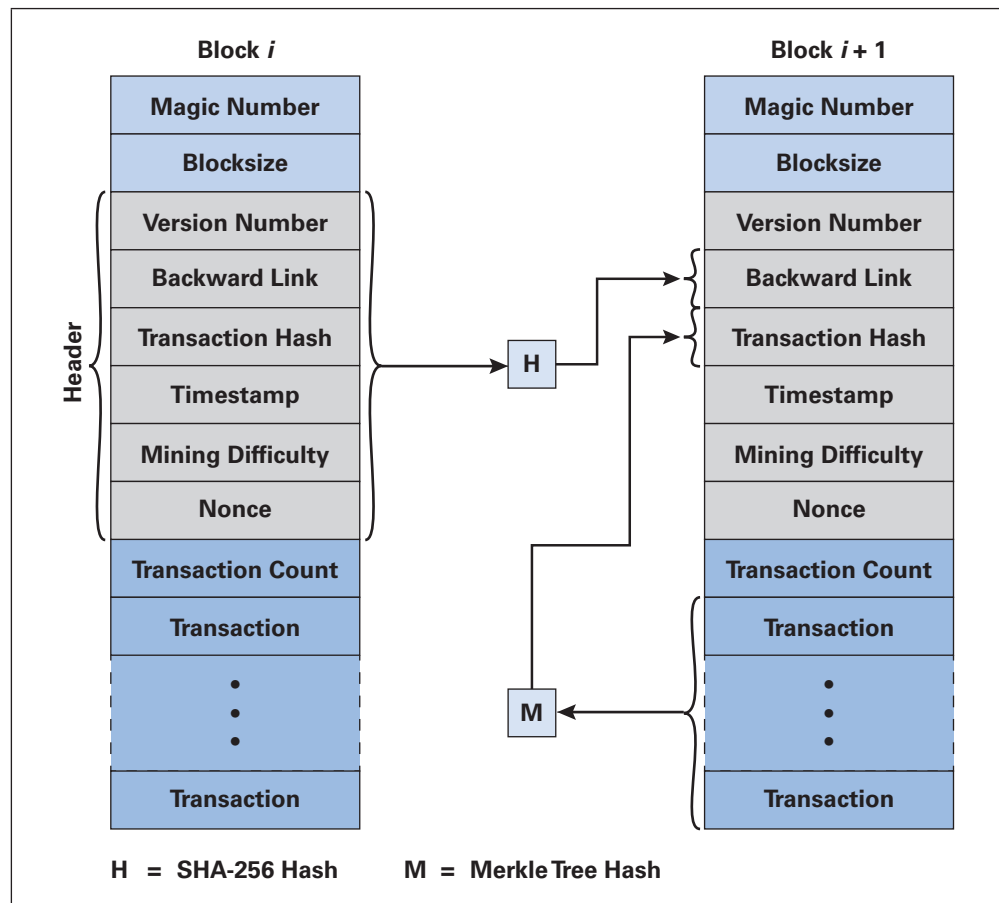

The header begins with a *Version Number*, to allow for future alterations to the block format. The blockchain application should be backward compatible so that older format versions can be processed. The foundation of the security of blockchain is found in the second field, which in effect provides a *Backward Link* to the preceding block. This backward link consists of the hash of all of the headers of the preceding block (Figure 4). By using a cryptographically strong hash function, such as SHA-256, this scheme secures the blockchain against an adversary’s altering a block or inserting a block.

In either case, the adversary would have to create a block with a header whose hash value equals a given value, and this creation is computationally infeasible for SHA-256.

Table 1: Contents of a Block

Item	Description
Magic Number	A unique identifier for the blockchain; remains constant for all subsequent blocks
Blocksize	Number of bytes following up to end of block
Version Number	Block format version
Link to Previous Block	Hash of preceding block header
Transaction Hash	The root node of a Merkle Tree, a descendant of all the hashed pairs in the tree. The root node is a 256-bit hash based on all of the transactions in the block.
Timestamp	When block was created
Mining Difficulty	A relative measure of how difficult it is to find a new block. The difficulty is adjusted periodically as a function of how much hashing power has been deployed by the network of miners.
Nonce	Used to calculate proof-of-work
Transaction Counter	Number of transactions in this block
Transactions	The (nonempty) list of transactions

Figure 4: Linkage Between Blocks

The next header field is the *Transaction Hash*. This hash value is computed from the set of data blocks that comprise the list of transactions. Rather than a single hash over this entire set, a *Merkle Tree* technique is used, illustrated in Figure 5. The transaction blocks are processed in pairs; if there is an odd number of transactions, the last transaction on the list is duplicated. Then, each pair of blocks is concatenated to form a binary block that is input to a hash function, typically SHA-256, which produces a 256-bit hash value. The resulting hash values are again paired, and each 512-bit pair is used as input to the hash function. This process continues until a single hash value results, known as the *Merkle Root*.

Figure 5: Example of a Merkle Tree

Following the transaction hash in the header is the *Timestamp* field, which indicates the relative time that this block was created, using a scheme specific to the application.

The next field, *Mining Difficulty*, is a measure of how difficult it is to find a new block. This procedure is explained subsequently. Finally, a one-time *Nonce* value is generated that is used for the proof-of-work concept, described subsequently.

Blockchain Mining

Consider an application that requires the storage of time-sequenced transactions for a distributed group of users. Numerous security issues arise, including authenticating users and ensuring the integrity of the sequence of stored transactions.

The latter includes the need for mechanisms to protect against malicious altering or insertion of transactions. Traditionally, these requirements are met by one or more trusted third parties that act as middleman. In a distributed environment with a large population of users, a peer-to-peer approach becomes more attractive as an efficient method for meeting these requirements. Such an approach is used in blockchain.

The distributed blockchain environment has the following characteristics:^[3]

- Each user has a copy of the blockchain.
- Each user running the blockchain client is part of the network.
- New blocks are broadcast to the network.
- Each user updates its local copy of the blockchain.
- If a user is behind the current height of the chain, it can ask other nodes for copies of the blocks needed to catch up.
- If every user has a copy of the blockchain, when the blockchain is queried, every user gets the same answer.

Within a given application, blocks are created periodically to be added to the chain. The linking of a new block to the end of the chain is most commonly done by a process called *mining*.

Each block in the blockchain is required to have evidence that a costly, nonreversible sacrifice of time and energy has been dedicated to that particular block and no others. This evidence is known as *Proof-of-Work*. The important characteristics of proof-of-work include that it represents a true sacrifice: the actions performed are absolutely useless for any purpose other than producing the proof; and that it is nonreversible: no matter what happens, the resources used to produce the proof cannot be recovered. When Bitcoin clients encounter two valid but different blockchains, they choose to accept the one that represents the highest total proof-of-work.

Some entities within a blockchain network act as miners. It is the task of the miners to add new blocks to the chain and, in effect, miners compete to do this task. Any user can create a set of transactions that are to be formed into a block and added to the end of the chain. The miners are a distributed, pooled resource that create the blocks and add them to the chain.

In a typical open, distributed blockchain application, there are no designated miners. The entity adding the next block to the chain is selected on a per-block basis based on whoever in the world chooses to produce the most proof-of-work. In effect, miners compete for the right to add the next block. The incentive for doing so is a reward based on the application, such as earning Bitcoins for adding to the Bitcoin blockchain.

Miners can enter the system without asking for or requiring anyone's permission, and the network will continue to operate seamlessly when any particular miner leaves the system. The system is kept stable by virtue of the nonrecoverable sacrifice and its ability to discourage non-cooperating miners.

The operation of the miners is governed by a *consensus protocol*. In general, a consensus protocol takes as an input the requests of the components and decides upon one of these requests^[4]. The blockchain consensus protocol ensures that among multiple conflicting proposed transactions, only one gets approved, preventing for example a double spending of the same coins.

A miner constructs a new block in the following fashion: Users broadcast transactions onto the network to be added to a new block. A miner collects these transactions to form a pool of transactions that are not yet part of a block.

Periodically, the miner constructs a new block with the pool of transactions it currently has. The miner validates all the transactions and decides on an ordering within the block. The miner then invests considerable computational effort to construct a new block; this process is called *solving* a block. This block is then broadcast to all the miners on the network and tentatively added to the end of the blockchain. The application requires that each block prove a significant amount of work was invested in its creation to ensure that untrustworthy peers who want to modify past blocks have to work harder than honest peers who only want to add new blocks to the blockchain.

In effect, the consensus mechanism for blockchain is a lottery race, in which the winner is rewarded in some fashion. The winner is the miner that is able to add a new block to the chain that is accepted by other miners.

The technique that is used for the proof-of-work may differ for different applications. Bitcoin uses a *cryptographic hash* technique that works as follows^[5]: The cryptographic hash value of the block header is calculated to form the backward link used by the next block in the chain. If any hash value is allowed, this operation is a simple one. To make the process more resource intensive, a *mining difficulty* is established, which defines how many leading zeros the header hash value must have. Thus, with a mining difficulty of 1, there must be one leading zero. The miner can vary the hash value of the header by varying the value of the nonce field. Typically, a miner will begin with the nonce equal to 1, calculate the hash, and see if it satisfies the difficulty requirement. If not, it increments the nonce and tries again, repeating the process until a hash value is produced that satisfies the difficulty measure.

This difficulty measure is simple to express and effective. For example, if a single leading zero is required, then half of the possible hash values meet the requirement; thus, on average every other hash attempt will result in a hit. If ten leading zeros are required, the level of effort is on the order of one thousand hash attempts. If twenty leading zeros are required, the level of effort is on the order of one million hash attempts. For the Bitcoin blockchain, the target time for solving a block is 10 minutes.

We can express the mining function as follows: For a difficulty level of *alpha*, the hash value *H* must satisfy the following inequality:

$$H(\text{version number}, \text{backward link}, \text{transaction hash}, \text{timestamp}, \text{alpha}, \text{nonce}) < \text{alpha}$$

The miner must choose a value of nonce that satisfies this inequality. For a secure hash function such as SHA-256, it is effectively impossible to guess a value of nonce that works. Instead, the miner must try out many different values of nonce (using much computing power) until the condition is satisfied. Moreover, the lower the value of *alpha*, the harder it is to satisfy the condition. A proposed solution, however, can easily be verified. That is, once the nonce value is fixed, it is easy to determine if $H(\text{version number}, \text{backward link}, \text{transaction hash}, \text{timestamp}, \text{alpha}, \text{nonce})$ is less than *alpha*.

A new block can be added to the Bitcoin blockchain only if its header hash is at least as challenging as a difficulty value expected by the consensus protocol. Every 2,016 blocks, the network uses timestamps stored in each block header to calculate the number of seconds elapsed between generation of the first and last of those last 2,016 blocks. The ideal value is 1,209,600 seconds (2 weeks). That is, if blocks are generated at a rate of once per 10 minutes (600 seconds), then 2,016 blocks should be generated in $2,016 \times 600 = 1,209,600$ seconds. If it took fewer than 2 weeks to generate the 2,016 blocks, the expected difficulty value is increased proportionally (by as much as 300%) so that the next 2,016 blocks should take exactly 2 weeks to generate if hashes are checked at the same rate. If it took more than 2 weeks to generate the blocks, the expected difficulty value is decreased proportionally (by as much as 75%) for the same reason.

Returning to a general discussion of blockchain, not specific to Bitcoin, we can now see how the interlocking values of the nonce, transaction hash, and header hash protect the blockchain. An adversary who wishes to successfully alter the transaction list is faced with two alternative challenges: (1) modify the transaction list in such a way that the transaction hash is unchanged, also leaving the header hash unchanged; this modification is computationally infeasible for a secure hash function such as SHA-256; or (2) allow the transaction hash to change but modify the nonce so that the header hash is unchanged; again, this modification is computationally infeasible. Similarly, to insert a new block interior to the chain, the adversary would have to find a nonce value so that the header hash of the inserted block equals that of the preceding block.

Note that the computational effort of the adversary is far greater than that of the miner. Using the Bitcoin difficulty measure, for example, a difficulty value of 30 means that 2^{226} possible hash values can satisfy the requirement and the level of effort is on the order of 2^{30} hash attempts. For an adversary, it is necessary to find a nonce value that will produce a given unique hash value out of the 2^{256} possible values. On average, this discovery will take about 2^{128} hash attempts.

Miner Selection

The *Proof-of-Work* mechanism discussed previously is a way of selecting which miner gets to append a block to the chain. As we have seen, in this scheme the miner is essentially chosen at random through the competition among miners to produce a proof-of-work that is costly to produce but easy to verify.

Other than proof-of-work, numerous alternative methods have been considered or implemented, including the following^[6]:

Proof-of-Stake grants mining rights to participants in proportion to their holding of the currency within the blockchain network. Miners must demonstrate that they hold more than a threshold amount of currency to be able to mine blocks. Proof-of-stake blockchains provide protection from a malicious attack because executing an attack would require the attackers to own a large amount of currency, which is very expensive. Besides, the miners owning a large stake most probably won't attack the system, for example, through double spending. Over time, such attacks will decrease the value of the cryptocurrency and the value of their stake.

The *Proof-of-Burn* process involves destroying Bitcoins by consuming them in a way that does not generate new Bitcoins^[7]. The idea is that miners should show proof that they burned some coins—that is, sent them to a verifiably unspendable address. This process is expensive from their individual point of view, just like proof-of-work; but it consumes no resources other than the burned underlying asset. To date, all proof-of-burn cryptocurrencies work by burning proof-of-work-mined cryptocurrencies, so the ultimate source of scarcity remains the proof-of-work-mined “fuel.”

Permacoin has proposed a modification to Bitcoin^[8], which uses *Proof-of-Retrievability* (POR) to re-purpose the mining resource of Bitcoin to distributed storage of archival data. A POR proves that a node is investing memory or storage resources to store a target file or file fragment. This approach provides additional incentives to contribute resources to the network.

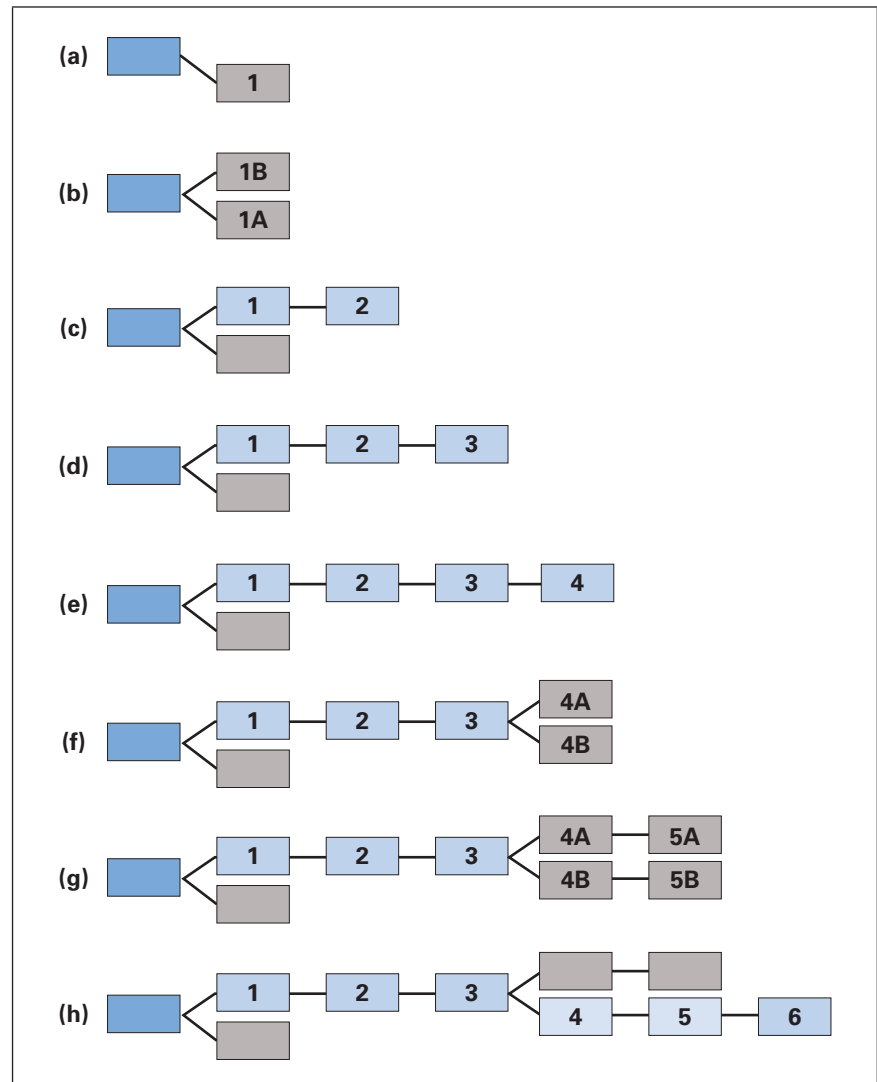

Building the Chain

After a miner has successfully hashed a block header, by finding a nonce value that satisfies the difficulty requirement, the miner can add the block to the end of the chain. It can happen that multiple blocks are created with the same height (distance from the origin block).

This situation occurs if more than one miner, working on different transactions, each produces a block at roughly the same time. This situation creates an apparent fork in the blockchain. Because the blockchain must be a linear, time-ordered sequence, the blocks in the branches following the fork are only provisional. The conflict is resolved when one of the branches exceeds the length of any competing branches.

Figure 6, based on [9], illustrates a typical sequence of events that resolves conflicts. There is an initial block at height 0. All miners try to solve the next block, and one miner solves a block at height 1 (see row *a* in the figure). But at almost the same time, another miner solves a block (row *b*). Block 1A may contain different transactions from 1B, and the users and miners in the network don't know which block should be the accepted one. So, both blocks are considered as provisional, and some miners work on adding to the chain at 1A, and some at 1B.

Figure 6: Adding Blocks to a Chain

Eventually, some miner creates a new block attached to 2B (row *c*). Because all miners must work at the highest height, those miners working on finding a successor to 1A stop that work. All miners are now working on creating a block to attach to the accepted block 2. At row *d* in Figure 6, one miner has successfully created and attached a block at height 3, and broadcasts this update to the network. All of the miners abandon their work at height two and now try to attach a block to the new block 4.

Next, a miner adds a block at height 4 and broadcasts it to the network (row *e*). Other miners, as soon as they receive this information, begin to work at block 4. However, at least one miner, before it receives this update, creates a block at height 4, creating a fork in the chain (row *f*), as happened back at row *c* in the figure. This situation creates a race condition that may continue. It is possible that both forks of the chain solve another block at about the same time (row *g*). In this example, the miners working on 5B solve a block, first adding a new block 6 (row *g*). This new chain, with block 6, is broadcast to all users and miners on the network. With block 6 in place, users are assured the blocks 4A and 5A are “locked in” to the blockchain. And miners who were working to add a block 6 realize they have lost the race. Now all miners begin working to try to append a new block after block 6. This activity continues as the chain grows, with occasional forks that are eventually discarded.

Confirming Transactions

As a miner is collecting transactions, it validates each one. The nature of the validation depends on the application but generally it depends on the use of public-key cryptography to authenticate the parties to the transaction and assure the integrity of the content of the transaction record^[10]. The miner then assembles its current pool of validated transactions into a block. When the block is established as the next block in the chain, it is referred to as a *confirmation*. If there is a fork in the chain, then this confirmation is only provisional until the fork is resolved.

The deeper a block is embedded in a chain (that is, farthest from the current height of the chain) the more difficult it would be for an adversary to alter the block. Thus, in any given application, a user of the distributed ledger can decide how many confirmations to wait for before acting with full confidence in a particular ledger entry.

Scalability

A blockchain in active use grows over time and never shrinks, raising the question of the scalability of a blockchain application. For example, Bitcoin allows a maximum block size of 2 MB and as of November 6, 2017, Bitcoin blockchain activity had the following characteristics (<https://blockchain.info>):

- Blockchain size (total size of all block headers and transactions, not including database indexes): 140.295 GB
- Average block size: 1.03 MB

- Transactions per day (most recent day): 333,161
- Aggregate size of transactions waiting to be confirmed: 40.31 MB

To perform all the Bitcoin functions and store the entire blockchain requires considerable processing and memory resources. For many blockchain applications, however, it is not necessary for all users to perform all the blockchain tasks, which include mining management, *Peer-to-Peer* (P2P) network communication and blockchain management, key management, and virtual asset management. For many blockchain applications, systems can be configured that provide only a subset of the tasks of a full implementation, with the handling of public-private key pairs as the most common core feature.

The authors of [11] define five categories of configuration:

- *Basic Client*: A client that runs on a user-controlled device and can perform key management operations, but cannot perform any P2P network communication. It is not a stand-alone solution. Examples include some dedicated hardware clients/wallets and cold-storage (offline storage) clients that require a second online device for transaction processing.
- *Thin Client*: A client that runs on a user-controlled device and can perform key management operations. It performs some P2P tasks related to network communication and blockchain verification but does not keep a copy of the full blockchain.
- *Thick Client*: A client that runs on a user-controlled device and performs all P2P tasks related to network communication and blockchain verification, keeps a copy of the full blockchain, and can perform all key management-related operations. This type of client is sometimes referred to as a *full node*.
- *Fully Functional Basic Client*: A node that performs all of the functions of a thick client, and executes the mining algorithm.
- *Hosted Client*: A client that does not run on a user-controlled device and all tasks are performed by a trusted third party on behalf of the user. This type of client is sometimes referred to as *hosted* or *web client/wallet*. In this case, it is not relevant whether key management is handled in the browser (for example, via JavaScript) because this requirement would in turn require users to download and verify the script code from the website of the third party every time they want to use it.

Depending on the blockchain application, even a full client may not need to store the full chain going back to the genesis block. That task can be reserved for a few archival nodes. The archival nodes can be used to bootstrap fully validating nodes from the beginning but are otherwise not active.

An example of a thin client is the *Simple Payment Verification* (SVP) client used in the Bitcoin application^[12]. The majority of nodes on the Bitcoin network are SVP clients.

An SVP client stores only the portions of a blockchain needed to verify specific transactions of interest to this client. The node downloads the block headers and transactions that represent payments to its addresses. An SPV node doesn't have the security level of a fully validating node. Since the node has block headers, it can check that the blocks were difficult to mine, but it can't check to see that every transaction included in a block is actually valid because it doesn't have the transaction history and doesn't know the set of unspent transactions outputs. SPV nodes can validate only the transactions that actually affect them. The SPV nodes trust the fully validating nodes to have validated all the other transactions that are out there. The cost savings of being an SPV node are substantial. The block headers are only about 0.1% the size of the block chain. So instead of storing tens of gigabytes, the SPV node stores only a few tens of megabytes. Even a smartphone can easily act as an SPV node in the Bitcoin network.

Blockchain Types

Broadly speaking, there are three types of blockchains^[13]. A *Public Blockchain* can be accessed and mined by anyone with Internet access. Access includes not only reading but also posting transactions, and they will be included if they are valid. Nodes participating in a public blockchain network do not have to obtain permission to access the ledger or add transactions. These blockchains are generally considered to be fully decentralized. Public blockchains have the benefit of information transparency and auditability, but they sacrifice information privacy.

A *Consortium Blockchain* is used across multiple organizations. The consensus process is controlled by authorized nodes. For example, one might imagine a consortium of 15 financial institutions, each of which operates a node and of which 10 must sign every block in order for the block to be valid. The right to read the blockchain may be public or restricted to the participants, and there are also hybrid variations such as the root hashes of the blocks being public together with an *Application Programming Interface* (API) that allows members of the public to make a limited number of queries and get back cryptographic proofs of some parts of the blockchain state. These blockchains may be considered partially decentralized.

A *Fully Private Blockchain*, or *Permissioned Blockchain*, limits write permissions to within a single organization that owns the blockchain. Read permissions may be public or restricted to an arbitrary extent. Likely applications include database management and auditing internal to a single company, so public readability may not be necessary in many cases at all, though in other cases public auditability is desired.

Currently, and projected for the foreseeable future, the majority of blockchain applications by market share are public. Most of the remainder are fully private^[14].

Bitcoin

The original application of blockchain, for which it was invented, is *Bitcoin*. Bitcoin is perhaps the most widely used alternative (non-state-issued) currency in the world. Bitcoin is a digital currency scheme^[15]. The network of miners literally creates money out of computer processing cycles. Currency within the system is given value (as it is in any money system) by its scarcity; in this system, the scarcity is created by requiring that money be processed by computationally intensive procedures. Having a great deal of computational power enables a miner to create Bitcoin value more quickly.

Blockchain provides the ledger for recording all of the digital currency transactions. Each transaction is potential only until it is recorded in a block that is accepted as valid and added to the chain. Recording requires the cooperative effort of the miners to achieve. As in incentive, miners are paid in Bitcoins for successfully adding a block to the blockchain.

Other Blockchain Applications

Great interest is being shown in applying blockchain technology to a wide variety of commercial and government applications. The following applications are listed in^[16]:

- *Nasdaq* is using its Linq blockchain technology to complete and record private securities transactions.
- *Depository Trust & Clearing Corporation*, working with market participants and technology firm Axoni, is managing post-trade events for credit default swaps.
- *Factom* is providing blockchain technology for the Honduran land registry project. The focus is data security.
- *Everledger's* focus is on the identity and legitimacy of objects. Blockchain works well here because its history cannot be changed and it enables trust by consensus. The company's initial work provides a distributed ledger of diamond ownership and transaction history verification for owners, insurance companies, claimants, and law enforcement agencies. The system assists with prevention of fraud in the supply chain, but also helps consumers decide whether to buy particular diamonds. The ultimate goal is to track diamonds from mine to market, so that consumers can see if correct duties and taxes have been paid and whether a diamond is a "blood diamond" that has been mined and traded in a war zone and contributed to human atrocity.

Blockchain technology has also caught the interest of numerous government agencies dealing with national security and homeland security, including *Defense Advanced Research Projects Agency* (DARPA) and the U.S. Air Force. The *Department of Homeland Security* (DHS) has awarded contracts for five projects that will use distributed ledger technology to develop new solutions for identity management and privacy protection^[17]:

- *Digital Bazaar* is developing a Linked Data ledger format and architecture to demonstrate how to publish identity credentials.
- *Respect Network Corporation* is developing a decentralized registry and discovery service to integrate with the public blockchain.
- *Narf Industries* is developing an identity management solution built on a permission-less blockchain, with a focus on confidentiality (with selective information disclosure), integrity, availability, non-DHS repudiation, provenance, and pseudo-anonymity.
- *Xcelerate Solutions* is researching blockchain solutions to enable users to establish and maintain trusted identity transactions with public and private organizations.
- *Factom* is studying possible blockchain-based advancements for the security of digital identities for the *Internet of Things* (IoT). The project will create an identity log that captures the identification of a device, who manufactured it, lists of available updates, known security issues, and granted authorities while adding the dimension of time for added security. The goal is to limit would-be hackers' abilities to corrupt the past records for a device, making it more difficult to spoof.

Another interesting development, one that indicates the growing and widespread popularity of the blockchain technology, is the *Initial Coin Offering* (ICO). With the ICO model, instead of selling ownership shares to investors to finance the start of the company, the startup sells digital coins, or tokens, that have value within the application or service the company offers. Sales of ICO tokens exceeded US\$250 million in 2016 and are estimated to exceed US\$1 billion in 2017^[18].

Open-Source Blockchain

In 2016, the Linux Foundation, a nonprofit that champions open-source technologies, announced the *Hyperledger* project, an effort to create an enterprise-grade distributed blockchain ledger framework (<https://www.hyperledger.org>)^[19, 20]. Participants in the group include R3, Cisco Systems, IBM, Intel, and VMware, among others. The objective of this project is to develop a standardized, production-grade digital ledger fabric. The project focuses on identifying and addressing important features for an enterprise-class, cross-industry open standard for distributed ledgers that can transform the way business transactions are conducted globally.

Figure 7 illustrates the current Hyperledger reference architecture within which open-source code is being developed.

Figure 7: Hyperledger Reference Architecture

Four main elements make up a Hyperledger-based application:

- *Membership*: Deals with registering, identifying, and auditing the activity of the peers who will use this particular ledger. The system distinguishes between two kinds of peers. A *validating peer* is a node on the network responsible for running consensus, validating transactions, and maintaining the ledger. A *non-validating peer* is a node that functions as a proxy to connect clients (issuing transactions) to validating peers.
- *Blockchain*: Consists of all the functions associated with building, storing, and providing access to a blockchain ledger.
- *Chaincode*: Implemented in Go, Chaincode is the realization of a smart contract. Each chaincode is encapsulated in a Docker container.
- *Transactions*: Examples of transaction types include the following: A *deploy* transaction takes a chaincode as a parameter; the chaincode is installed on the peers and is ready to be invoked. An *invoke* transaction invokes a transaction of a particular chaincode that has been installed earlier through a deploy transaction; the arguments are specific to the type of transaction. A *query* transaction returns an entry of the state directly from reading the peer's persistent state.

Smart Contracts

Smart Contracts (also called *Self-Executing Contracts*, *Blockchain Contracts*, or *Digital Contracts*) are computer programs that act as agreements, in which the terms of the agreement can be preprogrammed with the ability to self-execute and self-enforce itself. The main goal of a smart contract is to enable two anonymous parties to trade and do business with each other, usually over the Internet, without the need for a middleman.

The concept of smart contracts predates blockchain technology, but it is blockchain that has enabled the sudden growth in the use of smart contracts. One of the most prominent platforms for blockchain-based smart contracts is the open-source platform *Ethereum*^[21].

An example of the use of smart contracts is shown in Figure 8^[22].

Figure 8: Smart Contract Example

The steps involved follow:

1. Bob creates a digital contract to sell his car. He identifies himself with his blockchain address (757382), which is his public key, uses a smart contract to define the terms of the sale, and signs the contract with his private key. The terms might read as follows:

```

IF $20,000 is sent to my account number 757382
THEN Transfer car ID 73849Z to account number that transferred the money
Grant smart lock access to account number that transferred the money
  
```

That English language description corresponds to code embedded in the digital contract. When the contract is added to the blockchain ledger, the code is automatically executed.

2. Bob leaves his car and car key in a garage locked with a smart lock controlled by the smart contract. The car has its own blockchain address 73849Z, which is a public key stored on the blockchain.

3. Alice wants to buy the car and searches for a suitable contract via a web browser. She finds Bob's car listed and signs the contract with her private key, which triggers an automatic transfer of \$20,000 from her blockchain address (389157), which is her public key, to Bob's blockchain address 757382.
4. The signed smart contract is verified by each node in the blockchain network to verify that Bob is the owner of the car and that Alice has sufficient funds for the purchase.
5. If the network verifies the conditions, Alice automatically gets the access code to the smart lock for the garage (encrypted with Alice's public key), Alice is registered as the new owner, and \$20,000 is transferred to Bob.
6. Alice can obtain the access code using her private key and then use the access code to pick up her car.

The whole process is distributed, automated, and does not require a central authority. In general, any blockchain-based smart contract employs the following steps:

1. A contract is defined. For some applications, there is a pre-defined contract specifying the terms of the contract and conditions for execution.
2. An event triggers the execution of the contract. An event could be the initiation of a transaction or the receipt of information.
3. When the contract is added to the blockchain ledger, the contract is executed, a process that typically involves movement of some value based on conditions met.
- 4a. For digital assets on the blockchain, such as cryptocurrency, accounts are automatically settled.
- 4b. For assets that are not part of the blockchain, such as stocks, changes to accounts in the ledger will match settlement instructions off the blockchain.

The smart contract model is very flexible and can be used in a wide variety of applications; some of them are listed in Table 2^[23] on the following page.

Table 2: Blockchain Use Cases

Use Case	Description
Trade Clearing and Settlement	Manages approval workflows between counterparties, calculates trade settlement amounts, and transfers funds automatically
Coupon Payments	Automatically calculates and pays periodic coupon payments and returns principle upon bond expiration
Insurance Claims Processing	Performs error checking, routing, and approval workflows, and calculates payout based on the type of claim and underlying policy
Micro-insurance	Calculates and transfers micropayments based on usage data from an IoT-enabled device (for example, pay-as-you-go automotive insurance)
Electronic Medical Records	Provides transfer and/or access to medical records upon multi-signature approvals between patients and providers
Population Health Data Access	Grants health researchers access to certain health information; micropayments are automatically transferred to the patient for participation
Personal Health Tracking	Tracks patients' health-related actions through IoT devices and automatically generates rewards based on specific milestones
Royalty Distribution	Calculates and distributes royalty payments to artists and other associated parties according to the contract
Autonomous Electric Vehicle Charging Station	Processes a deposit, enables the charging station, and returns remaining funds when complete
Record Keeping	Updates private company share registries and capitalization table records, and distributes shareholder communications
Supply Chain and Trade Finance Documentation	Transfers payments upon multi-signature approval for letters of credit and issues port payments upon custody change for bills of lading
Product Provenance and History	Facilitates chain-of-custody process for products in the supply chain where the party in custody is able to log evidence about the product
Peer-to-Peer Transacting	Matches parties and transfer payments automatically for various peer-to-peer applications: lending, insurance, energy credits, etc.
Voting	Validates voter criteria, logs vote to the blockchain, and initiates specific actions as a result of the majority vote

Summary

Four elements characterize blockchain:

Blockchain is a Replicated Ledger. The ledger provides a history of all transactions that is immutable and is changed only by appending at the newest end of the linear chain of blocks that implements the ledger. The ledger is distributed and readable by all participants.

Blockchain operates by Consensus. Consensus is implemented by means of a shared, decentralized, peer-to-peer protocol. This shared control of the blockchain tolerates disruption, in that from time to time there may be temporary forks in the otherwise linear chain. The consensus mechanism is a means for validating transactions.

Fundamental to the operation of blockchain is *Cryptography*. Various cryptographic algorithms ensure the integrity of the ledger, the authenticity of transactions, the privacy of transactions, and the identity of participants.

Finally, blockchain is a versatile framework for implementing *Business Logic* that is embedded in the ledger. This logic is application-dependent and is reflected in the format and content of the transactions.

In Defence of NATs

by Geoff Huston, APNIC

Network Address Translation (NAT) has often been described as an unfortunate aberration in the evolution of the Internet, and one that will be expunged with the completion of the transition to *Internet Protocol Version 6* (IPv6). I think that this view, which appears to form part of today's conventional wisdom about the Internet, unnecessarily vilifies NATs. In my opinion, NATs are far from being an aberration; instead I see them as an informative and positive step in the evolution of the Internet, particularly as they relate to possibilities in the evolution of name-based networking. Here's why.

Background

It was in 1989, some months after the US National Science Foundation-funded IP backbone network had been commissioned, and at a time when there was a visible momentum behind the adoption of IP as a communications protocol of choice, that the first inklings of the inherent finite nature of the IPv4 address became apparent in the *Internet Engineering Task Force* (IETF)^[1].

Progressive iterations over the IP address consumption numbers reached the same general conclusion: that the momentum of IP deployment meant that the critical parts of the 32-bit address space would be fully committed within 6 or so years. It was predicted that by 1996 we would have fully committed the pool of Class B networks, which encompassed one quarter of the available *Internet Protocol Version 4* (IPv4) address space. At the same time, we were concerned about the pace of growth of the routing system, so stop-gap measures that involved assigning multiple Class C networks to sites could have staved off exhaustion for a while, but perhaps at the expense of the viability of the routing system^[2].

The IETF considered other forms of temporary measures, and the stop-gap measure that was adopted in early 1994 was the dropping of the implicit network/host partitioning of the address in classful addressing in favour of the use of an explicit network mask, or *classless* addressing. This change directly addressed the pressing nature problem of the exhaustion of the Class B address pool, as the observation at the time was that while a Class C network was too small for many sites given the recent introduction of the personal computer, Class B networks were too large, and many sites were unable to realise reasonable levels of address use with Class B addresses. This move to classless addressing (and classless routing, of course) gained some years of breathing space before the major impacts of address exhaustion, and the time gained was considered enough to complete the specification and deployment of a successor IP protocol^[3].

In the search for a successor IP protocol, several ideas were promulgated. The decisions around the design of IPv6 related to a desire to make minimal changes to the IPv4 specification, while changing the size of the address fields and changing some of the encoding of control functions by using the extension header concept, and changing the fragmentation behaviour to stop routers from performing fragmentation in real time^[4].

The common belief at the time was that the adoption of classless addressing in IPv4 bought sufficient time to allow the deployment of IPv6 to proceed. It was anticipated that IPv6 would be deployed across the entire Internet well before the remaining pools of IPv4 addresses were fully committed. This assumption, together with a deliberate approach for hosts to prefer to use IPv6 for communication when both IPv4 and IPv6 was available for use, would imply that the use of IPv4 would naturally dwindle away as more IPv6 was deployed, and that no “flag day” or other means of coordinated action would be needed to complete this Internet-wide protocol transition^[5].

In the flurry of documents that discussed a successor protocol was work that explored the concepts behind “address realms” where one single unique address realm could be replaced by a number of distinct address realms, where the addresses in a packet header could be rewritten when the packet passed across a realm boundary^[6]. One paper at that time described the concept of source address sharing^[7]. If a processing unit was placed on the wire, it was possible to intercept all outbound *Transmission Control Protocol* (TCP) and *User Datagram Protocol* (UDP) packets and replace the source IP address with a different address and change the packet header checksum, and then forward the packet on towards its intended destination. As long as this unit used one of its own addresses as the new address, then any response from the destination would be passed back to this unit. The unit could then use the other fields of the incoming IP packet header, namely the source address and the source and destination port addresses, to match this packet with the previous outgoing packet and perform the reverse address substitution, this time replacing the destination address with the original source address of the corresponding outgoing packet. This scenario allowed multiple internal end systems to use a “public” address, provided that they were not all communicating simultaneously. More generally, a pool of public addresses could be shared across a larger pool of internal systems.

It may not have been the original intent of the inventors of this address-sharing concept, but the approach was enthusiastically adopted by the emerging *Internet Service Provider* (ISP) industry in the 1990s. ISPs were seeing the emergence of the home network and were unprepared to respond to it. With the previous deployment model, using dial-up modems, each active customer was assigned a single IP address as part of the session start process.

A NAT in the gateway to the home network could extend this “single IP address per customer” model to include households with home networks and multiple attached devices. To do so efficiently a further refinement was added, namely that the source port was part of the translation. That way up to 65,535 simultaneous TCP sessions could theoretically share a single external address, provided that the NAT could rewrite the source port along with the source address^[8].

For the ensuing decade NATs were deployed at the edge of the network, and ISPs have used them as a means of externalising the need to conserve IP addresses. The address-sharing technology was essentially deployed by, and operated by, the end customer, and within the ISP network each connected customer still required just a single IP address.

But perhaps that role is underselling the value of NATs in the evolution of the Internet. NATs provided a *firewall* between the end customer and the carrier. The telephony model shared the same end-to-end service philosophy, but it achieved this protection by exercising overarching control over all components of the service. For many decades, the telephone network was a controlled monopoly that was intolerant of any form of competitive interest in the customer. The Internet did not go down this path, and one of the reasons why is that NATs allowed end customers to populate their home network with whatever equipment they chose, and via a NAT, present to the ISP carrier as a single “termination” with a single IP address. This effective segmentation of the network created a parallel segmentation in the market, which allowed the consumer services segment to flourish without carrier-imposed constraint. And at the time that was critically important. The Internet wasn’t the next generation of the telephone service. It was an entirely different utility service operating in an entirely different manner.

More recently, NATs have appeared within the access networks themselves, performing the address-sharing function across a larger set of customers. This function was first associated with mobile access networks but has been used in almost all recent deployments of access networks, as a response to the visible scarcity in the supply of available IPv4 addresses.

NATs have not been universally applauded. Indeed, in many circles within the IETF, NATs were deplored.

It was observed that NATs introduced active middleware into an end-to-end architecture, and divided the pool of attached devices into clients and servers. Clients (behind NATs) had no constant IP address and could not be the target of connection requests. Clients could communicate only with servers, not with each other. It appeared to some to be a step in a regressive direction that imposed a reliance on network middleware with its attendant fragility, and imposed an asymmetry on communication^[9].

For many years, the IETF did not produce standard specifications for the behaviour of NATs, particularly in the case of handling of UDP sessions. Because UDP has no specific session controls, such as session opening and closing signals, how was a NAT meant to maintain its translation state? In the absence of a specific standard specification, different implementations of this function made different assumptions and implemented different behaviour, introducing another detrimental aspect of NATs: *variability*.

How could an application operate through a NAT if the application used UDP? The result was the use of various NAT discovery protocols that attempted to provide the application with some understanding of the particular form of NAT behaviour that it encountered^[10].

NATs in Today's Internet

Let's now look at the situation today in the Internet of late 2017. The major hiatus in the supply of additional IPv4 addresses commenced in 2011 when the central *Internet Assigned Numbers Authority* (IANA) pool of unallocated IPv4 addresses was exhausted. Progressively the *Regional Internet Registries* (RIRs) ran down their general allocation address pools: *Asia Pacific Network Information Centre* (APNIC) in April 2011, *Réseaux IP Européens Network Coordination Centre* (RIPE NCC) in September 2012, *Latin America and Caribbean Network Information Centre* (LACNIC) in 2014, and *American Registry for Internet Numbers* (ARIN) in 2015. The intention from the early 1990s was that the impending threat of imminent exhaustion of further addresses would be the overwhelming impetus to deploy the successor protocol. By that thinking then the Internet would have switched to use IPv6 exclusively before 2011. Yet, that has not happened.

Today a minimum of 90% of the connected device population of the Internet still uses IPv4 exclusively, while the remainder use IPv4 and IPv6^[11]. This network is an all-IPv4 network with a minority proportion also using IPv6. Estimates vary of the device population of today's Internet, but they tend to fall within a band of 15 to 25 billion connected devices^[12]. Yet only some 2.8 billion IPv4 addresses are visible in the Internet routing system. This reality implies that on average each announced public IPv4 address serves from 3 to 8 hidden internal devices.

Part of the reason why estimates of the total population of connected devices are so uncertain is that NATs occlude these internal devices so effectively that no conventional Internet census can expose these hidden internal device pools with any degree of accuracy.

And part of the reason why the level of IPv6 deployment is still so low is that users, and the applications that they value, appear to operate perfectly well in a NATed environment. The costs of NAT deployment are offset by preserving the value of existing investment, both as a tangible investment in equipment and as an investment in knowledge and operational practices in IPv4.

NATS can be deployed incrementally, and they do not rely on some ill-defined measure of coordination with others to operate effectively. They are perhaps one of the best examples of a piecemeal incremental deployment technology where the incremental costs of deployment directly benefit the entity who deployed the technology. This situation is in direct contrast to IPv6 deployment, where the ultimate objective of the deployment, namely the comprehensive replacement of IPv4 in the Internet, can be achieved only after a significant majority of the population of the Internet are operating in a mode that supports both protocols. Until then the deployments of IPv6 are essentially forced to operate in a dual-stack mode, and also support IPv4 connectivity. In other words, the incremental costs of deployment of IPv6 generate incremental benefit only when others also take the same decision to deploy this technology. Viewed from the perspective of an actor in this space, the pressures and costs to stretch the IPv4 address space to encompass an ever-growing Internet are a constant factor. The decision to complement that factor with a deployment of IPv6 means an additional cost that in the short term does not offset any of the IPv4 costs.

So, for many actors the question is not “Should I deploy IPv6 now?” but “How far can I go with NATs?” By squeezing some 25 billion devices into 2 billion active IPv4 addresses, we have used a compression ratio of around 14:1, or the equivalent of adding 4 additional bits of address space. These bits have been effectively “borrowed” from the TCP and UDP port address space. In other words, today’s Internet uses a 36-bit address space in aggregate to allow these 25 billion devices to communicate.

Each additional bit doubles this pool, so the theoretical maximum space of a comprehensively NATed IPv4 environment is 48 bits, fully accounting for the 32-bit address space and the 16-bit port address space. This number is certainly far less than the IPv6 128 bits of address space, but the current division of IPv6 into a 64-bit network prefix and a 64-bit interface identifier drops the available IPv6 address space to 64 bits. The prevalent use of a /48 as a site prefix introduces further address use inefficiencies that effectively drop the IPv6 address space to span the equivalent of some 56 bits.

NATs can be pushed harder. The “binding space” for a NAT is a 5-tuple consisting of the source and destination IP address, a source and destination port address, and a protocol identifier. This 96-bit NAT address space is a highly theoretic ceiling, but the pragmatic question is how much of this space can be exploited cost-effectively such that the marginal cost of exploitation is lower than the cost of an IPv6 deployment.

NATs as Architecture

NATs appear to have pushed applications to a further level of refinement and abstraction that were at one point considered to be desirable objectives rather than onerous limitations.

The maintenance of both a unique fixed-endpoint address space and a uniquely assigned name space for the Internet could be regarded as an expensive luxury when it appears that only one of these spaces is strictly a necessity in terms of ensuring integrity of communication.

The IPv4 architecture made several simplifying assumptions—one of which was that an IPv4 address was overloaded with both the unique identity of an endpoint and its network location. In an age where computers were bolted to the floor of a machine room, this assumption seemed very minor. However, in today's world it appears that the overwhelming number of connected devices are portable devices that change their location constantly, both in a physical sense and in terms of network-based location. This paradigm places stress on the IP architecture, and the result is that IP is variously tunnelled or switched in the final-hop access infrastructure in order to preserve the overloaded semantics of IP addresses.

NATs deliberately disrupt this relationship, and the presented client-side address and port have a particular interpretation and context only for the duration of a session.

In the same way that clients now share IP addresses, services now also share addresses. Applications cannot assume that the association of a name to an IP address is a unique 1:1 relationship. Many service-identifying names may be associated with the same IP address, and in the case of multihomed services the name could be associated with several IP addresses.

With this change comes the observation that IP addresses are no longer the essential “glue” of the Internet. They have changed to a role of ephemeral session tokens that have no lasting semantics. NATs are pushing us to a different network architecture that is far more flexible—a network that uses names as the essential glue that binds it together.

We are now in the phase of the Internet evolution where the address space is no longer unique, and we rely on the name space to offer coherence to the network.

From that perspective, what does IPv6 really offer?

More address bits? Well perhaps not all that much. The space created by NATs operates from within a 96-bit vector of address and port components, and the usable space may well approach the equivalent of a 50-bit conventional address architecture. On the other hand, the IPv6 address architecture has stripped off some 64 bits for an interface identifier and conventionally uses a further 16 bits as a site identifier. The resulting space is of the order of 52 bits. It's not clear that the two pools of address tokens are all that much different in size.

More flexibility? IPv6 is a return to the overloaded semantics of IP addresses as being unique endpoint tokens that provide a connected device with a static location and a static identity. This situation appears to be somewhat ironic in view of the observation that increasingly the Internet is largely composed of battery-powered mobile devices of various forms.

Cheaper? Possibly, in the long term, but not in the short term. Until we get to the “tipping point” that would allow a network to operate solely using IPv6 without any visible impact on the user population of the network, then every network still must provide a service using IPv4.

Permanent address-to-endpoint association? Well, not really. Not since we realised that having a fixed interface identifier represented an unacceptable privacy leak. These days IPv6 clients use so-called *privacy addresses* as their interface identifier, and regularly change this local identifier value.

Perhaps we should appreciate the role of NATs in supporting the name-based connectivity environment that is today’s Internet. It was not a deliberately designed outcome, but a product of incremental evolution that has responded to the various pressures of scarcity and desires for greater flexibility and capability. Rather than eschewing NATs in the architecture as an aberrant deviation in response to a short-term situation, we may want to contemplate an Internet architecture that embraces a higher level of flexibility of addressing. If the name space is truly the binding glue of the Internet, then perhaps we might embrace a view that addresses are simply needed to distinguish one packet flow from another in the network, and nothing more.

Appreciating NATs

When NATs were first introduced to the Internet, they were widely condemned as an aberration in the Internet architecture. And in some ways NATs have directly confronted the model of a stateless packet switching network core and capable attached edge devices.

But that model has been a myth for decades. The Internet as it is deployed is replete with various forms of network “middleware,” and the concept of a simple stateless packet switching network infrastructure has been relegated to the status of an historical, but now somewhat abstract, concept.

In many ways, this condemnation of NATs was unwarranted, as we can reasonably expect that network middleware is here to stay, irrespective of whether the IP packets are formatted as IPv4 or IPv6 and irrespective of whether the outer IP address fields in the packets are translated or not.

Rather than being condemned, perhaps we should appreciate the role that NATs play in the evolution of the architecture of the Internet.

We have been contemplating what it means to have a name-based data network, where instead of using a fixed relationship between names and IP addresses, we eschew this mapping and perform network transactions by specifying the name of the desired service or resource^[13]. NATs are an interesting step in this direction, where IP addresses have lost their fixed association with particular endpoints, and are used more as ephemeral session tokens than endpoint locators. This step certainly appears to be an interesting one in the direction of named data networking.

The conventional wisdom is that the endpoint of this current transitioning Internet is an IPv6 network that has no further use for NATs. But it may not be true. We may find that NATs continue to offer an essential level of indirection and dynamic binding capability in networking that we would rather not casually discard. It may be that NATs are a useful component of network middleware and that they continue to have a role in the Internet well after this transition to IPv6 has been completed, whenever that may be!

Kimberly C. Claffy Honored with Postel Award

The Internet Society, a global non-profit dedicated to ensuring the open development, evolution and use of the Internet, recently announced that Dr. Kimberly C. Claffy, founder and director of the *Center for Applied Internet Data Analysis* (CAIDA) is this year's recipient of the prestigious *Jonathan B. Postel Service Award*.

© Stonehouse
Photographic/Internet Society

Dr. Claffy is a pioneer in the field of measuring and understanding the Internet, not only through her research contributions, but her commitment to establishing and operating infrastructure to support large-scale data collection, curation, and sharing with the scientific research community.

The Postel Award was established by the Internet Society to honor individuals or organizations that, like Jon Postel, have made outstanding contributions to the data communications community. The award is focused on sustained and substantial technical contributions, service to the community, and leadership.

Dr. Claffy was selected by an international award committee comprised of former Postel Award winners. The committee placed particular emphasis on candidates who have supported and enabled others in addition to their own contributions. The committee noted that the award is being presented to Dr. Claffy in recognition for: “her pioneering work on Internet measurement through the development of infrastructure and methodologies for data collection, analysis, and sharing around the world.”

The first of Dr. Claffy’s many papers on Internet traffic measurement and analysis was published in 1992, years before the Internet transitioned to the global, private sector led network it is today. Since then, she has published dozens of papers and received numerous grants and awards for her work.

In 1997 Dr. Claffy founded CAIDA, based at the University of California’s San Diego Super-computer Center, as a center which conducts network research and builds research infrastructure to support large-scale data collection, curation, and data distribution to the scientific research community.

“Simply put, Dr. Claffy’s long-standing and pioneering work has helped the global community better understand the Internet and how it is used,” explained Kathy Brown, President and CEO of the Internet Society, who presented the award.

“In addition to leading the way in the field of Internet measurement and analysis itself, her dedication of resources to ensure widespread access to measurement data has allowed a range of disciplines—from network science and network operations to political science and public policy—to benefit from her efforts.”

KSK Rollover Postponed

The *Internet Corporation for Assigned Names and Numbers* (ICANN) recently announced that the plan to change the cryptographic key that helps protect the *Domain Name System* (DNS) is being postponed. Changing the key involves generating a new cryptographic key pair and distributing the new public component to the *Domain Name System Security Extensions* (DNSSEC)-validating resolvers. Based on the estimated number of Internet users who use DNSSEC validating resolvers, an estimated one-in-four global Internet users, or 750 million people, could be affected by the KSK rollover.

The changing or “rolling” of the *Key Signing Keys* (KSK) was originally scheduled to occur on October 11, 2017, but it is being delayed because some recently obtained data shows that a significant number of resolvers used by *Internet Service Providers* (ISPs) and Network Operators are not yet ready for the rollover. The availability of this new data is due to a very recent DNS protocol feature that adds the ability for a resolver to report back to the root servers which keys it has configured. There may be multiple reasons why operators do not have the new key installed in their systems: some may not have their resolver software properly configured and a recently discovered issue in one widely used resolver program appears to not be automatically updating the key as it should, for reasons that are still being explored.

ICANN is reaching out to its community, including its Security and Stability Advisory Committee, the *Regional Internet Registries*, Network Operator Groups and others to help explore and resolve the issues. In the meantime, ICANN believes it prudent to follow its process and to delay the changing of the key rather than run the risk of a significant number of Internet users being adversely affected. ICANN is committed to continuing its education, communication and engagement with the relevant technical organizations to ensure readiness for the key change.

“The security, stability and resiliency of the domain name system is our core mission. We would rather proceed cautiously and reasonably, than continue with the roll on the announced date of 11 October,” said Göran Marby, ICANN CEO. “It would be irresponsible to proceed with the roll after we have identified these new issues that could adversely affect its success and could adversely affect the ability of a significant number of end users.”

A new date for the Key Roll has not yet been determined. ICANN’s Office of the Chief Technology Officer says it is tentatively hoping to reschedule the Key Roll for the first quarter of 2018, but that it will be dependent on more fully understanding the new information and mitigating as many potential failures as possible. ICANN will provide additional information as it becomes available and the new Key Roll date will be announced as appropriate.

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

We live in a complex and increasingly interconnected world. With this complexity comes a desire by network engineers to design systems that can cope with increasing demands while still offering predictable performance, manageability, and maintainability. In our first article, Russ White discusses ways to analyze network designs from a complexity point of view.

The *Internet Protocol* (IP) was designed to operate over a variety of underlying network technologies, such as Ethernet, X.25, FDDI, Frame Relay, WiFi, and even mobile telephone networks. Applications that use IP must deal with the fact that datagrams may be split into *fragments* as they travel across the network with subsequent *reassembly* at the receiving end. Previous articles in this journal have discussed fragmentation, largely in the context of IPv4. This time Geoff Huston describes fragmentation in IPv6 and the particular challenges that arise with this protocol in conjunction with applications such as the *Domain Name System* (DNS).

We usually provide a section of announcements entitled “Fragments,” but this time it has been replaced by a selection of Letters to the Editor—all in response to articles in our November 2017 issue. We are very happy to receive feedback on any aspect of this journal, and we would also point you to our website, which contains additional articles and material as well as all of our back issues in PDF format.

As mentioned in previous issues, if you have a print subscription to this journal, you will find an expiration date printed on the back cover. For the last couple of years, we have “auto-renewed” your subscription, but now we ask you to log in to our subscription system and perform this simple task yourself. The subscription portal is here: <https://www.ipjsubscription.org/> This process will ensure that we have your current contact information as well as delivery preference (print edition or download). For any questions, contact us by e-mail at: ipj@protocoljournal.org

Considerations in Network Complexity

by Russ White

Computer networks are complex—and getting more complex by the day. At one time, knowing the *Internet Protocol* (IP) was enough; today there are underlays, overlays, virtualized services, service chains, and a host of other technologies engineers need to plan around and for. With complexity on the rise, maybe it's time to ask some fundamental questions, such as—what does complexity mean? Can complexity be solved? How can engineers manage complexity?

Why So Complex?

While the most obvious place to begin might be with a definition of complexity, it's actually more useful to consider why complexity is required in a more general sense. To put it more succinctly, is it possible to “solve” complexity? Why not just design networks and protocols that are simpler? Why does every attempt to make anything simpler in the networking world end up apparently making things more complex in the long run? For instance, tunneling on top of (or through) IP reduces the complexity of the control plane and makes the network simpler overall. Why is it, then, that tunneled overlays end up containing so much complexity?

This question has two answers: The first is that human nature being what it is, engineers will always invent 10 different ways to solve the same problem. This reality is especially true in the virtual world, where new solutions are (relatively) easy to deploy, it's (relatively) easy to find a problem with the last set of proposed solutions, and it's (relatively) easy to move some bits around to create a new solution that is “better than the old one.” The virtual space, in other words, is partially so messy because it's so easy to build something new there.

- Abstract the complexity away, to build a black box around each part of the system, so each piece and the interactions among these pieces are more immediately understandable.
- Toss the complexity over the cubicle wall—to move the problem out of the networking realm into the realm of applications, or coding, or a protocol. As RFC 1925^[1] says, “It is easier to move a problem around (for example, by moving the problem to a different part of the overall network architecture) than it is to solve it.”
- Add another layer on top, to treat all the complexity as a black box by putting another protocol or tunnel on top of what's already there. Returning to RFC 1925, “It is always possible to add another level of indirection.”
- Become overwhelmed with the complexity, label what exists as “legacy,” and chase some new shiny thing that will solve all the problems in what is perceived as a much less complex way.

- Ignore the problem and hope it will go away. Argue for an exception “just this once,” to meet a particular business goal, or fix some problem, within a very tight schedule, with the promise that the complexity issue will be dealt with “later,” is a good example.

The second answer, however, lies in a more fundamental problem: complexity is necessary to deal with the uncertainty involved in problems that are difficult to solve (Figure 1).

Figure 1: Complexity, Effectiveness, and Robustness

Adding complexity, then, allows a network to handle future requirements and unexpected events more easily, as well as providing more services over a smaller set of base functions. If this condition is the case, why not simply build a single protocol running on a single network that can handle all the requirements potentially thrown at it, and can handle any sequence of events you can imagine? A single network running a single protocol would certainly reduce the number of moving parts network engineers need to deal with, making all our lives simpler, right?

Maybe not. At some point, any complex system becomes brittle—*robust yet fragile* is one phrase you can use to describe this condition. A system is robust yet fragile when it is able to react resiliently to an expected set of circumstances, but an unexpected set of circumstances will cause it to fail. As an example from the real world—knife blades are required to have a somewhat unique combination of characteristics. They must be hard enough to hold an edge and cut, and yet flexible enough to bend slightly in use, returning to their original shape without any evidence of damage, and they must not shatter when dropped. It has taken years of research and experience to find the right metal to make a knife blade, and there are still long and deeply technical discussions about which material is right for specific properties, under what conditions, etc.

Complexity is necessary, then: it cannot be “solved.”

Defining Complexity

Given complexity is necessary, engineers are going to need to learn to manage it in some way, by finding or building a model or framework. The best place to begin to build such a model is with the most fundamental question: what does complexity mean in terms of networks? Can you put a network on a scale and have the needle point to “complex?” Is there a mathematical model into which you can plug the configurations and topology of a set of network devices that will, in turn, produce a “complexity index?” How do the concepts of scale, resilience, brittleness, and elegance relate to complexity? The best place to begin in building a model is with an example.

Control-Plane State versus Stretch

What is network *stretch*? In the simplest terms possible, it is the difference between the shortest path in a network and the path traffic between two points actually takes. Figure 2 illustrates this concept.

Figure 2: A Small Network to Illustrate State and Stretch

Assuming the cost of each link in this network is the same, the shortest physical path between Routers A and C will also be the shortest logical path: [A,B,C]. What happens, however, if we change the metric on the [A,B] link to 3? The shortest physical path is still [A,B,C], but the shortest logical path is now [A,D,E,C]. The differential between the shortest physical path and the shortest logical path is the distance a packet being forwarded between Routers A and C must travel—in this case, the stretch can be calculated as $(4 [A,D,E,C]) - (3 [A,B,C])$, for a stretch of 1.

How Is Stretch Measured?

In terms of hop count, is stretch measured by the summary of the metrics, the delay through the network, or some other way? It depends on what is most important in any given situation, but the most common way is by comparing hop counts through the network, and this method is used in the examples here for simplicity. In some cases, it might be more important to consider the metric along two paths, the delay along two paths, or some other metric, but the important point is to measure it consistently across every possible path to allow for accurate comparison between paths.

It's sometimes difficult to differentiate between the physical topology and the logical topology. In this case, was the [A,B] link metric increased because the link is actually a slower link? If so, whether this is an example of stretch or an example of simply bringing the logical topology in line with the physical topology is debatable.

In line with this observation, it's much easier to define policy in terms of stretch than almost any other way. Policy is any configuration that increases the stretch of a network. Using *Policy-Based Routing* or *Traffic Engineering* to push traffic off the shortest physical path and onto a longer logical path to reduce congestion on specific links, for instance, is a policy—it increases stretch.

Increasing stretch is not always a bad thing. Understanding the concept of stretch simply helps us understand various other concepts, and put a framework around complexity tradeoffs. The shortest path, physically speaking, isn't always the best path.

Stretch, in this illustration, is very simple—it affects every destination, and every packet flowing through the network. In the real world, things aren't so simple. Stretch is actually per source/destination pair, making it very difficult to measure on a networkwide basis.

With all of this information in mind, let's look at two specific examples of the tradeoff between stretch and optimization.

Aggregation versus Stretch

Aggregation is a technique used to reduce not only the amount of information carried in the control plane, but also the rate of state change in the control plane. Aggregation is built into IP (both IPv4 and IPv6)—even a single subnet contains multiple host addresses. By connecting a single broadcast segment to a set of hosts, the IP routing protocol doesn't need to manage Layer 2 reachability, nor individual host addresses. Aggregation within the control plane can also cause stretch, as Figure 3 shows.

Figure 3: Aggregation and Stretch

Two different situations illustrate increasing stretch through route aggregation:

1. Assume the [A,B] link has a cost of 2, and all the other links in this network have a cost of 1. If Routers B and C both aggregate to `2001:db8::/61`, then the path through [A,C] would be preferred for everything within the aggregate. Traffic destined to `2001:db8:0:1::/64` will pass along the path [A,C,E,D] to reach its destination, even though the shortest (physical) path is [A,B,D]. The stretch for `2001:db8:0:2::/64` isn't changed, but the stretch for `2001:db8:0:1::/64` is increased by 1.
2. Assume all the links in the network have a cost of 1. If Routers B and C both aggregate to `2001:db8::/61`, then Router A will somehow load share traffic toward the two subnets behind Routers D and E across the two equal-cost paths it has available. Given perfect load sharing, 50% of the traffic destined to `2001:db8:0:1::/64` will flow along [A,C,E,D], with a stretch of 1, and 50% of the traffic destined to `2001:db8:0:2::/64` will flow along [A,B,D,E], with a stretch of 1.

Implementing aggregation removes specific reachability information about the two /64 prefixes behind Routers D and E from the state of Router A. Implementing aggregation also disconnects the state of the individual /64's behind Routers D and E from the state at Router A. Aggregation, then, decreases complexity from the perspective of Router A by reducing the *amount* and *speed* of state in the routing table of Router A.

Increasing stretch increases the overall use of the network without any actual increase in the amount of traffic being carried through the network. In the example given in Figure 2, traffic that would normally take a two-hop path is directed along a three-hop path, meaning one more link and router are involved in forwarding and switching the packets in the flow(s) across the network. In purely mathematical terms, increasing stretch decreases the overall efficiency of the network by increasing the number of devices and links used to forward any particular flow.

Finally, to implement aggregation Routers B and C must be configured to summarize the two longer prefixes into a single shorter one. This additional configuration introduces an additional bit of interaction between the human operator (or at least the configuration system) and the control plane. This situation can be described as an increase in *surface* in the network.

Defining Complexity: A Model

These three components—*state*, *optimization*, and *surface*—are common in virtually every network or protocol design decision. They can be seen as a set of tradeoffs, as illustrated in Figure 4.

Figure 4: The Plane of the Possible

Increasing optimization always moves towards more state or more interaction surfaces. Decreasing state always moves towards less optimization or more interaction surfaces. Decreasing interaction surfaces always moves towards less optimization or more state. These rules aren't ironclad, of course; they are contingent on the specific network, protocols, and requirements, but they are generally true often enough to make this model useful for understanding tradeoffs in complexity.

Interaction Surfaces

While state and optimization are fairly intuitive, it's worthwhile to spend just a moment more on interaction surfaces. The concept of interaction surfaces is difficult to grasp primarily because it covers such a wide array of ideas. Perhaps an example would be helpful; assume a function that:

- Accepts two numbers as input
- Adds them
- Multiplies the resulting sum by 100
- Returns the result

This single function can be considered a subsystem in some larger system. Now assume you break this single function into two functions, one of which does the addition, and the other of which does the multiplication. You've created two simpler functions (each one does only one thing), but you've created an interaction surface between the two functions—you've created two interacting subsystems within the system where there used to be only one. This example is really simple, I know, but consider a few more that might help.

The routing information carried in *Open Shortest Path First* (OSPF) is split into *external* routes being carried in *Border Gateway Protocol* (BGP) and *internal* routes being carried in OSPF. You've gone from one system with more state to two systems with less state, but you've created an interaction surface between the two protocols—they must now work together to build a complete forwarding table.

A single set of hosts with different access policies is split onto multiple virtual topologies on the same physical network. You've simplified the amount of state in filtering, but you've created an interaction surface between the two virtual topologies and between the two topologies and the control plane. In addition, you've exposed new shared risk groups where a single physical failure can cause multiple logical ones. Hence you've traded state in one control plane for interaction surfaces between multiple control planes.

Even two routers communicating within a single control plane can be considered an interaction surface. This breadth of definition is what makes it so very difficult to define what an interaction surface is.

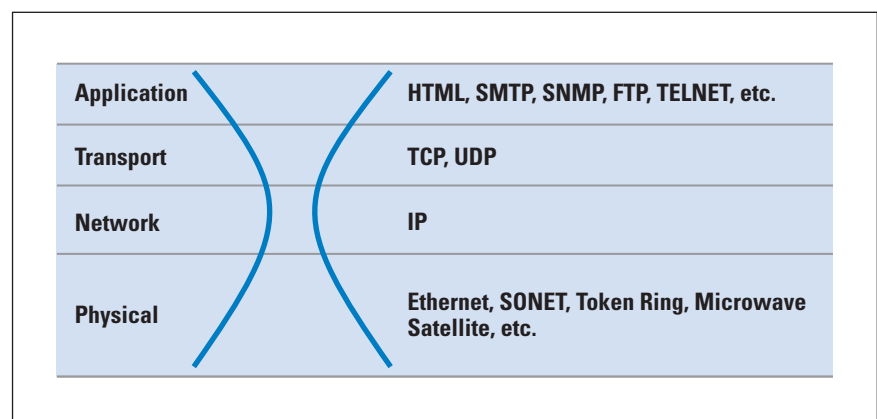

Interaction surfaces aren't a bad thing; they help engineers and designers divide and conquer in any given problem space, from modeling to implementation. At the same time, interaction surfaces are all too easy to introduce without thought.

Managing Complexity through the Wasp Waist

There is a simple model that is ubiquitous throughout the natural world, and is widely mimicked in the engineering world. While engineers don't often consciously apply this model, it's actually used all the time. What is this model?

Figure 5 illustrates the hourglass model in the context of the four-layer *Department of Defense* (DoD) model that gave rise to the *Internet Protocol Suite*.

Figure 5: The DoD Model and the "Wasp Waist"

At the bottom layer, the physical transport system, there is a wide array of protocols, from Ethernet to Satellite. At the top layer, where information is marshaled and presented to applications, there is a wide array of protocols, from *Hypertext Transfer Protocol* (HTTP) to TELNET (and thousands of others besides). A funny thing happens when you move towards the middle of the stack, however: the number of protocols decreases, creating an hourglass. Why does this work to control complexity?

Going back through the three components of complexity—*state*, *optimization*, and *surface*—exposes the relationship between the hourglass and complexity.

- *State* is divided by the hourglass into two distinct types of state: information about the network, and information about the data being transported across the network. While the upper layers are concerned with marshaling and presenting information in a usable way, the lower layers are concerned with discovering what connectivity exists and what the properties of that connectivity actually are. The lower layers don't need to know how to format a *File Transfer Protocol* (FTP) frame, and the upper layers don't need to know how to carry a packet over Ethernet—state is reduced at both ends of the model.
- *Optimization* is traded off by allowing one layer to reach into another layer, and by hiding the state of the network from the applications. For instance, the *Transmission Control Protocol*, (TCP) doesn't really know the state of the network other than what it can gather from local information. TCP could potentially be much more efficient in its use of network resources, but only at the cost of a layer violation, which opens up interaction surfaces that are difficult to control.
- *Surfaces* are controlled by reducing the number of interaction points between the various components to precisely one—IP. This single interaction point can be well defined through a standards process, with changes in the one interaction point closely regulated to prevent massive rapid changes that will reflect up and down the protocol stack.

The layering of a stacked network model is, then, a direct attempt to control the complexity of the various interacting components of a network.

Managing Complexity as an Engineer

Managing complexity in design in a general sense is just one application of the state/optimization/surface model. Another use is in learning how to understand complex systems quickly—a skill every engineer could use in everyday life. Here this three-sided model is used as part of a process, or a way of thinking about systems.

There are three steps in this model, or rather three questions:

- Why is this being done this way?
- What is being accomplished?
- What is this like?

Why acts as an abstractor, focusing on the problem at hand by excluding others. This question uncovers the purpose, or the goal, of the system. Asking why also connects the system to the business driver. As an example: “Why does OSPF elect a designated router?” might be a perfectly valid question in some settings, but not necessarily while you’re troubleshooting slow network convergence. Asking why can focus energy and uncover motives that drive configuration, policy, and other choices.

What is the question engineers normally engage with first, but they often do so with little structure. The three-pronged complexity model provides a solid model with which to find the right questions to ask. Figure 6 illustrates this method.

Figure 6: A Structure for Asking What

By focusing on questions about each of the three prongs of the complexity model, you can quickly uncover the tradeoffs made in system design—even if those tradeoffs weren’t made intentionally.

Finally, *what is this like* helps relate the problem space, the potential solutions, and even potential problems with potential solutions to the system being considered. Assume a new working group is formed to solve a particular problem in the routing space. The working group quickly decides on using Dijkstra's *Shortest Path First* (SPF) algorithm to find the solution to one particular problem the protocol is set out to solve.

Asking *what is this like* should immediately uncover the relationship of new solution to existing link-state protocols, such as OSPF. From there, given experience with OSPF, the engineer knows what sort of convergence characteristics the newly proposed solution is likely to have, and where to look for potential problems. As link-state protocols are subject to microloops in some situations, so the newly proposed solution is likely to be subject to microloops. As link-state protocols can suffer from overwhelming amounts of state during large-scale convergence events, so the new solution might suffer from the same sort of problem.

Concluding Thoughts

You can't run, and you can't hide from complexity; there's no point in even trying. You're going to encounter it; ignoring it doesn't make the problem go away, it just allows the problem to fester under some "rug" in some corner of your network. The complexity problems you create today will return as bigger, more complex problems in just a few years. To quote someone who's spent years looking at complexity:

"Trying to make a network proof against predictable problems tends to make it fragile in dealing with unpredictable problems (through an ossification effect as you mentioned). Giving the same network the strongest possible ability to defend itself against unpredictable problems, it necessarily follows, means that it MUST NOT be too terribly robust against predictable problems—not being too robust against predictable problems is necessary to avoid the ossification issue, but not necessarily sufficient to provide for a robust ability to handle unpredictable network problems."

—Tony Przygienda

That call at 2 a.m. might not be pleasant, but solving it the wrong way might cause a much worse call at 2 a.m. sometime later. Hardening the network against all failures eventually means to make it fail spectacularly when a failure that you didn't predict occurs—there's just no way around this reality.

When dealing with engineering problems, then, a little humility around what can, and cannot, be solved is in order. Don't ignore complexity, but don't think you can solve it, either. Instead, remember to treat every situation as a set of tradeoffs—and if you don't see the tradeoffs, you're not looking hard enough.

IPv6 and Packet Fragmentation

by Geoff Huston, APNIC

Version 6 of the Internet Protocol (IPv6) introduced very few changes to its Version 4 predecessor (IPv4). The major change was of course the expansion of the size of the IP source and destination address fields in the IP packet header from 32 bits to 128 bits. Some other changes, however, apparently were intended to subtly alter IP behaviour. One of them was the change in treatment of IP *packet fragmentation*.

It appears that rather than effecting a slight improvement from IPv4, the manner of fragmentation handling in IPv6 appears to be significantly more difficult. In light of these problems, it is perhaps unsurprising that calls have been made from time to time to dispense completely with packet fragmentation in IPv6^[1], as the current situation with IPv6 appears to be worse than both no fragmentation and the IPv4-style of fragmentation.

Packet Fragmentation

One of the more difficult design exercises in packet-switched network architectures is the design of packet fragmentation.

In time-switched networks, developed to support a common bearer model for telephony, each “unit” of information passed through the network occurred within a fixed timeframe (an analogue voice stream was digitized into 8,000 sample points per second, so the basic time unit for switching these digital samples was 1/8,000 of a second), which resulted in fixed-size packets, all clocked off a common time base.

Packet-switched data networks could dispense with a constant common time base, in turn allowing individual data packets to be sized according to the needs of the application as well as the needs and limitations of the network substrate.

For example, smaller packets have a higher packet header-to-packet payload ratio and are consequently less efficient in data carriage and impose a higher processing load as a function of effective data throughput. On the other hand, within a packet-switching system the smaller packet can be dispatched faster, reducing head-of-line blocking in the internal queues within a packet switch and potentially reducing network-imposed jitter as a result. This reduction can make it easier to use the network for real-time applications such as voice or video. Larger packets allow larger data payloads, in turn allowing greater carriage efficiency. Larger payloads per packet also allows a higher internal switch capacity when measured in terms of data throughput, in turn facilitating higher carriage capacity and higher-speed network systems.

Various network designs adopted various parameters for packet size. The original Ethernet specification, invented in the early 1970s, adopted a variable packet size, with supported packet sizes of between 64 and 1,500 octets. *Fiber Distributed Data Interface* (FDDI), a fibre ring local network, used a variable packet size of up to 4,478 octets. *Frame Relay* used a variable packet size of between 46 and 4,470 octets. The choice of variable-size packets allows applications to refine their behaviour. Jitter and delay-sensitive applications, such as digitised voice, may prefer to use a stream of smaller packets in an attempt to minimise jitter, while reliable bulk data transfer may choose a larger packet size to increase the carriage efficiency. The nature of the medium may also have a bearing on this choice. If there is a high *Bit Error Rate* (BER) probability, then reducing the packet size minimises the impact of sporadic errors within the data stream, possibly increasing throughput in such environments.

In designing a network protocol that is intended to operate over a wide variety of substrate networking media and support as wide a variety of applications as possible, the designers of IP could not rely on a single packet size for all transmissions. Instead, the designers of IPv4 provided a *packet length field* in the packet header. This field was a 16-bit octet count, allowing for an IP packet to be anywhere from the minimum size of 20 octets (corresponding to an IP header without any payload) to a maximum of 65,535 octets.

Obviously not all packets can fit into all underlying media. If the packet is too small for the minimum payload size, then it can be readily padded. But if it's too big for the maximum packet size of the media, then the problem is a little more challenging. IPv4 solved this problem using “forward fragmentation.” The basic approach is that any IPv4 router that is unable to forward an IPv4 packet into the next hop because the packet is too large for the next-hop network may split the packet into a set of smaller “fragments,” copying the original IP header fields into each of these fragments, and then forwarding each of these fragments instead. The fragments continue along the network path as autonomous IP packets, and the destination host is responsible for re-assembling them back into the original IP packet and pass the result, namely the packet as it was originally sent, back up to the local instance of the end-to-end transport protocol.

It is a clever approach, as it hides the entire network-level fragmentation issue from the upper-level protocols, including the *Transmission Control Protocol* (TCP) and *User Datagram Protocol* (UDP). The transport protocols and the upper-level application protocols can, in theory, treat the underlying network as capable of supporting any IP packet size, and the IP layer performs the necessary adaptation to allow the IP packet to traverse any media layer. However, even with this intended transparency of operation, this approach has managed to earn a very poor reputation.

Packet fragmentation was seen as being a source of performance inefficiency, a security vulnerability, and it even posed a cap on maximal delay-bandwidth product on data flows across networks. IP fragmentation was considered harmful^[2,3].

The IPv6 designers removed the fragmentation controls from the common IPv4 packet header and placed them into an 8-octet IPv6 *Extension Header*. This additional packet header, placed between the IPv6 packet header and the end-to-end transport packet header, was present *only* in fragmented packets (whereas the IPv4 fragmentation control fields are present in *all* IPv4 packet headers). Secondly, IPv6 did not permit fragmentation to be performed when the packet was in transit within the network: all fragmentation was to be performed by the packet source prior to transmission. This stipulation, too, has resulted in an uncomfortable compromise, where an unforeseen need for fragmentation relies on *Internet Control Message Protocol for IPv6* (ICMPv6) signalling from the interior of the network back to the original packet source and retransmission.

In the case of TCP, a small amount of layer violation goes a long way. If the sending host is permitted to pass an IPv6 *Packet Too Big* (PTB) ICMPv6 diagnostic message up to the TCP session that generated the original packet, then it's possible for the TCP driver to adjust its sending *Maximum Segment Size* (MSS) to the new, smaller value and carry on. In this case, no fragmentation is required.

UDP is different. In UDP a functional response to path message size issues inevitably relies on interaction with the upper-level application protocol.

It appears that when we consider fragmentation in IPv6 we have to consider the treatment of IPv6 Extension Headers and UDP. And that story is not a robust one^[4].

The DNS and IPv6 Packet Fragmentation

The *Domain Name System* (DNS) is the major user of UDP. As a consequence of the increasing use of *Domain Name System Security Extensions* (DNSSEC) as a security mechanism, coupled with the increasing use of IPv6 as the IP protocol transition gathers momentum, it is time to look once more at the interaction of larger DNS payloads over IPv6.

To illustrate this situation, here are two DNS queries, both made by a recursive resolver to an authoritative name server, both using UDP over IPv6.

Query 1:

```
$ dig +bufsize=4096 +dnssec 000-4a4-000a-000a-  
0000-b9ec853b-241-1498607999-2a72134a.ap2.  
dotnxdomain.net. @8.8.8.8  
139.162.21.135
```

```
(MSG SIZE rcvd: 1190)
```

Query 2:

```
$ dig +bufsize=4096 +dnssec 000-510-000a-000a-0000-
b9ec853b-241-1498607999-2a72134a.ap2.
dotnxdomain.net. @8.8.8.8
status: SERVFAIL

(MSG SIZE rcvd: 104)
```

What we see here are two almost identical DNS queries that have been passed to Google's Public DNS service to resolve.

In the first case, the DNS response is 1,190 octets long, and in the second case the response is 1,346 octets long. The DNS server is an IPv6-only server, and the underlying host of this name server is configured with a local maximum packet size of 1,280 octets. Therefore, in the first case the response being sent to the Google resolver is a single, unfragmented IPv6 UDP packet, and in the second case the response is broken into two fragmented IPv6 UDP packets. And it is this single change that triggers the Google Public DNS Server to provide the intended answer in the first case, but to return a SERVFAIL failure notice in response to the fragmented IPv6 response. When the local *Maximum Transmission Unit* (MTU) on the server is lifted from 1,280 octets to 1,500 octets, the Google resolver returns the server DNS response in both cases.

The only difference in these two responses is IPv6 fragmentation, but there is perhaps more to it than that.

IP fragmentation in both IPv4 and IPv6 “raises the eyebrows” of firewalls. Firewalls typically use the information provided in the transport protocol header of the IP packet to decide whether to admit or deny the packet. For example, you may see firewall rules admitting packets using TCP ports 80 and 443 as a way of allowing web traffic through the firewall filter. For this process to work, the inspected packet needs to contain a TCP header and use the fields in the header to match against the filter set. Fragmentation in IP duplicates the IP portion of the packet header, but the inner IP payload, including the transport protocol header, is not duplicated in every ensuing packet fragment. Thus trailing fragments pose a conundrum to the firewall. Either all trailing fragments are admitted, a situation that has its own set of consequent risks, or all trailing fragments are discarded, a situation that also poses connection issues^[5].

IPv6 adds a further factor to the picture. In IPv4 every IP packet, fragmented or not, contains IP fragmentation control fields. In IPv6 these same fragmentation *control fields* are included in an IPv6 *Extension Header* that is attached only to packets that are fragmented.

This 8-octet Extension Header is placed immediately after the IPv6 packet header in all fragmented packets, meaning that a fragmented IPv6 packet does not contain the *Upper Level Protocol Header* starting at octet offset 40 from the start of the IP packet header. But in the first packet of this set of fragmented packets, the Upper Level Protocol Header is chained off the fragmentation header, at byte offset 48, assuming that there is only a *Fragmentation Extension Header* in the packet. The implications of this fact are quite significant. Instead of always looking at a fixed point in a packet to determine its upper-level protocol, the packet-handling device needs to unravel the Extension Header chain, raising two rather tough questions. First, how long is the device prepared to spend unravelling this chain? And second, would the device be prepared to pass on a packet with an Extension Header that it did not recognise?

In some cases, implementers of IPv6 equipment have found it simpler to just drop all IPv6 packets that contain Extension Headers. Some measurements of this behaviour are reported in RFC 7872^[6]. This document reports a 38% packet-drop rate when sending fragmented IPv6 query packets to DNS Name servers. But the example provided previously is in fact the opposite case to that reported in RFC 7872, and the example illustrates a more conventional case. It's not the queries in the DNS that can readily grow to sizes that require packet fragmentation, but the responses. The relevant question concerns the anticipated probability of packet drop when sending fragmented UDP IPv6 packets as responses to DNS queries. To rephrase the question slightly, how do DNS recursive resolvers fare when the IPv6 response from the server is fragmented?

For a start, it appears from the example cited here that Google's Public DNS resolvers experienced some packet-drop problem when they passed a fragmented IPv6 response (this problem was noted in mid-2017, and Google has subsequently corrected it). But was this problem limited to just one or two DNS resolvers, or do many other DNS resolvers experience a similar packet-drop issue? How widespread is this problem?

We used an experiment that tested resolver capabilities in handling DNS responses that entailed the use of fragmented UDP IPv6 packets. The experiment used a measurement script embedded in an online ad to enlist a large number of endpoints to perform resolution of a domain name^[7]. For this measurement, we altered the DNS resolution system to fragment certain DNS responses.

The approach we took in this experiment was to use a user-level packet-processing system that listens on UDP port 53 and passes all incoming DNS queries to a back-end DNS server. When it receives a response from this back-end server it generates a sequence of IPv6 packets that fragments the DNS payload and uses a raw device socket to pass these packets directly to the device interface.

We are relying on the observation that IPv6 packet fragmentation occurs at the IP level in the protocol stack, so the IPv6 driver at the remote end will reassemble the fragments and pass the UDP payload to the DNS application, and if the resolver receives the payload packets, there will be no trace that the IPv6 packets were fragmented.

The results of this experiment follow:

- 10,851,323 experiments used IPv6 queries for the name server address.
- 6,786,967 experiments queried for the terminal DNS name.
- Fragmented response: $6,786,967 / 10,851,323 = 62.54\% = 37.45\%$ drop.

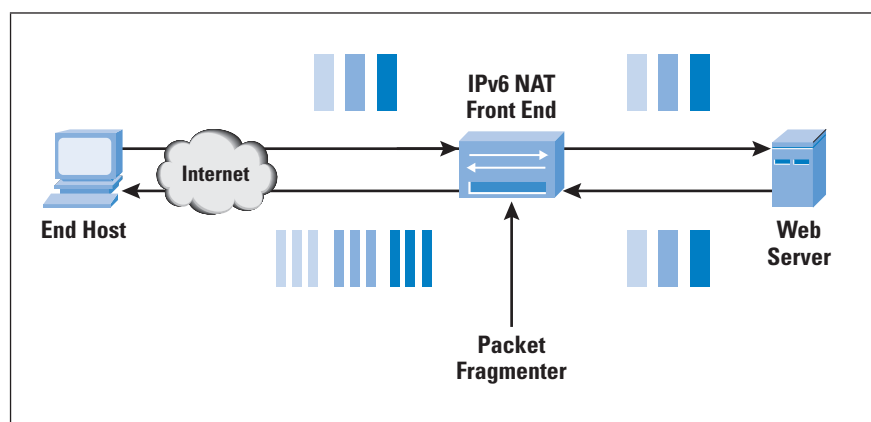

Some 37% of client endpoints used IPv6-capable DNS resolvers that were incapable of receiving a fragmented IPv6 response.

TCP and IPv6 Packet Fragmentation

The use of IPv6 Extension Headers implies that any transport protocol-sensitive functions within network equipment must follow the Extension Header chain of the packet header. This process takes a variable number of cycles for the device. It also requires that the device should recognise all the Extension Headers encountered on the header chain as passing through Extension Headers that the device either does not understand or is not prepared to check to determine whether or not it is a security risk. It's easier to drop all packets with Extension Headers! And that is what a lot of deployed equipment evidently does.

To measure the extent to which equipment drops fragmented IPv6 packets in TCP, we used a front-end unit to a web server and configured this front end to perform packet fragmentation on outbound packets as required. All TCP packets passed across the unit from the back end towards the Internet that contain a TCP payload larger than 15 octets are fragmented (Figure 1).

Figure 1: Experiment Configuration

The subsequent data-analysis phase can detect if the end host has received and successfully reassembled the set of fragments by looking at a log of packets. If an incoming TCP *Acknowledgement* (ACK) has a sequence number that encompasses the sending sequence number of outbound fragments within the same TCP session, that is evidence that the remote end has successfully reassembled the fragmented packet.

How “Real” Is This Experiment?

Before looking at the results, it may be useful to ask whether this experiment represents a “real” scenario that is commonly encountered on the Internet.

It’s certainly the case that in TCP over IPv6 we do not expect to see packet fragmentation in the normal course of events.

A TCP sender should ensure that all outbound TCP segments fit within the local interface MSS size, so in the absence of network path MTU issues, a sender should not be fragmenting outbound TCP packets before sending them.

What about the case where the path MTU is smaller than the local interface MTU? When a packet encounters a network path next hop where the packet is larger than the next-hop MTU, the IPv6 router constructs an ICMPv6 PTB message, noting the size of the next hop, and also including the original packet headers as the payload of this ICMPv6 message. It sends this ICMPv6 diagnostic message back to the original sender and discards the original packet.

When a sending host receives this ICMPv6 PTB message, it also has the TCP packet header as part of the inner payload. This information can be used to find the local TCP control entry for this session, and the outbound MSS value of this TCP session can be updated with the new value. In addition to the updated size information, the TCP header in the ICMPv6 PTB message payload also contains the sequence number of the lost packet. The sending TCP process can interpret the ICMPv6 PTB message as an implicit *Negative Acknowledgement* (NACK) of the lost data, and resend the discarded data, using the updated MSS size. Again, no packet fragmentation is required.

All this sounds like a blatant case of “layer violation” and we should call in the Protocol Police. But before we do so, maybe we should think about the hypothetical situation where the host did not pass the ICMPv6 PTB message to the TCP control block. This situation is analogous to the case where the ICMPv6 PTB message is not passed to the host at all, where, for example, some unhelpful piece of network filtering middleware is filtering out all ICMPv6 messages.

In this case, the sending TCP session has sent a TCP segment and is waiting to receive an ACK. The receiver will not get this packet, so it cannot ACK it. The sender might have a retransmission timer and it might try to resend the offending large packet, but that too will get lost, so it will never get the ACK.

This situation results in a wedged TCP state, or a *Path MTU Black Hole* condition. Hiding ICMPv6 PTB messages from the TCP controller, either because of local processing rules within the host or because some network element has decided to drop them, is invariably harmful.

In that sense, we have constructed a somewhat “unreal” experiment, and we should not expect to see applications that critically depend on the correct working of packet fragmentation in TCP experiencing the same network conditions as those we’ve set up here.

On the other hand, fragmentation is an IP function, not a function performed by an end-to-end transport protocol. Therefore, the question of whether a host can receive a fragmented UDP packet is essentially the same question as whether a host can receive a fragmented TCP packet—at least from the perspective of the host itself. In both cases the real question is whether the IPv6 process on the host can receive fragmented IPv6 packets.

While the experiment itself uses conditions that are essentially an artifice, the result, namely the extent to which IPv6 Extension Header drop occurs when passing fragmented IPv6 packets towards end hosts, is nevertheless a useful and informative result.

Results

Over a period in August 2017, this experiment presented fragmented TCP packets to 1,702,949 unique IPv6 addresses. The results are summarized in Table 1.

Table 1: Results of Fragmentation Test

	Count	% of Total
Sent Fragmented TCP Packets	1,675,898	
Acknowledged Fragmented TCP Packets	1,324,834	79.03%
Failed to Acknowledge Fragmented TCP Packets	351,514	20.97%

Compared to the earlier DNS packet fragmentation result, namely that some 37% of endpoints who used IPv6-capable DNS resolvers used resolvers that were incapable of receiving IPv6 Fragmentation Extension Headers, the overall failure rate observed here of some 21% looks somewhat better. However, “better” is a relative term, as it is still the case that one-fifth of IPv6-capable endpoints are unable to receive a fragmented IPv6 packet.

Having one-fifth of the end-user population incapable of receiving fragmented large responses over IPv6 is indeed a serious problem.

Let's look briefly at the IPv6-over-IPv4 auto-tunnelling techniques Teredo and 6to4 (Table 2), as these two auto-tunnelled IPv6 bridging technologies just don't seem to want to die!

Table 2: Results of IPv6 Fragmentation Test for Teredo and 6to4 Prefixes

	Teredo	%	6to4	%
Sent Fragmented TCP Packets	53,780		24,384	
Acknowledged Fragmented TCP Packets	263	0.5%	1,486	6.1%
Failed to Acknowledge Fragmented TCP Packets	53,517	98.5%	22,898	93.9%

Both of these auto-tunnelling services are atrocious in this respect! Almost no Teredo endpoints can handle IPv6 fragmentation, and the 6to4 failure rate is not much better. Having no IPv6 at all is far better than having such a terrible service, and I can think of few better justifications for turning off the remaining Teredo and 6to4 gateways than these figures! What is even more depressing is that these two auto-tunnelling technologies represent one-quarter of the count of unique /64 prefixes seen in this experiment.

There is a considerable level of variation in the extent to which networks support the delivery of IPv6 Fragmentation Extension Headers to hosts. In some cases, it appears that the choice of customer premises equipment, or the configuration of IPv6 firewalls, may be a factor. Where the failure rate is very high it would point to the drop point being part of the behaviour of the provider network rather than the behaviour of the customer premises equipment.

Conclusions

Whatever the reasons, the conclusion here is unavoidable: IPv6 fragmentation is just not a viable component of the IPv6 Internet.

We need to adjust our protocols to avoid fragmentation.

For TCP, this adjustment should not be a major issue. Of course, this assertion relies on ICMPv6 PTB messages getting back to the sender's TCP process, but that is a major topic in its own right, so we won't delve deeper into this subject right now.

However, for UDP, this conclusion should be cause for some major rethinking of the way the DNS works, as the combination of DNSSEC, UDP, and IPv6 is really not going to work very well. It has implications for other UDP-based protocols as well, particularly where the protocol can generate large payloads.

The *Quick UDP Internet Connections* (QUIC) protocol, which uses a TCP-like control protocol embedded within a UDP encapsulation^[8], has taken the pragmatic position of using a maximum packet size of 1,350 octets as a universal base and does not expect to encounter fragmentation issues given this somewhat conservative choice of packet size. If the DNS over IPv6 used a similar upper limit of UDP packet size and always sent back truncated responses for larger answers, we could probably avoid many of the packet-loss problems that we encounter today. Of course, the consequent larger use of TCP has its own implications in terms of query processing capacity for DNS resolvers and servers, so there are no free points here.

However, one conclusion looks starkly clear to me from these results. We can't just assume that the DNS as we know it today will just work in an all IPv6 future Internet. We must make some changes in some parts of the protocol design to get around this current widespread problem of IPv6 Extension Header packet loss in the DNS, assuming that we want to have a DNS at all in this all-IPv6 future Internet.

GEOFF HUSTON, B.Sc., M.Sc., is the Chief Scientist at APNIC, the Regional Internet Registry serving the Asia Pacific region. He has been closely involved with the development of the Internet for many years, particularly within Australia, where he was responsible for building the Internet within the Australian academic and research sector in the early 1990s. He is author of numerous Internet-related books and was a member of the Internet Architecture Board from 1999 until 2005. He served on the Board of Trustees of the Internet Society from 1992 until 2001. He is an active contributor to the Internet Engineering Task Force. At various times Geoff has worked as an Internet researcher, an ISP systems architect, and a network operator. E-mail: gih@apnic.net

Letters to the Editor

Ole and William,

As a loyal IPJ reader for decades, I think you did a terrific job on your blockchain piece in the November 2017 issue of IPJ. I don't think I have seen anything yet as comprehensive, understandable, and interesting to read on this subject. Thanks for writing and publishing the piece. There is far too much fluff and misinformation on blockchain and cryptocurrencies, so it is nice to see a solid treatment that provides helpful information to further everyone's understanding of this important technology.

—David Strom, david@strom.com

The author responds:

David,

Thank you for the kind words. A lot of credit goes to the reviewers, who did an awesome job of providing detailed feedback on the first draft.

—Bill Stallings, ws@shore.net

Ole,

I just re-read Geoff Huston's article on *Network Address Translation* (NAT) in the November 2017 issue (Volume 20, No. 3), and needed to applaud—possibly for the second time. Geoff is in a league of his own—the clear thinking, the pragmatism, the ability to communicate clearly and understandably—and not the least, the perspective on history. How we got here and why. Enlightening. NAT changed the Internet and continues to do so in ways I had never thought of until I read the article. Understanding that the 2018 Internet is vastly different in almost every possible way from the 1995 and 2005 Internet is extremely important. Otherwise we continue to plan for an historic model rather than the future. IPJ rocks!

—Helge Skrivervik, helge@mymayday.com

Ole,

As a data-networking engineer and architect of 20 years on the front line of fortune 100 network projects, I would like to offer a counter perspective from the recent article “In Defence of NATs” (Volume 20, No. 3).

The networking world seems to be losing sight that NAT is a “crutch” of sorts, a way of dealing with the primary problem in a lack of IPv4 address space.

By trying to justify NAT as a way to scale up IPv4 future potential scalability by “stealing” port/socket bits for something other than their originally intended purpose is nonsensical. One correction I would like to make on the article is the claim that NAT provides a firewall function. NAT and firewall functionality are mutually exclusive mechanisms, even if they are most often found on the same network device. NAT provides an obscured view of a host from elsewhere via address/port translation but does not by itself provide natural protection from the host on the other side of the translation point. Firewall protection encompasses the scrutinizing and controlling of the traffic that is allowed to traverse the NAT point. Firewalls provide this function with or without NAT, and NAT can function with or without a firewall mechanism.

Slow adoption of IPv6 has nothing to do with any perceived brilliant nature of NAT, and NAT does present real-world problems for several types of very important software; Microsoft’s *Active Directory Replication* and IBM’s *Virtual Tape Library (VTL)/Virtual Tape Server (VTS)* are two examples off the top of my head. When traversing a NAT point, many applications that share their host IP address in the data field with other hosts require active “swapping” of this payload-imbedded IP address or another compensating mechanism. The communication would “break” the application’s intended communication model without the addition of a compensating mechanism.

The question in the article “should I deploy IPv6 now?” is the wrong question. The Internet was first “born” in a practical sense at the point it became commercially available to the world to use. In the first 25 years it grew at an amazing rate, doubling its size several times over in a very natural and organic way. It has been almost a quarter century since IPv6 was released, and its resistance has been *significant* for good reasons beyond the scope of this letter. IPv6 is “The Emperor’s New Clothes,” otherwise IPv4 would have been replaced by now if IPv6 had been a natural and organic progression of IPv4, and there would be no need to “defend” NAT or speak up against its forced ubiquitous overuse. Someone once told me that IPv6 was here to stay. To my way of thinking it has not yet arrived after almost a quarter century.

While IPv4 port/socket numbers can be seen as “borrowed address bits” for NAT, I believe it is a distorted view of port/socket intended use. Fields and protocols are defined and delineated for a reason. If you wish to repurpose bits—for example, *Type of Service (ToS)* to *Differentiated Services Code Point (DSCP)* use—then repurpose them officially. Until then, fields and protocols should be respected as originally intended and not subject to implied de-facto depreciation by NAT’s liberal theft. Field definitions and structure have purpose.

The sirens' song that I believe we collectively are starting to fall for is that NAT is a "one-size-fits-all" solution for all forms of network scalability in a ubiquitous way. This is not the real-world case. Resource hosts need (in a practical sense) globally unique Layer 3 identifiers. Consider corporate mergers/acquisitions as well as divestitures leading to merging of a divested entity. Trying to merge two significant company networks together that both use NAT RFC 1918 on the "inside" for resource hosts is overly complex in a way that it would not have to be if a viable replacement for IPv4 had been rolled out in a manner that world corporations could embrace commercially. That protocol does not exist. While I agree with the notion that the Internet cannot be "stateless," this does not uniquely justify NAT as "middleware." End hosts ideally should be ultimate keepers of their stateful connections; justifying NAT just for the sake of IPv4 continued life-support is nonsensical.

NAT has a proper use; middleware that uses NAT as a complementary protocol along with others, such as "load balancing" [for example, the *Local Traffic Manager* (LTM) product by F5] is justifiable, but in this case application scalability and fault tolerance encompass the direct purpose of this middleware, not compensating for world IPv4 address depletion. Other forms of network middleware are perfectly justifiable, even if NAT did not need to exist; firewalls and *Intrusion Prevention Systems* (IPS) are examples. We should appreciate NAT for its role as a "tactical" compensating mechanism for IPv4 address space depletion, not as a "strategic future-proofing" scalability mechanism for IPv4. People with broken legs appreciate a crutch, but would not appreciate needing to use a crutch for the rest of their lives if their body decided not to heal itself because the body viewed the crutch as "good enough." NAT seen as a long-term way of extending IPv4 scalability and, therefore, lifespan is just putting lipstick on the IPv4 pig.

NAT is a mechanism to be used (like any other protocol) where it makes sense to use it and no further. If IPv6 or some other more sensible replacement for IPv4 were completely rolled out with IPv4 relegated to the history books, then the practical use of NAT in such a future environment would be a single-digit fraction of its current existence. That existence would be primarily in terms of resiliency mechanisms such as load balancing, as previously mentioned, and certain (client) mobility cases. One of the most memorable pieces of wisdom I have ever heard about IT applies here very well: "There is nothing more permanent than a temporary solution." Let us not fall victim to this easy psychological trap only because we seem to have collectively painted ourselves into a corner of sorts.

—Leroy Harvey, leroy.harvey@hotmail.com

The author responds:

The purpose of any opinion piece is to provoke the reader into thinking about the issue, and perhaps looking at it from a set of different perspectives. For more than two decades the *Internet Engineering Task Force* (IETF) viewed NATs as a somewhat ugly hack, and from time to time attempted to discourage its use in various ways. However, the undeniable observation is that NATs keep today's Internet running. Perhaps there is more to NATs than a rather ugly short-term hack that should disappear. What if they are here to stay? The opinion piece was intended to look at NATs from a perspective that shared little with the orthodox view of NATs, and provoke readers to think about this unanticipated direction that the Internet has taken and wonder where it may lead. I'm pleased to see that this provocation has motivated one reader to provide a thoughtful response.

—Geoff Huston, APNIC

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

In June 1998 we published the first issue of *The Internet Protocol Journal* (IPJ). Since then, we have produced 75 issues and a total of 2,848 pages. Today, IPJ has about 22,000 subscribers all around the world. Although two-thirds of our readers prefer the paper edition, a growing number of subscribers are downloading the PDF version instead. As we remarked in 2008, this shift in reading habits is related to the emergence of low-cost, high-resolution displays and printers, as well as improvements in Internet access technologies, particularly with respect to mobile devices.

In this 20th anniversary year, we decided to ask our most frequent contributor, Geoff Huston, to reflect on Internet developments since 2008. His article, “Another 10 Years,” outlines the many ways in which the Internet has changed in this period, as well as a few areas where developments are still lacking.

The Internet continues to be used for numerous unsavory activities including fraud, identity theft, malicious software intrusion, denial-of-service incursions, and much more. These cyber attacks are getting increasingly sophisticated, as David Strom explains in his article entitled “Fileless Malware.”

As I did 10 years ago, let me take this opportunity to thank all those people who make IPJ possible. Our authors deserve a round of applause for carefully explaining both established and emerging technologies. They are assisted by an equally insightful set of reviewers and advisors who provide feedback and suggestions on every aspect of our publications process. The process itself relies heavily on two individuals: Bonnie Hupton, our copy editor, and Diane Andrada, our designer. Of equal importance are our numerous individual donors and corporate sponsors, without whom we would be unable to publish and distribute the journal. Last, but not least, our readers give us encouragement, suggestions, and feedback that enables us to provide the most relevant material.

If you are wondering why this issue has a cover date of “August” rather than “June,” I can only apologize and blame it on a busy summer and a broken arm. I appreciate your continued patience and support.

Another 10 Years

by Geoff Huston, APNIC

The evolutionary path of any technology can often take strange and unanticipated turns and twists. At some points simplicity and minimalism can be replaced by complexity and ornamentation, while at other times a dramatic cut-through exposes the core concepts of the technology and removes layers of superfluous additions. The evolution of the Internet appears to be no exception, and it contains these same forms of unanticipated turns and twists. In thinking about the technology of the Internet over the last 10 years, it appears that it's been a very mixed story about what has changed and what has stayed the same.

A lot of the Internet today looks much the same as the Internet of a decade ago^[0,1]. Much of the infrastructure of the Internet has stubbornly resisted various efforts to engender change. We are still in the middle of the process to transition the Internet to IPv6, as was the case a decade ago. We are still trying to improve the resilience of the Internet to various attack vectors, as also was true a decade ago. We are still grappling with various efforts to provide defined *Quality of Service* (QoS)^[2] in the network, also true a decade ago. It seems that the rapid pace of technical change in the 1990s and early 2000s has simply run out of momentum, and that the dominant activity on the Internet over the past decade was consolidation rather than continued technical evolution. Perhaps this increased resistance to change is because as the size of the network increases, its inertial mass also increases. We used to quote *Metcalf's Law*^[3] to each other, reciting the mantra that the value of a network increases in proportion to the square of the number of users.

A related observation appears to be that the inherent resistance of a network to change, or its inertial mass, is also directly related to the square of the number of users. Perhaps as a general observation, all large, loosely coupled, distributed systems are strongly resistant to efforts to orchestrate a coordinated change. At best, these systems respond to various forms of market pressures, but because the overall system of the Internet is so large and so diverse, these market pressures manifest themselves in different ways in different parts of this network. Individual actors operate under no centrally orchestrated set of instructions or constraints. Where change occurs, it is because some sufficiently large body of individual actors sees opportunity in undertaking the change or perceives unacceptable risk in not changing. The result for the Internet appears to be that some changes are very challenging, while others look like natural and inevitable progressive steps.

But the other side of the story is one that is about as diametrically opposed as it's possible to paint. Over the last decade, we've seen another profound revolution in the Internet as it embraced a combination of wireless-based infrastructure and a rich set of services at a speed that has been unprecedented. We've seen a revolution in content and content provision that has changed the Internet, and as collateral damage the Internet appears to be decimating the traditional newspaper and broadcast television sectors. Social media has all but replaced the social role of the telephone and the practice of letter writing. We've seen the rise of the resurgence of a novel twist to the old central mainframe service in the guise of the *cloud*^[4,5] and the repurposing of Internet devices to support views of a common cloud-hosted content that in many ways mimic the function of display terminals of a bygone past. All of these developments are fundamental changes to the Internet and all of them have occurred in the last decade!

That's a significant breadth of material to cover, so I'll keep the story to the larger themes, and to structure this story, rather than offer a set of unordered observations about the various changes and developments over the past decade, I'll use a standard model of a protocol stack as the guiding template. I'll start with the underlying transmission media and then look at IP, the transport layer, and applications and services, and then close by looking at the business of the Internet to highlight developments of the last decade.

Below the IP Layer

What's changed in network media?

Optical systems have undergone sustained change in the past decade. A little over a decade ago production optical systems used simple on-off keying to encode the signal into the optical channel. The speed increases in this generation of optical systems relied on improvements in the silicon control systems and the laser driver chips. The introduction of *Wavelength-Division Multiplexing* (WDM) in the late 1990s allowed the carriers to greatly increase the carrying capacity of their optical cable infrastructure. The last decade has seen the evolution of optical systems into areas of polarisation and phase modulation to effectively lift the number of bits of signal per baud. These days 100-Gbps optical channels are commonly supportable, and we are looking at further refinements in signal detection to lift that beyond 200 Gbps. We anticipate 400-Gbps systems in the near future, using various combinations of a faster basic baud rate and higher levels of phase amplitude modulation, and dare to think that 1 Tbps is now a distinct near-term optical service.

Radio systems have seen a similar evolution in overall capacity. Basic improvements in signal processing, analogous to the changes in optical systems, have allowed the use of phase modulation to lift the data rate of the radio bearer.

The use of *Multiple-Input* and *Multiple-Output* (MIMO) technology, coupled with the use of higher carrier frequencies, has allowed the mobile data service to support carriage services of up to 100 Mbps in today's *Fourth-Generation* (4G) networks. The push to even higher frequencies promises speeds of up to 1 Gbps for mobile systems in the near future with the deployment of 5G technology.

While optical speeds are increasing, Ethernet packet framing still persists in transmission systems long after the original rationale for the packet format died along with that bright-yellow coaxial cable! Oddly enough, the Ethernet-defined minimum and maximum packet sizes of 64 and 1500 octets still persist. The inevitable result of faster transmission speeds with constant packet sizes results in an upper bound of the number of packets per second increasing more than 100-fold over the past decade, in line with the increase of deployed transmission speeds from 2.5 to 400 Gbps. As a consequence, silicon-based switches are demanding higher packet-processing rates. But one really important scaling factor has not changed for the past decade, namely the clock speed of processors and the cycle time of memory, which have not moved at all. The response so far has been in increasing reliance of parallelism in high-speed digital switching applications, and these days multi-core processors and highly parallel memory systems are used to achieve performance that would be impossible in a single threaded processing model.

In 2018, it appears that we are close to achieving 1-Tbps optical systems and up to 20 Gbps in radio systems. Just how far and how quickly these transmission models can be pushed into supporting ever-higher channel speeds is an open question.

The IP Layer

The most notable aspect of the network that appears to stubbornly resist all forms of pressure over the last decade, including some harsh realities of acute scarcity, is the observation that we are still running what is essentially an IPv4 Internet.

Over the past decade, we have exhausted our pools of remaining IPv4 addresses, and in most parts of the world the IPv4 Internet is running on some form of empty. We had never suspected that the Internet would confront the exhaustion of one of its most fundamental pillars—the basic function of uniquely addressing connected devices—and apparently shrug it off and continue on blithely. But, unexpectedly, that's exactly what has happened.

Today we estimate that some 3.4 billion people regularly use the Internet, and some 20 billion devices are connected to it. We have achieved this feat by using some 3 billion unique IPv4 addresses. Nobody thought that we could achieve this astonishing feat, yet it has happened with almost no fanfare.

Back in the 1990s we had thought that the prospect of address exhaustion would propel the Internet to use IPv6, which was the successor IP protocol that comes with a four-fold increase in the bit width of IP addresses. By increasing the IP address pool to some esoterically large number of unique addresses (340 *undecillion* addresses, or 3.4×10^{38}), we would never have to confront network address exhaustion again. But this transition was not going to be easy. There is no backward compatibility in this protocol transition, so everything has to change. Every device, every router, and even every application needs to change to support IPv6. Rather than perform comprehensive protocol surgery on the Internet and change every part of the infrastructure to support IPv6, we changed the basic architecture of the Internet instead. Oddly enough, it looks like this option was the cheaper one!

Through the almost ubiquitous deployment of *Network Address Translators* (NATs)^[6, 7] at the edges of the network, we've transformed the network from a *peer-to-peer* network into a *client/server* network. In today's client/server Internet clients can talk to servers, and servers can talk back to these connected clients, but that's it. Clients cannot talk directly to other clients, and servers need to wait for the client to initiate a conversation in order to talk to a client. Clients "borrow" an endpoint address when they are talking to a server and release this address for use by other clients when they are idle. After all, endpoint addresses are only useful to clients in order to talk to servers. The result is that we've managed to cram some 20 billion devices into an Internet that has deployed only 3 billion public address slots. We've achieved this result though embracing what could be described as *time-sharing* of IP addresses.

All well and good, but what about IPv6? Do we still need it? If so, then are we going to complete this protracted transition? Ten years later the answer to these questions remains unclear. On the positive side, there is a lot more IPv6 usage around now than there was 10 years ago. *Internet Service Providers* (ISPs) are deploying much more IPv6 today than they did in 2008. When IPv6 is deployed within a service provider's network, we see an immediate uptake from these IPv6-equipped devices. In 2018, it appears that one-fifth of Internet users (that itself is now estimated to number around one-half of the human population on the planet) are capable of using the Internet over IPv6, and most of this capability has developed in the past 10 years. However, on the negative side the question must be asked: What's happening with IPv6 for the other four-fifths of the Internet? Some ISPs have made the case that they would prefer to spend their finite operating budgets on other areas that improve their customers' experience, such as increasing network capacity, removing data caps, or acquiring more on-net content. Such ISPs continue to see deployment of IPv6 as a deferrable measure.

It seems that today we are still seeing a mixed picture for IPv6. Some service providers simply see no way around their particular predicament of IPv4 address scarcity, and these providers see IPv6 as a necessary decision to further expand their network. Other providers are willing to defer the question to some undefined point in the future.

Routing

While we are looking at what's largely unchanged over the past decade we need to mention the routing system. Despite dire predictions of the imminent scaling death of the *Border Gateway Protocol* (BGP)^[8] 10 years ago, BGP has steadfastly continued to route the entire Internet. Yes, BGP is as insecure as ever, and yes, a continual stream of fat-finger foul-ups and less common but more concerning malicious route hijacks continue to plague our routing system, but the routing technologies used in 2008 are the same as those we use in today's Internet.

The size of the IPv4 routing table has tripled in the past 10 years, growing from 250,000 entries in 2008 to slightly more than 750,000 entries today. The IPv6 routing story is more dramatic, growing from 1,100 entries to 52,000 entries. Yet BGP just quietly continues to work efficiently and effectively. Who would've thought that a protocol that was originally designed to cope with a few thousand routes announced by a few hundred networks could still function effectively across a routing space approaching a million routing entries and a hundred thousand networks!

In the same vein, we have not made any major change to the operation of our interior routing protocols. Larger networks still use either *Open Shortest Path First* (OSPF)^[9] or *Intermediate System-to-Intermediate System* (IS-IS) depending on their circumstances, while smaller networks may opt for some distance vector protocol like *Routing Information Protocol Version 2* (RIPv2)^[10] or even *Enhanced Interior Gateway Routing Protocol* (EIGRP)^[11]. The work in the *Internet Engineering Task Force* (IETF) on more recent routing protocols such as the *Locator Identifier Separation Protocol* (LISP)^[12] and the *Babel Routing Protocol*^[13] seem to lack any real traction with the Internet at large. While they both have interesting properties in routing management, neither has a sufficient level of perceived benefit to overcome the considerable inertia of conventional network design and operation. Again, this example looks like another instance where inertial mass is exerting its influence to resist change in the network.

Network Operations

Speaking of network operation, we are seeing some stirrings of change, but it appears to be a rather conservative area, and adoption of new network management tools and practices takes time.

The Internet converged on using the *Simple Network Management Protocol* (SNMP) a quarter of a century ago, and despite its security weaknesses, its inefficiency, its incredibly irritating use of *Abstract Syntax Notation One* (ASN.1), and its use in sustaining some forms of *Distributed Denial-of-Service* (DDoS) attacks, it still enjoys widespread use. But SNMP is only a network monitoring protocol, not a network configuration protocol, as anyone who has attempted to use SNMP write operations can attest.

The more recent *Network Configuration Protocol* (NETCONF) and the *Yet Another Next Generation* (YANG) data modelling language are attempting to pull this area of configuration management into something a little more usable than *Command-Line Interface* (CLI) scripts driving interfaces on switches. At the same time, we are seeing orchestration tools such as *Ansible*, *Chef*, *Network Automation and Programmability Abstraction Layer with Multivendor* (NAPALM) and SALT enter the network operations space, permitting the orchestration of management tasks over thousands of individual components. These network operations management tools are welcome steps forward to improve the state of automated network management, but it's still far short of a desirable endpoint.

In the same time period as we appear to have advanced the state of automated control systems to achieve the driverless autonomous car, the task of fully automated network management appears to have fallen way short of the desired endpoint. Surely it must be feasible to feed an adaptive autonomous control system with the network infrastructure and available resources, and allow the control system to monitor the network and modify the operating parameters of network components to continuously meet the service-level objectives of the network? Where's the driverless car for driving networks? Maybe the next 10 years might get us there.

The Mobile Internet

Before we move up a layer in the Internet Protocol model and look at the evolution of the end-to-end transport layer, we probably need to talk about the evolution of the devices that connect to the Internet.

For many years, the Internet was the domain of the desktop personal computer, with laptop devices serving the needs to those with a desire for a more portable device. At the time the mobile phone was still just a phone, and its early forays into the data world were unimpressive.

Apple's iPhone, released in 2007, was a revolutionary device. Boasting a vibrant-colour touch-sensitive screen, just four keys, a fully functional operating system with Wi-Fi and cellular radio interfaces, and a capable processor and memory, its entry into the consumer market space was perhaps the major event of the decade. Apple's early lead was rapidly emulated by Windows and Nokia with their own offerings.

Google's position was more as an active disruptor, using an open licensing framework for the Android platform and its associated application ecosystem to empower a collection of handset assemblers. Samsung, LG, HTC, Huawei, Sony, and Google, to name a few, all use Android. These days almost 80% of the mobile platforms use Android, and some 17% use Apple's iOS.

For the human Internet, the mobile market is now the Internet-defining market in terms of revenue. There is little in terms of margin or opportunity in the wired network these days, and even the declining margins of these mobile data environments represent a vague glimmer of hope for the one dominant access provider industry.

Essentially, the public Internet is now a platform of apps on mobile devices.

End-to-End Transport Layer

It's time to move up a level in the protocol stack and look at end-to-end transport protocols and changes that have occurred in the past decade.

End-to-end transport was the revolutionary aspect of the Internet, and the *Transmission Control Protocol* (TCP)^[14] was at the heart of this change. Many other transport protocols require the lower levels of the network protocol stack to present a reliable stream interface to the transport protocol. It was up to the network to create this reliability, performing data integrity checks and data flow control, and repairing data loss within the network as it occurred. TCP dispensed with all of that, and simply assumed an unreliable datagram transport service from the network and pushed the responsibility for data integrity and flow control to the transport protocol.

In the world of TCP, not much appears to have changed in the past decade. We've seen some further small refinements in the details of the TCP controlled rate increase and rapid rate decrease, but nothing that shifts the basic behaviours of this protocol. TCP tends to use packet loss as the signal of congestion and oscillates its flow rate between some lower rate and this loss-triggering rate.

Or at least that was the case until quite recently. The situation is poised to change, and change in a very fundamental way, with the debut of Google's offerings of *Bottleneck Bounded Rate* (BBR) and *Quick UDP Internet Connections* (QUIC).

The BBR control algorithm is a variant of the TCP flow-control protocol that operates in a very different mode from other TCP protocols. BBR attempts to maintain a flow rate that sits exactly at the delay bandwidth product of the end-to-end path between sender and receiver. In so doing, BBR tries to avoid the accumulation of data buffering in the network (when the sending rate exceeds the path capacity), and also tries to avoid leaving idle time in the network (where the sending rate is less than the path capacity).

The side effect is that BBR tries to avoid the collapse of network buffering when congestion-based loss occurs. BBR achieves significant efficiencies from both wired and wireless network transmission systems.

The second recent offering from Google also represents a significant shift in the way we use transport protocols. The QUIC protocol looks like a *User Datagram Protocol* (UDP) protocol from the perspective of the network. But in this case looks are deceiving. The inner payload of these UDP packets contain a more conventional TCP flow-control structure and a TCP stream payload. However, QUIC encrypts its UDP payload so the entire inner TCP control is completely hidden from the network. The ossification of the Internet transport is due in no small part to the intrusive role of network middleware that is used to discard packets that it does not recognise. Approaches such as QUIC allow applications to break out of this regime and restore end-to-end flow management as an end-to-end function without any form of network middleware inspection or manipulation. I'd call this development as perhaps the most significant evolutionary step in transport protocols over the entire decade.

The Application Layer

Let's keep on moving up the protocol stack and look at the Internet from the perspective of the applications and services that operate across the network.

Privacy and Encryption

As we noted in looking at developments in end-to-end transport protocols, encryption of the QUIC payload is not just to keep network middleware from meddling with the TCP control state, although it does successfully achieve that objective. The encryption applies to the entire payload, and it points to another major development in the past decade. We are now wary of the extent to which various forms of network-based mechanisms are used to eavesdrop on users and services. The documents released by Edward Snowden in 2013 portrayed a very active US Government surveillance program that used widespread traffic-interception sources to construct profiles of user behaviour and inference profiles of individual users. In many ways this effort to assemble such profiles is not much different from what advertising-funded services such as Google and Facebook have been (more or less) openly doing for years, but perhaps the essential difference is that of knowledge and implied consent. In the advertisers' case this information is intended to increase the profile accuracy and hence increase the value of the user to the potential advertiser. The motivations of government agencies are more open to various forms of interpretation, and not all such interpretations are benign.

One technical response to the implications of this leaked material has been an overt push to embrace end-to-end encryption in all parts of the network. The corollary has been an effort to allow robust encryption to be generally accessible to all, and not just a luxury feature available only to those who can afford to pay a premium.

The *Let's Encrypt*^[15] initiative has been incredibly successful in publishing X.509 domain name certificates that are free, and the result is that all network service operators, irrespective of their size or relative wealth, can afford to use encrypted sessions, in the form of *Transport Layer Security* (TLS)^[16], for their web servers.

The push to hide user traffic from the network and network-based eavesdroppers extends far beyond QUIC and TLS session protocols. The *Domain Name System* (DNS) is also a rich source of information about what users are doing; it also is used in many places to enforce content restrictions. There have been recent moves to try to clean up the overly chatty nature of the DNS protocol, using query name minimisation to prevent unnecessary data leaks, and developing both DNS over TLS and DNS over *Secure HTTP* (HTTPS) to secure the network path between a stub resolver and its recursive server. This effort is very much a work in progress at present, and it will take some time to see if the results of this work will be widely adopted in the DNS environment.^[20, 21]

We are now operating our applications in an environment of heightened paranoia. Applications do not necessarily trust the platform on which they are running, and we are seeing efforts from the applications to hide their activity from the underlying platform. Applications do not trust the network, and are increasingly using end-to-end encryption to hide their activity from network eavesdroppers. The use of identity credentials within the encrypted session establishment also acts to limit the vulnerability of application clients to be misdirected to masquerading servers.

The Rise and Rise of Content

Moving further up the protocol stack to the environment of content and applications, we have also seen some revolutionary changes over the past decade.

For a small period of time the content and carriage activities of the Internet existed in largely separate business domains, tied by mutual interdependence. The task of carriage was to carry users to content, which implied that carriage was essential to content. But at the same time a client/server Internet bereft of servers is useless, so content is essential to carriage. In a world of re-emerging corporate behemoths, such mutual interdependence is unsettling, both to the actors directly involved and to the larger public interest.

The content industry is largely the more lucrative of these two industries and enjoys far less in the way of regulatory constraint. There is no concept of any universal service obligation, or even any effective form of price control in the services content providers offer. Many content service providers use internal cross-funding that allows them to offer free services to the public, as in free e-mail, free content hosting, free storage, and similar services, and fund these services through a second, more occluded, transaction that essentially sells the user's consumer profile to the highest-bidding advertiser.

All this activity happens outside of any significant regulatory constraint, a situation that has given the content-services industry both considerable wealth and considerable commercial latitude.

It should be no surprise that this industry is now using its capability and capital to eliminate its former dependence on the carriage sector. We are now seeing the rapid rise of the *Content Delivery Network* (CDN) model, where instead of an Internet carrying the user to a diverse set of content stores, the content stores are opening local content outlets right next to the user. As all forms of digital services move into CDN hostels, and as the CDN opens outlets that are positioned immediately adjacent to pools of economically valuable consumers, then where does that leave the traditional carriage role in the Internet? The outlook for the public carriage providers is not looking all that rosy given this increasing marginalisation of carriage in the larger content economy.

Within these CDNs we've also seen the rise of a new service model enter the Internet in the form of cloud services. Our computers are no longer self-contained systems with processing and compute resources; they look more and more like a window that sees the data stored on a common server. Cloud services are very similar, where the local device is effectively a local cache of a larger backing store. In a world where users may have multiple devices, this model makes persuasive sense, because the view to the common backing store is constant irrespective of the device used to access the data. These cloud services also make data sharing and collaborative work far easier to support. Rather than creating a set of copies of the original document and then attempting to stitch back all the individual edits into a single common whole, the cloud model shares a document by simply altering the access permissions of the document. There is only ever one copy of the document, and all edits and comments on the document are available to all.

The Evolution of Cyber Attacks

At the same time as we have seen announcements of ever-increasing network capacity within the Internet, we've seen a parallel set of announcements that note new records in the aggregate capacity of *Denial-of-Service* (DoS) attacks. The current peak volume is an attack of some 1.7 Tbps of malicious traffic.

Attacks are now commonplace. Many of them are brutally simple, relying on a tragically large pool of potential zombie devices that are readily subverted and co-opted to assist in attacks. The attacks are often simple, such as UDP reflection attacks where a single UDP query generates a large response. The source address of the query is forged to be the address of the intended attack victim, and not much more needs to be done. A small query stream can result in a massive attack. UDP protocols such as SNMP, the *Network Time Protocol* (NTP)^[17], the DNS, and *memcached* have been used in the past and doubtless will be used again.

Why can't we fix this problem? We've been trying for decades, and we just can't seem to get ahead of the attacks. Advice to network operators to prevent the leakage of packets with forged source addresses was published nearly two decades ago, in 2000.^[18] Yet massive UDP-based attacks with forged source addresses still persist today. Aged computer systems with known vulnerabilities continue to be connected to the Internet and are readily transformed into attack bots.

The picture of attacks is also becoming more ominous. Although we previously attributed these hostile attacks to "hackers," we quickly realised that a significant component of them had criminal motivations. The progression from criminal actors to state-based actors is also entirely predictable, and we are seeing an escalation of this cyber warfare arena with the investment in various forms of vulnerability exploitation that are considered desirable national capabilities.

It appears that a major problem here is that collectively we are unwilling to make any substantial investment in effective defence or deterrence. The systems that we use on the Internet are overly trusting to the point of irrational credulity. For example, the public key certification system used to secure web-based transactions is repeatedly demonstrated to be entirely untrustworthy, yet that's all we trust. Personal data is continually breached and leaked, yet all we seem to want to do is increase the number and complexity of regulations rather than actually use better tools that would effectively protect users.

The larger picture of hostile attack is not getting any better. Indeed, it's getting very much worse. If any enterprise has a business need to maintain a service that is always available for use, then any form of in-house provisioning is just not enough to withstand attack. These days only a handful of platforms can offer resilient services, and even then it's unclear whether they could withstand the most extreme of attacks.

A constant background level of scanning and probing goes on in the network, and any form of visible vulnerability is ruthlessly exploited. One could describe today's Internet as a toxic wasteland, punctuated with the occasional heavily defended citadel. Those who can afford to locate their services within these citadels enjoy some level of respite from this constant profile of hostile attack, while all others are forced to try to conceal themselves from the worst of this toxic environment, while at the same time aware that they will be completely overwhelmed by any large-scale attack.

It is a sobering thought that about one-half of the world's population are now part of this digital environment. A more sobering thought is that many of today's control systems, such as power generation and distribution, water distribution, and road-traffic-control systems are exposed to the Internet.

Perhaps even more of a worry is the increasing use of the Internet in automated systems that include various life-support functions. The consequences of massive failure of these systems in the face of a sustained and damaging attack cannot be easily imagined.

The Internet of Billions of Tragically Stupid Things

What makes this scenario even more depressing is the portent of the so-called *Internet of Things* (IoT). In those circles where Internet prognostications abound and policy makers flock to hear grand visions of the future, we often hear about the boundless future represented by this Internet of Things.^[19] This phrase encompasses some decades of the computing industry's transition from computers as esoteric pieces of engineering affordable only by nations to mainframes, desktops, laptops, handheld devices, and now wrist computers. Where next? In the vision of the IoT we are going to expand the Internet beyond people and press on using billions of these chattering devices in every aspect of our world.

What do we know about the “things” that are already connected to the Internet?

Some of them are not very good. In fact, some of them are just plain stupid. And this stupidity is toxic, in that their sometime-inadequate models of operation and security affect others in potentially malicious ways. If such devices were constantly inspected and managed, we might see evidence of aberrant behaviour and correct it. But these devices are unmanaged and all but invisible. Examples include the controller for a web camera, the so-called “smart” thing in a smart television, or the controls for anything from a washing machine to a goods locomotive. Nobody is looking after these devices.

When we think of an IoT we think of a world of weather stations, webcams, “smart” cars, personal fitness monitors, and similar things. But what we tend to forget is that all of these devices are built on layers of other people's software that is assembled into a product at the cheapest possible price point. It may be disconcerting to realise that the web camera you just installed has a security model that can be summarised with the phrase: “no security at all,” and it's actually offering a view of your house to the entire Internet. It may be slightly more disconcerting to realise that your electronic wallet is on a device that is using a massive compilation of open source software of largely unknown origin, with a security model that is not completely understood, but appears to be susceptible to be coerced into being a “yes, take all you want” device.

It would be nice to think that we've stopped making mistakes in code, and from now on our software in our things will be perfect. But that's hopelessly idealistic. It's just not going to happen. Software will not be perfect. It will continue to have vulnerabilities.

It would be nice to think that this Internet of Things is shaping up as a market where quality matters, and consumers will select a more expensive product even though its functional behaviour is identical to a cheaper product that has not been robustly tested for basic security flaws. But that too is hopelessly naive.

The Internet of Things will continue to be a marketplace where the compromises between price and quality will continue to push us on to the side of cheap rather than secure. What's going to stop us from further polluting our environment with a huge and diverse collection of programmed unmanaged devices with inbuilt vulnerabilities that will be all too readily exploited? What can we do to make this world of these stupid cheap toxic things less stupid and less toxic? So far we have not found workable answers to this question.

The Next 10 Years

The silicon industry is not going to shut down anytime soon. It will continue to produce chips with more gates, finer tracks, and more stacked layers for some years to come. Our computers will become more capable in terms of the range and complexity of the tasks that they will be able to undertake.

At the same time, we can expect more from our network. Higher capacity certainly, but also greater levels of customisation of the network to our individual needs.

However, I find it extremely challenging to be optimistic about security and trust in the Internet. We have made little progress in this area over the last 10 years, and there is little reason to think that the picture will change in the next 10 years. If we can't fix it, then, sad as it sounds, perhaps we simply need to come to terms with an Internet jammed full of tragically stupid things

However, beyond these broad-brush scenarios, it's hard to predict where the Internet will head. Technology does not follow a predetermined path. It's driven by the vagaries of an enthusiastic consumer marketplace that is readily distracted by colourful bright shiny new objects, and easily bored by what we quickly regard as commonplace.

What can we expect from the Internet in the next 10 years that can outdo a pocket-sized computer that can converse with me in a natural language? That can offer more than immersive 3D video with outstanding quality? That can bring the entire corpus of humanity's written work into a searchable database that can answer any of our questions in mere fractions of a second?

Personally, I have no clue what to expect from the Internet. But no matter what manages to capture our collective attention, I am pretty confident that it will be colourful, bright, shiny, and entirely unexpected!

Fileless Malware

by David Strom

Malware authors have gotten more clever and sneaky over time to make their code more difficult to detect and prevent. One of the more worrying recent developments goes under the name “fileless.” There is reason to worry because these kinds of attacks can do more damage and the malware can persist on your computers and networks for weeks or months until they are finally neutralized. Let’s talk about what this malware is and how to understand it better so we can try to stop it from entering our networks to begin with.

Usually, the goal of most malware is to leave something behind on one of your endpoints: one or more files that contain an executable program that can damage your computer, corral your PC as part of a botnet, or make copies of sensitive data and move them to an external repository. Over the years, various detection products have gotten better at finding these *residues*, as they are called, and blocking them.

But the malware game is one of “cat-and-mouse,” and as defenders get better at stopping the malware, the malware authors get better at evading these blockades. Back in the early days of the Internet, most blocking routines looked for certain signatures, either as the name of one of the running programs on your computer or specific patterns of behavior across your network. These options worked until the malware authors got better at hiding their signature moves.

This point is where the fileless versions come into play. They aim to leave as little residue as possible, so the detection products can’t easily find them. Or better yet, to do something misleading, or under the guise of something that an uninfected operating system might do.

Actually, the fileless designation is somewhat of a misnomer since there is still something left behind. It may not be a complete executable file or *Dynamic Linked Library* (DLL), but enough of some code is used to actually be able to run some series of processes that can do the “dirty work” of the malware. Starting in 2016, researchers began to see more of these fileless efforts from attackers, and they have continued to become more popular because the malware can be a powerful infection that is neither easily found nor prevented.^[1]

Fileless Attack Types

Fileless malware uses three different attack types: *Return-Oriented Programming*, *Scripting-Based Attacks*, and *Polymorphic Attacks*. Each is somewhat different.

The first type of attack is called *Return-Oriented Programming*, which is the most popular and could be considered the “classic” version. The malware can execute standard DLLs and other sequences of code that can compromise an otherwise uninfected system. This code could also be part of your desktop web browser, or common *Operating System* (OS) tools such as desktop applications. Since the code is already present in these operating system functions, there is no particular “file” actually being run that is unique to the malware itself. Instead, the malware author piggybacks on these routines to get the job done.

To make this kind of attack work, you have to be familiar with the program code that you intend to hijack for evil purposes, and be reasonably assured that the target endpoint is running the particular version of code for that operating system. Small variations in OS versions, such as from Windows 7 to 7.1 or MacOS 10.12.5 to 10.12.6, could foil the attack because the code base has changed. Or if Microsoft or Apple (in particular, given their popularity and installed base) has issued a patch to fix the potential exploit.

Scripting-Based Attacks are the second fileless category. Another avoidance technique is to execute malware using built-in Windows scripting engines such as Microsoft Office, Windows *PowerShell*, or Microsoft’s HTML Application Host. These attacks typically take advantage of process hooking and don’t leave any file-based residues on the endpoint. If your detection systems can’t see the script execution or understand the command-line arguments, you can’t readily figure out that it is malware.

For example, a typical malware script allocates memory, resolves Windows application program interfaces, and downloads some executable directly to the memory of the target PC. After it gets in memory, it starts up a malicious service and begins to use the target to explore the local network to find other targets, often by starting other malicious PowerShell scripts that use privilege escalation and remote execution. That is a lot of stuff going on to avoid detection and to do the dirty work of the malware. But most of these activities can operate “under the radar,” and perhaps be discovered only months later with detailed forensic analysis that can capture the sequence of events that played out for the particular attack.

Scripting attacks are gaining favor, mainly because there is so much built-in software on a typical modern PC that can do most of what a piece of malware needs to do: to access a shared network drive, copy portions of files, set up some sort of monitoring tool, and so forth. Why reinvent the criminal’s wheel when it is sitting on the average desktop or laptop?

A third method is called *Polymorphic Attacks*. These attacks adapt to a variety of conditions, operating systems, and circumstances and try to evade security scans and protection products to infect your endpoints. They are called polymorphic because they shift their signatures, attack methods, and targets so that you can't easily identify and catch them. Attackers typically use polymorphism as just one of many code obfuscation methods to hide from defenders, such as determining if they are running inside a *Virtual Machine* (a favorite ploy researchers use), or encrypting their code to mask their executables.

Over the past several years, security vendors have begun to take this notion of polymorphism that attackers use and turn it into a defensive maneuver. The idea is to make a target Web server or other piece of network infrastructure appear to change frequently so it can't be easily identified or infected. Sometimes this method is called a *moving-target defense*, which could be a synonym or refer to some aspect of the defense that changes the nature of your applications or code locations. These vendors include Morphisec, Shape Security, and Polyverse, all startup companies. One startup, CyActive, was successful enough to be purchased by PayPal.

Polymorphic defenses can limit the amount of time a potential attacker can invade a network, since their target system appears to move around the network or change properties.

Researchers are seeing combinations of all three types of attacks to make them even more sophisticated and difficult to track down. Sometimes, malware authors program multiple attack types to ensure that something will evade your defenses and penetrate your network. As I said earlier, it is a game of cat and mouse.

Fileless Samples

Let's look at a few recent examples of fileless malware to illustrate the differences and how fileless malware has evolved over time.

Back in 2014, the retailer Target experienced a now-infamous breach. It turns out malware was placed on its network through a very simple strategy: someone's network access credentials were discovered and copied, in this case belonging to an employee of Target's heating vendor. What is noteworthy about this attack is its simplicity, and the fact that Target's network was a flat topology with no *virtual LANs* (vLANs) or other segments. This example is a reminder that bad network practice can make any kind of malware—fileless or otherwise—dangerous. Brian Krebs studied what went wrong and reported on this attack in his blog.^[2]

As most of us know by now, back in 2016, the *Democratic National Committee* (DNC) was hacked. The attack used a fileless malware product that took advantage of both PowerShell and *Windows Management Instrumentation* (WMI) in order to “get a foot into the door” of the political party's systems.

WMI is commonly used for day-to-day management tasks such as deploying automation scripts, running a process at a given time, or getting information about the installed applications or hardware.

The DNC malware also used PowerShell as a staging tool to execute other scripts to compromise a system. It used WMI to install backdoors that allow persistence by enabling the adversary to launch malicious code automatically, after a specified period of system uptime or according to a specific schedule. Again, the malware used all of these tactics to avoid detection.^[3]

August Stealer was discovered at the end of 2016 and was attributed to the TA530 criminal group. Targeted at customer service and call center staffs, it used infected Word macros and PowerShell scripts that were delivered via phished e-mails. The e-mails were designed to look like queries from users over support issues and used various subject lines such as the following:

- Erroneous charges from [recipient's domain]
- [recipient's domain] - Help: Items vanish from the cart before checkout
- [recipient's domain] Support: Products disappear from the cart during checkout
- Need help with order on [recipient's domain]
- Duplicate charges on [recipient's domain]

August contains stealing functionality targeting credentials, cryptocurrency wallets, and sensitive documents from the infected computers.^[4]

Discovered earlier in 2017, *Duqu2* is a good example of the first fileless malware products. The malware was found in more than 140 enterprise networks of banks, government offices, and telecom companies across 40 different countries.

It takes the form of a malicious PowerShell script and a series of the following Windows Registry values that at the time were unique to the malware and used to identify the infected systems:

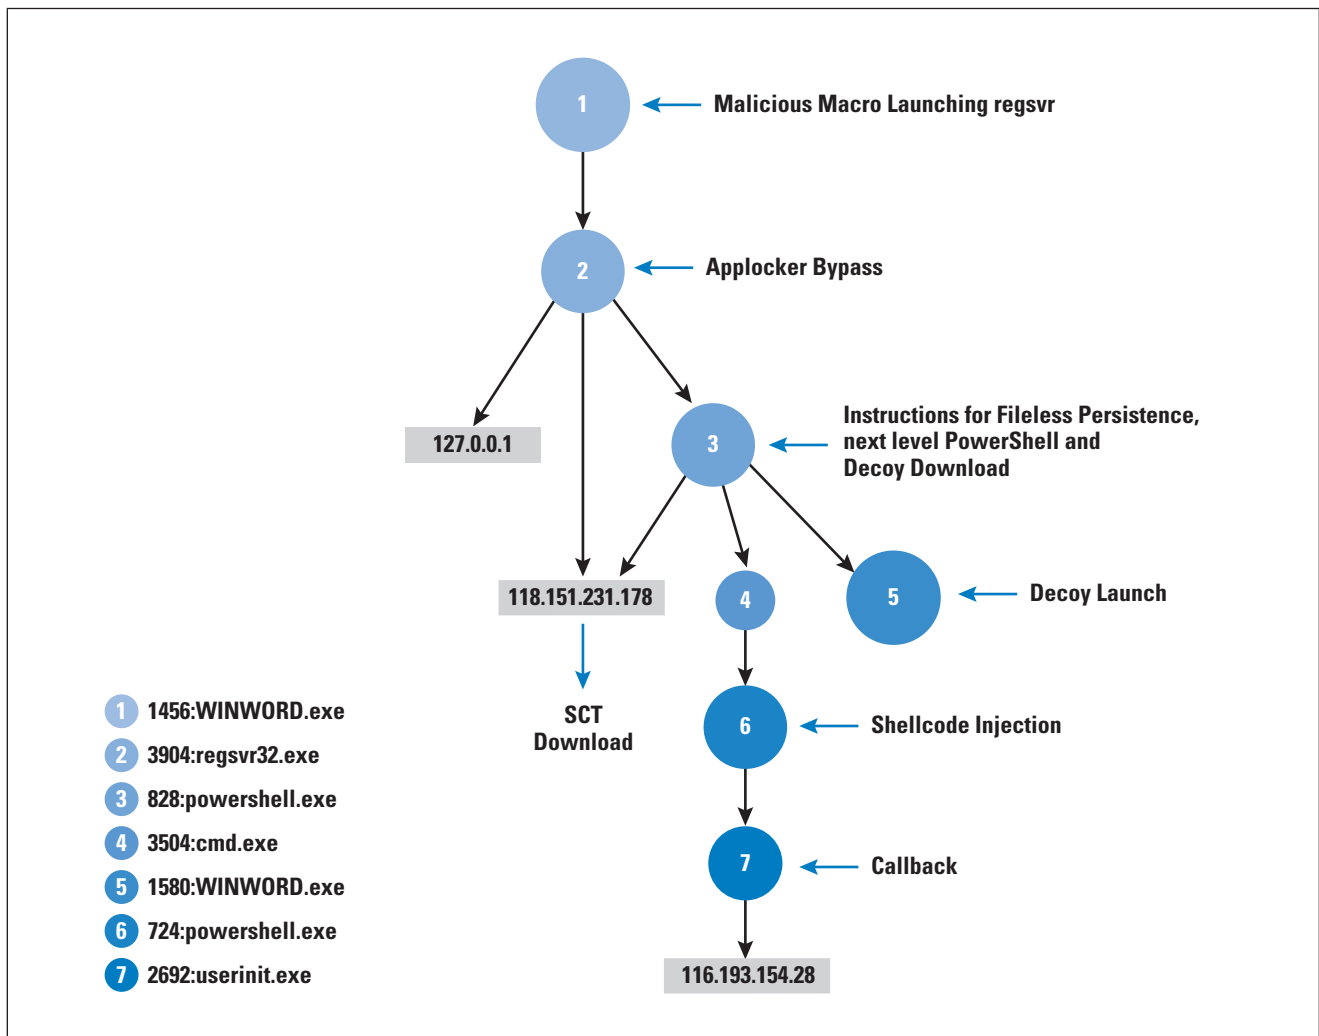

- `HKLM\SYSTEM\ControlSet001\services\` – path is modified after using the SC utility
- `HKLM\SYSTEM\ControlSet001\services\PortProxy\v4tov4\tcp` – path is modified after using the NETSH utility

After finding its way onto the target hard drives, it then starts up via a malicious Windows installer or MSI file, which then deletes itself and renames various files to hide its operations. After the malware is installed on a PC, it just runs in the memory of the PC.

“That’s why memory forensics is critical to the analysis of malware and its functions. In fact, detection of this attack would be possible in memory, network, and Windows Registry only,” says one group of researchers from Kaspersky Labs that studied its operations.^[5] Obviously, running in memory means the Duqu2 malware won’t last after the PC is rebooted—one drawback of many fileless products.

Poison Ivy, also discovered earlier this year, is an example of fileless malware that was used on a specific target, in this case Mongolian government officials. It takes the form of a malicious Microsoft Word macro. If the target has enabled macros—which is a typical setting for most users—it runs and creates a remote-access connection to log keystrokes and capture screens and videos from the PC. All these actions are done from memory-resident programs taking advantage of certain PowerShell command sequences. Figure 1 shows its various modules (courtesy of FireEye).

Figure 1: *Poison Ivy* Modules

Poison Ivy also tried to evade detection by Microsoft's *AppLocker* protection system by inserting a reference to itself in AppLocker's whitelisted applications using a series of Windows programs and scripts. It also created a series of decoy documents to make its operations seem benign to the infected user. As you can see, this software is very complex, with several different stages and methods to find its way into a user's PC. It has also been used in other circumstances besides the Mongolian case.^[6]

Other targeted fileless campaigns, such as the *OilRig* malware^[7], have been attributed to Iranian state-sponsored actors. This campaign targeted 250 e-mail accounts of various Israelis, including ironically cybersecurity researchers at Ben Gurion University. While Microsoft released a patch back in April 2017 that prevents this malware from spreading, many enterprises haven't yet applied it. Ironically (again), the malware authors used the details from a published proof-of-concept to design their tool accordingly.

This particular malware used an infected Word document that was sent as an attachment and used to steal information from targeted PCs. It used a specialized fileless version of the *Helminth Trojan* malware. Earlier versions of OilRig used infected macros, but this attack used an embedded Web link using an **.HTA** executable file. This type of file is automatically run by the Windows program **MSHTA.EXE** (for Microsoft HTML applications). Normally, when this program runs an **.HTA** file, it displays the following warning message:

Figure 2: This warning about file permissions from Windows is only briefly seen by users when they click on an infected file.

However, this malware anticipates this situation, and automatically sends an “Enter” command so that the warning window is quickly dispatched and the malware does its business. Other targeted malware campaigns include one targeting American restaurant computers using the *Fin7* malware^[8]. In the past, this malware targeted banks and government financial filing documents. And like other fileless attacks, it hides inside a Microsoft Word document that is attached to phishing e-mails. One new twist with the Fin7 restaurant attacks is that it executes various attacks completely in memory, without using any PowerShell commands.

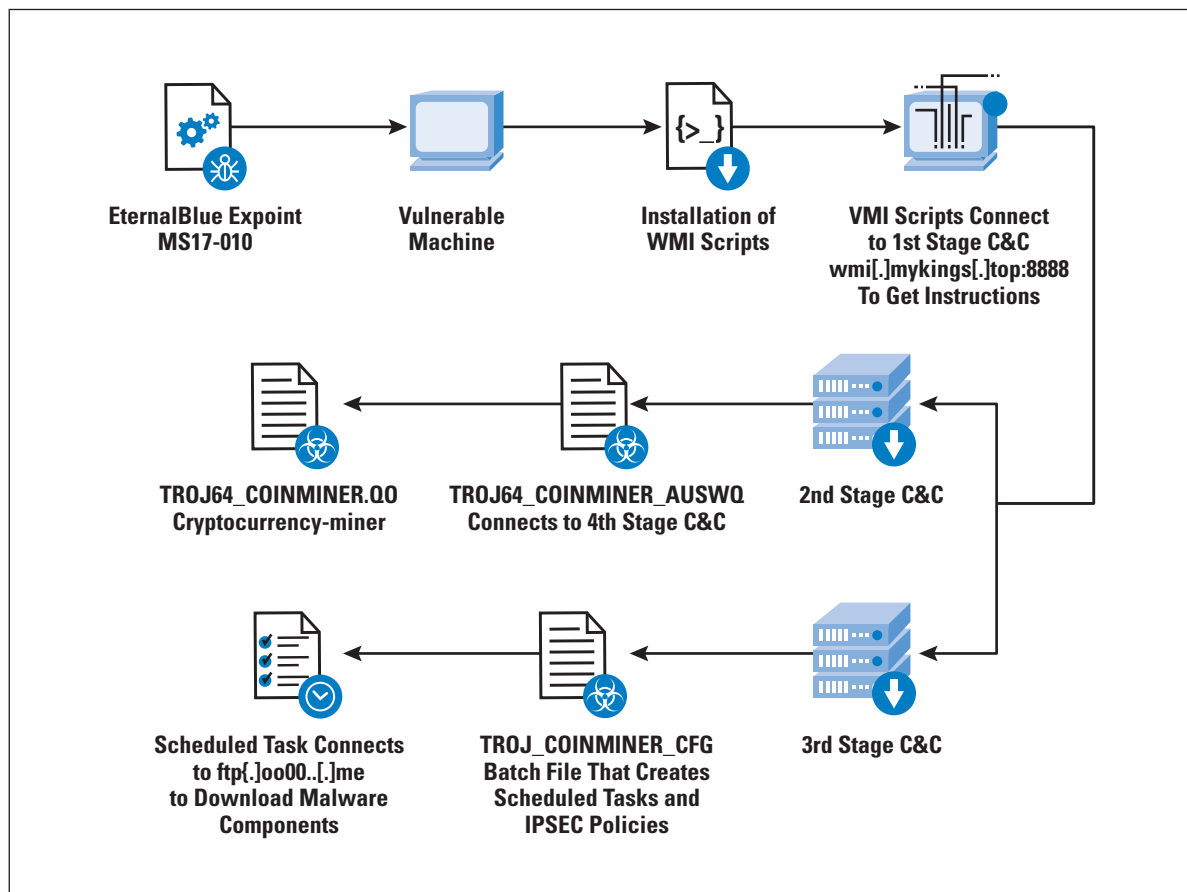

Another obfuscation technique goes by the name of *DoubleAgent*. It takes advantage of an undocumented feature in Microsoft Application Verifier. This verifier is code that has been around since at least Windows XP and is a Windows feature that lets developers do runtime verifications of their applications for finding and fixing security problems.

Unfortunately, it has an undocumented feature that security researchers from Cybellum discovered. The feature gives attackers a way to replace the legitimate verifier with a rogue one so they can gain complete control of the application. Cybellum said, “DoubleAgent gives the attacker the ability to control the AV and perform all the operations above without being detected, while keeping the illusion that the AV is working normally.”^[9]

Security vendors have recently issued patches to correct this flaw, but again this example demonstrates that malware writers are getting better at finding these sorts of hidden mechanisms to avoid discovery and being blocked.

In July 2017, a new fileless malware was discovered called *CoinMiner*^[10], which was found mainly in Japan and Indonesia. The purpose of this malware was to create a hidden bitcoin mining application, to generate cryptocurrency for the attacker. It uses WMI to persist beyond reboots and execute a series of scripts. CoinMiner invades a PC through the *EternalBlue* exploit^[11], which is the same method that was used by the *WannaCry* worm. Figure 3 is a diagram of its logic flow (courtesy of Trend Micro):

Figure 3: CoinMiner Logic Flow

Common Prevention Steps

Given the scope of these exploits, here are a few steps to take to prevent infections across your network:

- Apply patches quickly and across all systems. Microsoft issues regular patches for Windows, and the other operating system vendors do the same for their systems. Don't delay an update, because you can see some criminals take advantage of unpatched systems with their malware. The EternalBlue exploit is a good example: the patch to prevent this attack was available for more than a month before this exploit was launched.
- Segment your network carefully and make sure you understand access rights, especially of third parties.
- Restrict administrator rights to the minimum number of systems. Many of the WMI-based exploits count on profligate use of admin rights that aren't needed.
- Disable Windows programs that aren't needed, such as WMI, PowerShell, and support for ancient protocols such as *Server Message Block* (SMB) v1.
- Whitelist applications to further restrict what can run on most endpoints.

Conclusion

As you can see, the bad guys have gotten better at plying their trade, and through the use of fileless techniques, they are making their malware harder to detect and protect. Hopefully, by learning about some of these past examples, you can tune your own defenses accordingly and do a better job of keeping them infection-free.

Postel Award Presented to Steven G. Huter

The Internet Society, a global non-profit dedicated to ensuring the open development, evolution, and use of the Internet, recently presented the prestigious *Jonathan B. Postel Service Award* to Steven G. Huter, Director for the *Network Startup Resource Center* (NSRC) and a Research Associate at the University of Oregon. For decades he has worked with people around the world to strengthen the infrastructure, partnerships, and expertise upon which the Internet has been developed in more than 120 countries, particularly in support of research and education.

Photographic/Internet Society

“Steve Huter is the quintessential candidate for the Postel Award. For a quarter of a century, Steve has enabled hundreds of institutions to build and operate new components of the Internet. His dedication to this task mirrors Postel’s own and continues to this day. Literally millions have benefited from Steve’s work,” explains Vint Cerf, founding president of the Internet Society.

Mr. Huter was selected by an international award committee comprised of former Postel Award winners. The committee placed particular emphasis on candidates who have supported and enabled others in addition to their own contributions. The award is being presented to Mr. Huter in recognition of “his leadership and personal contributions at the Network Startup Resource Center that enabled countless others to develop the Internet in more than 120 countries.” The NSRC was formally begun in 1992 by Randy Bush and John Klensin with funding from a U.S. National Science Foundation grant to provide technical assistance to people setting up networks in developing areas to support scientific collaboration.

“Steve epitomizes the values and spirit of the Postel Award. For more than twenty-five years he has energetically brought the fruits of the Internet to developing countries using his unique combination of a multicultural background, technical knowledge, unfailing energy and commitment,” adds Steve Crocker, CEO and co-founder of Shinkuro, Inc.

Mr. Huter joined the NSRC in 1993, where he has led the development and implementation of programs that provide technical training, equipment, and expertise across Africa, Asia-Pacific, Latin America-Caribbean, and the Middle East.

“It is a tremendous honor to be acknowledged for helping to advance Jon’s vision and philosophy of developing the Internet into a global resource,” said Mr. Huter on receiving the award.

“The most important thing I learned from Jon Postel and the founders of the NSRC is to cultivate a culture of network operators who help each other via technical exchange and resource sharing; this is an effective way to empower more network engineers and enable continuous progress for a community of peers in all regions of the world. Thank you to the NSRC team and all who have contributed over the years towards achieving this objective and enriching the Internet.”

The Postel Award was established by the Internet Society to honor individuals or organizations that, like Jon Postel, have made outstanding contributions to the data communications community. The award is focused on sustained and substantial technical contributions, service to the community, and leadership. Kathy Brown, President and CEO of the Internet Society presented the award including a US\$20,000 honorarium and a crystal engraved globe, during the 102nd meeting of the *Internet Engineering Task Force* (IETF) held in Montreal, Canada, July 14–20, 2018.

Founded by Internet pioneers, the *Internet Society* (ISOC) is a non-profit organization dedicated to ensuring the open development, evolution and use of the Internet. Working through a global community of chapters and members, the Internet Society collaborates with a broad range of groups to promote the technologies that keep the Internet safe and secure, and advocates for policies that enable universal access. The Internet Society is also the organizational home of the IETF.

The NSRC, which is based at the University of Oregon, was established in 1992 to provide technical assistance to organizations setting up computer networks in new areas to connect scientists engaged in collaborative research and education. For the past few decades, the NSRC has helped develop Internet infrastructure and network operations communities in Africa, Asia-Pacific, Latin America-Caribbean, and the Middle East. The NSRC is partially funded by the *International Research Network Connections* (IRNC) program of the U.S. National Science Foundation and Google, with additional contributions from dozens of public and private organizations.

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

The *Transmission Control Protocol* (TCP) is a core component of the Internet Protocol Suite. TCP has proven robust and flexible in the face of changing network infrastructures, but may not be the most efficient way to retrieve the many components of today's complex web pages. The *Quick UDP Internet Connection* (QUIC) protocol is an alternative to TCP for web traffic. QUIC was initially developed and deployed by Google and is now being standardized in the *Internet Engineering Task Force* (IETF). In our first article, Geoff Huston examines the motivations for QUIC and describes the protocol and its implementation.

According to *Wikipedia*: "A *checksum* is a small-sized datum derived from a block of digital data for the purpose of detecting errors that may have been introduced during its transmission or storage. It is usually applied to an installation file after it is received from the download server. By themselves, checksums are often used to verify data integrity but are not relied upon to verify data authenticity." In preparation for the "rolling" of the root *Key Signing Key* of the *Domain Name System* (DNS), tests were developed to create so-called *key-tags*. This key-tag generation process "...became an adventure in itself that included beautiful discrete math, flawed functions, carefully crafted primes, multiple cryptographic libraries, and some brilliant people," according to Roy Arends, author of our second article, "The Quest for the Missing Checksums." IPJ doesn't normally delve into complex mathematics, but in this case the interplay of various software libraries and methods provides some valuable lessons for anyone involved in code generation and testing.

We would like to remind you that this journal depends on the generous support of numerous individuals and organizations. If you would like to help support IPJ, please contact us for further details. Comments, suggestions, book reviews, and articles are always welcome. Send your messages to ipj@protocoljournal.org

A Quick Look at QUIC

by Geoff Huston, APNIC

Quick UDP Internet Connection (QUIC) is a network protocol initially developed and deployed by Google, and is now being standardized in the *Internet Engineering Task Force* (IETF). In this article we'll take a quick tour of QUIC, looking at the goals that influenced its design, and the implications QUIC might have on the overall architecture of the Internet Protocol Stack.

QUIC is not exactly a recent protocol, as the concept appears to have been developed by Google in 2012, and initial public releases of this protocol were included in Chromium version 29, released in August 2013. QUIC is one of many transport-layer network protocols that attempt to refine the basic operation of the *Transmission Control Protocol* (TCP).

Why are we even thinking about refining TCP?

TCP is now used in billions of devices and is perhaps the most widely adopted network transport protocol that we've witnessed so far. If this protocol weren't fit for our use, then we would have moved on and adopted some other protocol or protocols instead. Part of the reason for the broad adoption of TCP is its incredible flexibility. The protocol can support a diverse variety of uses, from micro-exchanges to gigabyte data movement, transmission speeds that vary from hundreds of bits per second to tens and possibly hundreds of gigabits per second. TCP is the workhorse of the Internet. But even so, there is room for refinement. TCP is used in many different ways, and its design represents a set of trade-offs that attempt to be a reasonable fit for many purposes but not necessarily an ideal fit for any particular one.

One of the aspects of the original design of the Internet Protocol Suite was that of elegant brevity and simplicity. The specification of TCP^[1] is not a single profile of behavior that has been cast into a fixed form that was chiseled into the granite slab of a rigid standard. TCP is malleable in many important ways. Numerous efforts over the years have shown that it is possible to stay within the standard definition of TCP, in that all the packets in a session use the standard TCP header fields in mostly conventional ways, but also to create TCP implementations that behave radically differently from each other. Critically, the TCP standard does not strictly define how the sender can control the amount of data in flight across the network. There is a convention to adopt an approach of slowly increasing the amount of data in flight while there are no visible errors in the data transfer (as shown by the stream of received acknowledgement [ACK] packets) and quickly responding to signals of network congestion (packet drop, as shown by duplicate acknowledgements) by rapidly decreasing the sending rate.

Variants of TCP use different controls to manage this “slow increase” and “rapid drop” behavior^[2] and may also use different signals to control this data flow. These signals include measurements of end-to-end delay, or inter-packet jitter (such as the recently published *Bottleneck Bandwidth and Round-trip Propagation Time* (BBR) protocol^[3]). All of these variants still manage to fit with the broad parameters of what is conventionally called TCP.

It is also useful to understand that most variants of TCP need to be implemented only on the data sender (the “server” in a client/server environment). The common assumption of all TCP implementations is that clients will send a TCP ACK packet on successful receipt of both in-sequence and out-of-sequence data. It is left to the server’s TCP engine to determine how the received ACK stream will be applied to its internal model of network capability and how it will modify its subsequent sending rate accordingly. The implication is that deployment of new variants of TCP flow control is essentially based on deployment within service-delivery platforms and does not necessarily imply changing the TCP implementations in all the billions of clients. This feature also contributes to the flexibility of TCP.

But despite its considerable flexibility, TCP has its problems, particularly with web-based services. These days most web pages are not simple monolithic objects. They typically contain many separate components, including images, scripts, customized frames, and others. Each of these is a separate web “object,” and if you are using a browser that is equipped with the original implementation of the *HyperText Transfer Protocol* (HTTP) each object will be loaded in a new TCP session, even if the objects are served from the same IP address. The overheads of setting up both a new TCP session and a new *Transport Layer Security* (TLS)^[4] session for each distinct web object within a compound web resource can become quite significant, and the temptation to reuse an already established TLS session is close to overwhelming. But this approach of multiplexing a number of data streams within a single TCP session also has issues. Multiplexing multiple logical data flows across a single session can generate unwanted interdependencies between the flow processors and generate *Head of Line Blocking* situations. It appears that while it makes some logical sense to share a single end-to-end security association and a rate-controlled data-flow state across a network across multiple logical data flows, TCP represents a rather poor way of achieving this outcome. The conclusion is that if we want to improve the efficiency of such compound transactions by introducing parallel behaviors into the protocol, we need to look beyond TCP.

Why not just start afresh and define a new transport protocol that addresses these shortcomings of TCP? The answer is simple: *Network Address Translators* (NATs)!

NATs and Transport Protocols

The original design of IP allowed for a clear separation between the network element that allowed the network to accept an IP packet and forward it onto its intended destination (the “Internet” part of the IP protocol suite) and the end-to-end transport protocol that enabled two applications to communication via some form of “session.” The transport protocol field in the IPv4 packet header and the Next header field of the IPv6 packet header uses an 8-bit field to identify the end-to-end protocol. This design assumed that the network had no need to “understand” what end-to-end protocol was being used within a packet. Ideally an IP packet switch will not differentiate in its treatment of packets depending on the inner end-to-end protocol.

Some 140 protocols are listed in the IP protocol field registry^[5]. TCP and the *User Datagram Protocol* (UDP) are just two of these protocols (protocol values 6 and 17, respectively). In theory at any rate, there is room for a least 100 more. However, in the public Internet the story is somewhat different. TCP and UDP are widely accepted protocols, and the *Internet Control Message Protocol* (ICMP) (protocol 2) is generally accepted, but little else. How did this situation happen?

NATs changed the assumption about network devices not looking inside the packet (to be precise, port-translating NATs changed that assumption). NATs are network devices that look inside the IP packet and re-write the port addresses used by TCP and UDP^[6]. What if an IP packet contains an end-to-end transport protocol identifier value that is neither TCP nor UDP? Most NATs will simply drop the packet, on the basis of a security paradigm that “what you don’t recognize is likely to be harmful.” The pragmatic result is that NATs have limited the choice of transport protocols of an application in the public Internet to just two: TCP and UDP.

If the aim is to deploy a new transport protocol—but not confuse active network elements that are expecting to see a conventional TCP or UDP header—then how can we achieve this goal?

This question was the challenge of the QUIC developers.

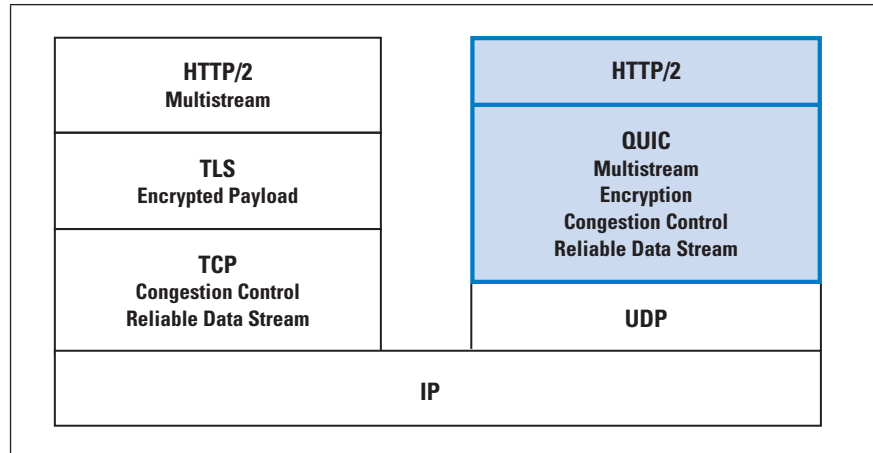

QUIC over UDP

The solution that QUIC chose was a UDP-based approach. UDP is a minimal framing protocol that allows an application to access the basic datagram services that IP offers. Apart from the source and destination port numbers, the UDP header adds a length header and a checksum that covers the UDP header and UDP payload. It is essentially an abstraction of the underlying datagram IP model with just enough additional information to allow an IP protocol stack to direct an incoming packet to an application that has bound itself to a nominated UDP port address. If TCP is an overlay across the underlying IP datagram service, then it’s a small step to think about layering TCP as a payload within a UDP packet.

Using our standard Internet model, QUIC is—strictly speaking—a datagram transport application. An application that uses the QUIC protocol sends and receives packets using UDP port 443.

Technically, this change is very small to an IP packet, adding just 8 bytes to the IP packet by placing a UDP header between the IP and TCP packet headers (Figure 1). The implications of this change are far more significant than these 8 bytes would suggest. However, before we consider these implications, let’s look at some QUIC services.

Figure 1: The QUIC Protocol Architecture

QUIC and the Connection ID

If the choice of UDP as the visible end-to-end protocol for QUIC was a choice dictated by the inflexibility of the base of deployed NAT devices in the public Internet and their collective inability to accommodate new protocols, the way that NATs handle UDP packets has further implications for QUIC.

NATs maintain a *translation table*. In the most general model, a NAT takes the 5-tuple of incoming packets, using the destination and source IP addresses, the destination and source port addresses, and the protocol field, and performs a lookup into the table to find the associated translated fields. The address headers of the packet are rewritten to these new values, *checksums* are recomputed, and the packet is passed onward. Certain NAT implementations may use variants of this model. For example, some NATs use only the source IP address and port address on *outbound* packets as the lookup key, and the corresponding destination IP address and port address in *incoming* packets.

Typically, the NAT generates a new translation table entry when a triggering packet is passed from the *inside* to the *outside* and subsequently removes the table entry when the NAT assumes that the translation is no longer needed. For TCP sessions it is possible to maintain this translation table quite accurately.

New translation-table entries are created in response to *outbound* TCP SYN connection establishment packets and removed either when the NAT sees the TCP FIN exchange or in response to a TCP RST packet or when the session is idle for an extended period.

UDP packets do not have these clear packet exchanges to start and stop sessions, so NATs need to make some assumptions. Most NATs create a new translation table entry when they see an outbound UDP packet that has not matched any existing translation table. The entry is then maintained for some period of time (as determined by the NAT) and is then removed if there are no further packets that match the session signature. Even when there are further matching UDP packets, the NAT may use an overall UDP session timer and remove the NAT entry after some predetermined time interval.

For QUIC and NATs, this situation is a potential problem. The QUIC session is established between a QUIC server on UDP port 443 and the NAT-generated source address and port. However, at some point in the session lifetime the NAT may drop the translation-table entry, and the next outbound client packet will generate a new translation-table entry that may use a different source address and port. How can the QUIC server recognize that this next-received packet, with its new source address and source port number, is actually part of an existing QUIC session?

QUIC uses the concept of *Connection Identifiers* (Connection IDs). Each endpoint generates connection IDs that will allow received packets with that connection ID to be routed to the process that is using that connection ID. During QUIC version negotiation these connection IDs are exchanged, and thereafter each sent QUIC packet includes the current connection ID of the remote party.

This form of semantic distinction between the identity of a connection to an endpoint and the current IP address and port number that QUIC uses is similar to the *Host Identity Protocol* (HIP)^[7]. This protocol also uses a constant endpoint identifier that allows a session to survive changes in the endpoint IP addresses and ports.

QUIC Streams

TCP provides the abstraction of a reliable order byte stream to applications. QUIC provides a similar abstraction to the application, termed within QUIC as *streams*. The essential difference here is that TCP implements a single behavior, while a single QUIC session can support multiple streams profiles.

Bidirectional streams place the client and server transactions into a matched context, as is required for the conventional request/response transactions of HTTP/1. A client would be expected to open a bidirectional stream with a server and then issue a request in a stream which would generate a matching response from the server. It is possible for a server to initiate a bidirectional *push stream* to a client, which contains a response without an initial request.

Control information is supported using unidirectional *control streams*, where one side can pass a message to the other as soon as they are able. An underlying *unidirectional stream* interface, used to support control streams, is also exposed to the application.

Not only can QUIC support many different stream profiles, it can also support different stream profiles within a single end-to-end QUIC session. This concept is not a novel one, of course, and the HTTP/2 protocol is a good example of an application-level protocol adding multiplexing and stream framing in order to carry multiple data flows across a single transport data stream. However, a single TCP transport stream as used by HTTP/2 may encounter *Head of Line Blocking* where all overlay data streams fate-share across a single TCP session. If one of the streams stalls, all overlay data streams could be affected and could stall as well.

QUIC allows for a slightly different form of multiplexing where each overlay data stream can use its own end-to-end flow state, and a pause in one overlay stream does not imply that any other simultaneous stream is affected.

Part of the reason to multiplex multiple data flows between the same two endpoints in HTTP/2 was to reduce the overhead of setting up a TLS security association for each TCP session. This overhead can be quite significant when the individual streams are each sending a small object, and it's possible to encounter a situation where the TCP and TLS handshake component of a compound web object fetch dominates both the total download time and the data volume.

QUIC pushes the security association to the end-to-end state that is implemented as a UDP data flow, so that streams can be started in a very lightweight manner because they essentially reuse the established secure session state.

QUIC Encryption

As is probably clear from the references to TLS already, QUIC uses *end-to-end encryption*. This encryption is performed on the UDP payload, so once the TLS handshake is complete very little of the subsequent QUIC packet exchange is in the clear (Figure 2).

Figure 2: Comparison of TCP and TLS with QUIC

What is exposed in QUIC are the *public flags*. This initial part of a QUIC packet consists of the connection ID, which allows the receiver to associate the packet with an endpoint without decrypting the entire packet. The QUIC version is also part of the public flag set, which is used in the initial QUIC session establishment and can be omitted thereafter.

The remainder of the QUIC packet includes *private flags* and the payload. They are encrypted and are not directly visible to an eavesdropper. This private section includes the packet sequence number. This field is used to detect duplicate and missing packets. It also includes all the flow-control parameters, including window advertisements.

This encryption is one of the critical differences between TCP and QUIC. With TCP the control parts of the protocol are in the clear, so that a network element would be able to inspect the port addresses (and infer the application type), as well as the flow state of the connection. Connection of a sequence of such TCP packets, even if only looking at the packets flowing in one direction within the connection, would allow the network element to infer the round-trip time and the data-transmission rate. And, like a NAT, manipulation of the receive window in the ACK stream would allow a network element to apply a throttle to a connection and reduce the transfer rate in a manner that would be invisible to both endpoints. Placing all of this control information inside the encrypted part of the QUIC packet ensures that no network element has direct visibility to this information, and no network element can manipulate the connection flow.

One could take the view that QUIC enforces a perspective that was assumed in the 1980s: that the end-to-end transport protocol is not shared with the network. All the network “sees” are stateless datagrams, and the endpoints can safely assume that the information contained in the end-to-end transport control fields is carried over the network in a manner that protects it from third-party inspection and alteration.

QUIC and IP Fragmentation

The short answer is “no!” QUIC packets cannot be fragmented^[7, 8]. The way this feature is achieved is by having the QUIC HELLO packet be padded out to the maximal packet size, and not completing the initial HELLO exchange if the maximally sized packet is fragmented.

For IPv4 the maximum QUIC packet size is 1,350 bytes. Adding 8 bytes for the UDP header, 20 bytes for IPv4, and 14 bytes for the Ethernet frame means that a QUIC packet on Ethernet totals 1,392 bytes. There is no particular rationale for this choice of 1,350 other than the results of empirical testing on the public Internet.

For IPv6 the QUIC maximum packet size is reduced by 20 bytes to 1,330. The resultant Ethernet packet is still 1,392 bytes because of the larger IPv6 IP packet header.

What happens if the network path has a smaller *Maximum Transmission Unit* (MTU) than this value? The answer is in the next section.

QUIC and TCP

QUIC is not intended as a replacement for TCP. Indeed, QUIC relies on the continued availability of TCP.

Whenever QUIC encounters a fatal error—such as fragmentation of the QUIC HELLO packet—the intended response from QUIC is to shut down the connection. Since QUIC itself lies in the application space, not the kernel space, the client-side application can be directly informed of this closure of the QUIC connection and it can re-open a connection to the server using a conventional TCP transport protocol.

The implication is that QUIC does not necessarily have to have a robust response for all forms of behavior, and when QUIC encounters a state where it has no clear definition of the desired behavior, it is always an option to signal a QUIC failure to the application. The failure need not be fatal to the application, because such a signal can trigger the application to repeat the transaction using a conventional TCP session.

I can QUIC, do you?

Unlike all other TCP services that use a dedicated TCP port address to distinguish themselves from all other services, QUIC does not advertise itself in such a manner. That reality leaves numerous ways in which a server could potentially advertise itself as being accessible over QUIC.

One such possible path is the use of *Domain Name System* (DNS) *Service Records* (SRV)^[9]. The SRV record can indicate the connection point for a named service using the name of the transport protocol and the protocol-specific service address. This usage may be an option for the future, but no such DNS service record has been defined for QUIC.

Instead, in keeping with the overall QUIC approach of loading up most of the service functionality into the application itself, a server that supports QUIC can signal its capability within HTTP itself. The way it signals is defined in an Internet standard for “Alternative Services”^[10], which is a means to list alternative ways to access the same resources.

For example, the Google homepage, www.google.com, includes the HTTP header:

```
alt-svc: quic=":443"; ma=2592000; v="44,43,39"
```

This entry indicates that the same material is accessible using QUIC over port 443. The “**ma**” field is the time to keep this information on the local client, which in this case is 30 days, and the “**v**” field indicates that the server will negotiate QUIC versions 39, 43, and 44.

QUIC Lessons

QUIC is a rather forceful assertion that the Internet infrastructure is now heavily ossified and more highly constrained than ever. There is no room left for new transport protocols in today’s network. If what you want to do can’t be achieved within TCP, then all that’s left is UDP.

The IP approach to packet-size adaptation through fragmentation was a powerful concept once upon a time. A sender did not need to be aware of the constraints that may apply on a path. Any network-level packet fragmentation and reassembly was invisible to the end-to-end packet transfer. This invisibility is no longer wise. Senders need to ensure that their packets can reach their intended destinations without any additional requirement for fragmentation handling.

Mutual trust is over. Applications no longer trust other applications. They don’t trust the platform that hosts them or the shared libraries that implement essential functions. Applications no longer trust a network to keep their secrets. More and more functions and services are being pulled back into the application and are passed out from an application as much as possible in packets that are cloaked in a privacy shroud.

There is a tension between speed, security, and paranoia. An ideal outcome is one that is faster, private, and secure. Where it is not obvious and the inevitable trade-offs emerge, it seems that we have some minimum security and privacy requirements that simply must be achieved. But once we have achieved these minimum requirements, we are then happy to trade off incremental improvements in privacy and security for better session performance.

The traditional protocol-stack model was a convenient abstraction, not a design rule. Applications do not necessarily need to bind to transport-layer sockets provided by the underlying platform. Applications can implement their own end-to-end transport if necessary.

The infrastructure of the Internet might be heavily ossified, but the application space is seeing a new set of possibilities open up. Applications need not wait for the platform to include support for a particular transport protocol or await the deployment of a support library to support a particular name-resolution function. Applications can solve these issues for themselves directly. The gain in flexibility and agility is considerable.

There is a price to pay for this new-found agility, and that price is broad interoperability. Browsers that support QUIC can open up UDP connections to certain servers and run QUIC, but browsers cannot assume—as they do with TCP—that QUIC is a universal and interoperable lingua franca of the Internet. While QUIC is a fascinating adaptation with some very novel concepts, it is still an optional adaptation. For those clients and servers that do not support QUIC, or for network paths where UDP port 443 is not supported, the common fallback is TCP. The expansion of the Internet is inevitably accompanied by inertial bloat, and as we’ve seen with the extended saga of IPv6 deployment, it is a formidable expectation to think that the entire Internet will embrace a new technical innovation in a timeframe of months, years, or possibly even decades! That does not mean that we can’t think new thoughts, and that we can’t realize these new ideas into new services on the Internet. We certainly can, and QUIC is an eloquent demonstration of exactly how to craft innovation into a rather stolid and resistant underlying space.

Further Reading

QUIC has excited considerable interest over the past couple of years, and there are many posts to be found on the ‘net. Here’s a small sample of this online material that you may find to be of interest:

The Quest for the Missing Checksums

by Roy Arends, ICANN

The *Domain Name System* (DNS) is a hierarchical namespace that provides a method to look up Internet identifiers such as IP addresses using easy-to-remember domain names. This hierarchy starts at the root,^[0] where the actual namespace is delegated to several registries. The data at the root is signed with cryptographic keys, using *Domain Name System Security Extensions* (DNSSEC)^[1, 2, 3]. These cryptographic keys are replaced over time.

In an effort to change the top cryptographic key for the DNS, the so-called root *Key Signing Key*^[4], several testbeds were created to emulate the process in a lab environment. In those testbeds, the actual root DNS keys are not used since the testbed operators do not have control of the private keys; rather keys of the same size using the same cryptographic algorithms and functions are generated. Apart from the fact that the key material is different, this emulated root zone cannot be distinguished from the real root zone.

This effort to generate certain cryptographic keys became an adventure in itself that included beautiful discrete math, flawed functions, carefully crafted primes, multiple cryptographic libraries, and some brilliant people.

The result of this effort shows that using an ancient checksum function to identify cryptographic keys is not optimal.

The problem

DNSSEC protects the DNS. To be precise, it protects validating resolvers' caches. DNSSEC uses cryptographic keys to validate signatures, and these signatures contain a *key-tag* that helps to identify which key to use. This key-tag is merely a hint; it doesn't have to be collision-free, and the function to generate it is similar to an IP header checksum (the difference between the two functions is that the key-tag function does not include a final end-around carry).

Technically, a key-tag is a 16-bit unsigned value. For our testbed, to clearly identify which keys were introduced in what year, the idea was to generate some vanity key-tags with the year in them; that is, "2010" for a key that was introduced in 2010, and "2015" for a key introduced in 2015. One way to generate those key-tags is to simply generate all possible key-tags in order to pick the desired ones. This process can be done by repeatedly generating a single key. Since the key-tag is based on the contents of the key, and since the contents of the key contain a lot of random bits, it was assumed that the resulting key-tag would be as random as the key.

After the process to generate keys ran long enough, the expectation was to have 65,536 keys—one for each tag. Surprisingly, it was possible to generate only 16,387 keys with unique tags, even after generating millions of keys. Specifically, the key-tags “2010” and “2015” were not included. It turns out that key-tag “2015” was excluded for a different reason than why key-tag “2010” was excluded!

Is it the software?

In order to track down this non-intuitive result, suspicion first fell on the software used to generate the keys. The *BIND* software package from *Internet Systems Consortium, Inc.* (ISC) has a command-line tool named *dnssec-keygen*. The convention it uses is to embed the key-tag in the filename. When a new key is generated, *dnssec-keygen* checks to determine if a key with a certain tag already exists to avoid overwriting it.

The *Flags* field in a DNSSEC key influences the value of the key-tag. For instance, if a key is revoked in the future, the “REVOKE” flag is set and that changes the value of the key-tag. To make sure that a new key-tag doesn’t collide with any existing key, *dnssec-keygen* checks if a new key-tag (and its revoked equivalent) matches an existing key-tag (and its revoked equivalent as well). Initially, it was thought that this key-tag collision check was the culprit.

Since those vanity key-tags were still desired, and since revoked equivalents of keys with the 2010 and 2015 key-tag would not collide with any existing key-tags, it was decided to try to work around this specific check.

One way to avoid this check is to simply use another tool. The LDNS library from NLNetLabs comes with a set of examples. One of these examples is a utility named *ldns-keygen*, which produces DNSSEC keys and does not have the key-tag collision check to protect against accidentally overwriting an existing key. However, after generating millions of keys again, it too generated about 16,384 keys.

The two software tools used have no authors in common, but they do share a cryptographic library: *OpenSSL*. Both pieces of software independently had the limitation of producing only a subset of all possible key-tags. Both used a well-known, widely used cryptographic library. At this discovery the worrying started. If it is the library, and the tags are not distributed evenly, is the quality of the entropy in question? Does the library have any bugs?

To make sure this anomaly was not user error, different versions of *OpenSSL* were tested. Additionally, different entropy sources were used, and lastly, different key sizes were tried. Still, the same number of key-tags was generated.

Is it the library?

The folks on DNS-OARC's operations list came to the rescue. Peter van Dijk from PowerDNS used the PowerDNS management tool: *pdnsutil add-zone-key*, and was able to generate 32,769 unique key-tags. More key-tags than before, but still only about 50% of all possibilities. The tools in PowerDNS, BIND, and LDNS do not share any code or any authors. All three tools were written "from scratch." Additionally, PowerDNS does not use OpenSSL at all; rather it uses *mbedTLS*, a different cryptographic library. That means a problem related solely to the cryptographic libraries or the tools can be ruled out. There was still the observation that *pdnsutil* was able to produce twice as many key-tags as the other tools, but we'll get to that later.

Is it the checksum algorithm?

The next step was testing the key-tag function in RFC 4034^[5]. The key-tag function is very similar to the radix-minus-one complement function for the *Internet Header Checksum*—a radix-minus-one complement function. Note that it is not exactly the same, but the minor difference could not fundamentally reduce the possible number of key-tags.

To test this possibility, a loop was created that fed random numbers into the key-tag algorithm. When using 2,048-bit random numbers as the input (instead of cryptographic keys), all possible key-tags could be produced in a short amount of time. This experiment ruled out that the limiting part was the key-tag algorithm itself. However, we'll come back to that later as well.

Is it purely a math problem?

Meanwhile, Florian Maury and Jérôme Plût from ANSSI took a good look at the problem and discovered it was none of the possibilities mentioned previously. It turns out that an interesting combination of the properties of the Internet Header Checksum and RSA moduli rules out certain results.

The input to the Internet Header Checksum function is treated as blocks of 16 bits and the output is a 16-bit checksum. Radix-minus-one complement methods are as old as accounting itself. The nine's complement method (where the radix is base 10) was used in Pascal's calculator. The method of complements is a technique used to subtract one number from another using only addition of positive numbers. We're not using the complements part here, only the part where we add, with carry, a bunch of bits.

A description of the Internet Header Checksum function follows: Add the 16-bit values with end-around carry; that is, if adding two 16-bit values results in a carry, then add that carry bit to the result of the addition.

Following is the end-around-carry part of the checksum function:

```
($sum AND 65535) + ($sum >> 16)
```

What Jérôme Plût observed is that this expression can be reduced to:

```
$sum mod 65535
```

Since modular arithmetic has the addition property, we can also deduce:

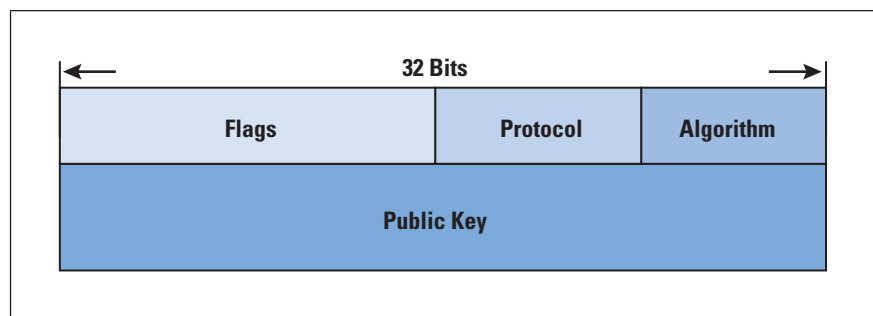

```
($Value1 + $Value2) mod 65535
```

or:

```
($value1 mod 65535) + ($value2 mod 65535)
```

Calculating a key-tag

As said earlier, the Internet Header Checksum is very similar to the key-tag function. The input for this key-tag algorithm is the RDATA part of a DNSKEY record:

For all keys generated in this exercise, all the fields remain the same, except for the modulus in the *Public Key* field.

For a *Key Signing Key*, the value of the *Flags* field is 257, and the *Protocol* field always has the value of 3. The *Algorithm* field has the value 8 (RSASHA256)^[7]. With those parameters, the *Public Key* field consists of an *Exponent* and a *Modulus*. For this exercise, the exponent has value 65537 and is preceded with an *Exponent Length* field (value 3).

The constant part of this input can now simply be added up as a series of 16-bit unsigned values:

```
$value1 = Flags + Protocol*256 + Algorithm + ExpLen*256 + Exponent
```

```
$value1 = 257 + 3*256 + 8 + 3*256 + 65537
```

```
$value1 = 67338
```

Using the deduction from before:

$$\text{keytag} = (\text{value1} \bmod 65535) + (\text{value2} \bmod 65535)$$

$$\text{keytag} = (67338 \bmod 65535) + (\text{value2} \bmod 65535)$$

$$\text{keytag} = 1803 + (\text{value2} \bmod 65535)$$

The part of the checksum that is not constant is the *RSA-modulus*. The RSA-modulus is a composite number with two very large prime factors. In the previous equation, value2 is the RSA-modulus. The last substitution becomes:

$$\text{keytag} = 1803 + (\text{RSA-modulus} \bmod 65535)$$

Since the value 1803 is constant, it has no influence on the number of possible key-tags, hence the solution to the reduced set of possible key-tags may be found in the RSA-modulus modulo 65535 part of the equation.

Number theory

What Jérôme Plût observed is that the value 65535 is a composite number with four prime factors: 3, 5, 17, and 257. Since the RSA-modulus and 65535 do not share any factors, the RSA-modulus can't be congruent with 0 modulo 65535.

Therefore, the modulus is not congruent with 0 modulo 3, 0 modulo 5, 0 modulo 17, or 0 modulo 257.

All other congruence values are possible, so the set of possible values is simply a combination of the possible values:

$$2 * 4 * 16 * 256 = 32768.$$

We can now check if we indeed can't have 2010 as a value:

Before, we noted that:

$$\text{keytag} = 1803 + (\text{RSA-modulus} \bmod 65535)$$

We can now substitute the key-tag with our desired value:

$$2010 = 1803 + (\text{RSA-modulus} \bmod 65535)$$

$$2010 - 1803 = \text{RSA-modulus} \bmod 65535$$

$$207 = \text{RSA-modulus} \bmod 65535$$

However, 207 is congruent with 0 modulo 3, meaning that in order for 207 to be possible, the RSA-modulus must have 3 as a factor. We know this is not the case, so 2010 (that is, $207 + 1803$) can't be a key-tag.

The remainder of the problem

Remember that the first exercise led to 16,387 key-tags, not 32,768 as predicted before, or 32,769 as found by Peter van Dijk. Additionally, 32,769 is not 32,768 (and 16,387 is not 16,384, half of the 32,768 space).

32,769 is not 32,768

The key-tag function is similar to the Internet Header Checksum, but not the same. The crucial difference is the last end-around carry.

The last part of the key-tag function is defined in RFC 4034, and reads as follows:

```
ac += (ac >> 16) & 0xFFFF;
return ac & 0xFFFF;
```

The first line adds the carry bits to the accumulator. As a result, the accumulator might be a value larger than fits in a 16-bit value. Instead of again adding the carry bits to the value, it ignores those.

Ignoring the carry bits can, in some cases, result in an off by one value, compared to the Internet Header Checksum. With the Internet Header Checksum, only 32,768 values are possible, as we've seen in the previous section. Since the key-tag function might be off by one, a few more key-tag values are possible.

16,387 is not 32,769

Why was Peter able to produce about twice as many key-tags? Assuming that the values could have been 16,384 and 32,768 (as explained before), the only remaining difference is the library used.

OpenSSL generates primes that are congruent with 2 modulo 3. The resulting modulus is thus always congruent with 1 modulo 3, since:

```
(2 modulo 3) * (2 modulo 3) =
4 modulo 3 =
1 modulo 3
```

This formula reduces the possible key-tag space from $2 * 4 * 16 * 256$ to $1 * 4 * 16 * 256$, which is 16384.

This reduction is the reason why it was not possible to generate a key-tag with the value 2015. Using the same reduction as before, we can now substitute key-tag with 2015:

```
2015 = 1803 + (RSA-modulus mod 65535)
2015 - 1803 = RSA-modulus mod 65535
212 = RSA-modulus mod 65535
```

However, 212 is congruent with 2 modulo 3. We now know that RSA moduli from OpenSSL are always congruent with 1 modulo 3, so key-tag 2015 is simply not possible when using OpenSSL.

The library that Peter is using, *mbedTLS*, does generate primes that are congruent with 1 modulo 3.

Conclusion

The limited key-tag space does not present a security issue. The key-tag is merely a hint and it is well known that different cryptographic keys may lead to the same key-tag. However, the decision to use a checksum as an identifier is poor at best. A checksum is designed to check if an error exists in data, and not, in general, designed to be an identifier. Additionally, using a function that is nearly identical to the well-known Internet Header Checksum seems to be an error in the design stage.

Acknowledgements

I cannot begin to thank adequately those who helped me to understand and explain the various compounding issues that resulted in the absence of 75% of all possible key-tags. Florian Maury and Jérôme Plût from ANSSI explained the core issue with the Internet Header Checksum over RSA moduli. Without them, I would still be searching in the dark. Peter van Dijk and Bert Hubert of PowerDNS consumed uncountable electrons and brainwaves to reproduce my findings with different tools and libraries. Google's Ben Laurie held my hand while I was drowning in modular arithmetic and brought me ashore. Finally, it was ICANN's David Conrad who made my broken English and various grammar faux pas readable.

New DNS Terminology RFC

A *Request For Comments* (RFC) updating *Domain Name System* (DNS) terminology was recently published^[10], continuing a decades-long IETF practice of publishing documents to help introduce interested readers to protocol topics by going through the most important terms.

The list of topics with terminology documents includes general terminology^[1], *Network Address Translators* (NATs)^[2], *Diffserv*^[3], Internet connectivity^[4], internationalization^[5], and *Internet of Things* (IoT) networks^[6]. Although these documents are not meant to be step-by-step introductions to the topics, they help someone who already has some understanding go deeper into the topic, and often help clarify terms that are often misused in common writing.

There are many dozens of RFCs defining the DNS, so the terminology is often hard to find. Some common terms such as “host name” are not defined in any RFCs; some are defined only by example; worse, some are defined differently in different RFCs. RFC 8499, “DNS Terminology,” was published as an update to an earlier work to address these issues.

This document is the result of long discussions in the *Domain Name System Operations* (DNSOPS) Working Group^[7], where dozens of DNS operators, software developers, and other experts brought up terms to be covered and argued over the current meaning of terms that are more than 30 years old. A common glossary is necessary to operate the DNS, and to continue to develop the DNS, so that people know what each other mean. The Working Group also hoped that the document would be useful to people who used the DNS tangentially, such as developers of other protocols and non-technical people who interact with the DNS in their work.

RFC 8499 is an update to the first DNS terminology document, RFC 7719^[8]. While the first document was being written, the Working Group agreed that some definitions (such as for “domain name”) needed more work, and it was so difficult to get consensus on other terms that they were left out. The new document is much more complete, and contains some common terms not covered in the earlier document, such as “recursive query,” “lame delegation,” and “split DNS.”

Another significant addition to the document is the first definition of a standards-track document of “the global DNS” and “private DNS.” Many people think they know what “the DNS” is but may not have a specific definition for it; these new terms helps get everyone using the same definitions. Overall, nearly 40 terms that are not defined in other RFCs are defined in this document.

Of course, the DNS will continue to evolve, and new terminology may appear. RFC 8499 is stable, but it might be revised a few years down the road to add these new terms.

DNS-OARC

The *DNS Operations, Analysis, and Research Center* (DNS-OARC) brings together key operators, implementers, and researchers on a trusted platform so they can coordinate responses to attacks and other concerns, share information and learn together. DNS-OARC has five key functions:

Information Sharing: DNS-OARC provides a trusted, shared platform to allow the DNS operations community to share information and data. Stringent confidentiality requirements and secure communications mean that proprietary information can be shared on a bilateral basis.

Operational Characterization: As Internet traffic levels continue to grow, the demand on root and other key name servers will outgrow the current infrastructure: this year's DDoS attack traffic levels will become next year's steady state load. DNS-OARC measures the performance and load of key name servers and publish statistics on both traffic load and traffic type (including error types).

Workshops: DNS-OARC organizes semi-annual workshops where members and the public are invited to give presentations on timely topics relevant to DNS both operations and research.

Analysis: Leading researchers and developers provide long-term analysis of DNS performance and post-mortems of attacks so that institutional learning occurs. A well-provisioned system allows members to upload traces and logs, and to perform their own analysis.

Tools and Services: As vulnerabilities and DNS problems come to light, DNS-OARC develops publicly available tools and services to assist with highlighting, diagnosing, and remedying such problems.

DNS-OARC participants fall into one or more of the following categories:

- Operators of root, TLD, or large commercial name servers who consume DNS technology and produce DNS services.
- Implementers who produce DNS technology including software, appliances, and network elements such as load balancing hardware
- Researchers whose work has a strong DNS emphasis and who need access to trace and log data about the global DNS under both “normal” and “abnormal” conditions.
- Security Providers whose companies offer products and services that utilize DNS information to improve the security of their customers.

Letters to the Editor

Ole,

Geoff Huston's most recent article on the last 10 years of the Internet is absolutely brilliant (IPJ Volume 21, No. 2, August 2018). As one of the early implementers of our dear Internet, I am of course amazed at its evolution these past decades, and Geoff has more than "kept up"! His ability to summarize quickly and accurately is without peer. Thank you all.

—Dan Lynch
dan@lynch.com

Geoff,

Thank you very much for your article "Another 10 Years" in *The Internet Protocol Journal*. I enjoyed your perspective and your writing style very much. You have a great skill at explaining a great amount of information.

I subscribed to the early *ConneXions*—*The Interoperability Report* and later IPJ. I've been glad to see your articles over the many years.

Sincerely,

—Richard Berke
Richard_Berke@troweprice.com

The author responds:

I really appreciate your kind words, and I am glad you liked the article.

—Geoff Huston
gih@apnic.net

Letters may be edited for clarity. We'd love to hear from you. Send us your feedback via e-mail to ipj@protocoljournal.org

From the Editor	1
DNS Privacy and the IETF	2
Improving Routing Security..	14
Fragments	22
Thank You!	24
Call for Papers	26
Supporters and Sponsors	27

Security and privacy have received much attention and treatment in this journal over the years. The original ARPANET protocol suite had few if any security features, but over time a great deal of effort has gone into retrofitting existing protocols with security and privacy features, and adding new technologies such as encryption and authentication mechanisms. In this issue we look at two areas of protocol development related to security and privacy.

The *Domain Name System* (DNS) provides a vital function for everything we do on the Internet, namely translating human-friendly names such as **google.com** to machine-friendly numbers such as **17.172.224.47** or **2001:4860:4860::8888**. A typical DNS entry not only contains the IP address for the server you are trying to reach, but also tells you how to send e-mail to that server. If you tried to contact us between May 31st and June 14th using any of our e-mail addresses such as **ipj@protocoljournal.org**, your message did not get delivered or was delayed. This happened because the DNS registrar for **protocoljournal.org** was changed and the corresponding *Mail Exchange* (MX) records were not updated accordingly. We apologize for this glitch; service has now been restored.

The topic of *DNS Privacy*, originally discussed in this journal in our March 2017 issue, has recently sparked considerable debate following the specification and deployment of *DNS over Hypertext Transfer Protocol Secure* (DoH). In our first article, Geoff Huston explains the motivations for DoH and explores its wider implications.

Routing Security is also an important component for a stable and reliable Internet. The *Mutually Agreed Norms for Routing Security* (MANRS) are a set of “best practice” operational agreements as explained in our second article, by Andrei Robachevsky.

We welcome two new sponsors of IPJ: Akamai and PKNIC. Publication of this journal is made possible by the generous support of numerous individuals and organizations. If you would like to help support IPJ, please contact us for further details. Comments, suggestions, book reviews, and articles are always welcome.

Send your messages to **ipj@protocoljournal.org**

DNS Privacy and the IETF

by Geoff Huston, APNIC

From time to time the *Internet Engineering Task Force* (IETF) seriously grapples with its role with respect to technology relating to users' privacy. Should the IETF publish standard specifications of technologies that facilitate third-party eavesdropping on communications, or should it refrain from working on such technologies? Should the IETF take a further step and publish standard specifications of technologies that directly impede various forms of third-party eavesdropping on communications? Is a consistent position from the IETF on personal privacy preferred? Or should the IETF be as agnostic as possible and publish protocol specifications based solely on technical coherency and interoperability without particular regard to issues of personal privacy?

These are not new questions for the IETF. Going back some twenty years, the IETF was working on a standardization of a suite of media gateway protocols when the request was raised to make the protocols compliant with the US *Communications Assistance for Law Enforcement Act* (CALEA)^[16]. This situation excited passions both within the IETF and in the broader circle of observers and commentators. The *Electronic Privacy Information Center* (EPIC) communicated to the IETF its position, which resonated with many IETF participants at the time: "We are writing to urge the IETF not to adopt new protocols or modify existing protocols to facilitate eavesdropping. [...] we believe that such a development would harm network security, result in more illegal activities, diminish users' privacy, stifle innovation, and impose significant costs on developers of communications."^[10]. After much angst and debate, the IETF refused to act on this request, and published its position in RFC 2804: "The IETF has decided not to consider requirements for wiretapping as part of the process for creating and maintaining IETF standards."^[11].

To put this situation into some context, the telephone networks that preceded the Internet typically operated under a framework of interception capability, and this capability was a mandatory requirement for licensed service operators for both their voice and data services. For the IETF to place interception capabilities out of scope for their standards work was not only a strong break from an established public carriage function, but it also threw into some confusion how vendors and operators could define an interoperable standard for interception requests. The *European Telecommunications Standards Institute* (ETSI) has evidently filled this gap with a set of standards for lawful interception^[2]. However, this set of standards still presents real issues to both network operators and law enforcement agencies. One interesting approach in the New Zealand networking community was to support the development of a tool called *OpenLI*, an open source implementation of the ETSI protocols^[13] for use by local network operators.

The IETF's position of refusal to standardize surveillance-enabling architecture modifications twenty years ago did not settle the matter then and hasn't settled it now. Code and standard specifications of network protocols do not necessarily usurp our laws, and code, law, and markets are all elements in a political tussle over what ultimately determines social policies and practices.

The time following the CALEA matter saw an uneasy stand-off between the IETF, as the most visible body associated with the Internet code base, and various public bodies wanting to undertake various forms of surveillance on the Internet. The situation changed in response to the revelations in the documents leaked by Edward Snowden in 2013. Snowden's disclosures of mass surveillance by the US *National Security Agency* (NSA)—evidently working in close cooperation with related agencies in Australia, the United Kingdom, and Canada—prompted the IETF to take a very strong public position in RFC 7258: “Pervasive monitoring is a technical attack that should be mitigated in the design of IETF protocols, where possible.”^[3] This position means that the IETF has crossed into the second of the previous questions. Rather than simply refusing to work on interception technologies, as espoused in RFC 2804, this later RFC advocates that the IETF should publish standard specifications of technologies that directly impede third-party eavesdropping on communications.

It's a noble position that the IETF has taken, but it is perhaps a rather unworldly one in the light of subsequent concerns about the extent of corporate activities in this same area, activities that now have their own name: *surveillance capitalism*. The world of the Internet is now a world where surveillance dominates every aspect of its environment. The online market for goods and services is distorted by the presence of “free” products and services that are funded through a back flow of advertising revenue based on a thorough and comprehensive knowledge of individual users, gained only by using thorough and comprehensive surveillance frameworks that target every user.

The Internet is largely dominated, and indeed driven, by surveillance, and pervasive monitoring is a feature of this network, not a bug. Indeed, perhaps the only debate left today is one over the respective merits and risks of surveillance undertaken by private actors and surveillance by state-sponsored actors. The pronouncement of the IETF denouncing state-sponsored surveillance can only generate a wry smile in retrospect. Sadly, pervasive monitoring is what generates the revenue that propels today's Internet, and the IETF is a coerced fellow traveler, despite the occasional bursts of sometimes hysterical rhetoric that attempts to disavow any such relationship. We have come a very long way from this lofty moral stance on personal privacy into a somewhat tawdry and corrupted digital world, where “do no evil!” has become “don't get caught!”

It has been five years since RFC 7258 was published, and the privacy issue refuses to go away. It seems that the IETF is heading into this turgid and complex field of privacy once more, this time because of the *Domain Name System* (DNS).

DNS Privacy

The DNS has always been a fertile field of opportunity for both surveillance and access control. The basic DNS name-resolution protocol has always worked in a totally unencrypted mode, so that queries and responses are available to any party who can see these transactions on the wire. The wire protocol has no authentication, so network actors can intercept DNS queries addressed to any IP address and provide a response in their name, while the querier may be none the wiser that this substitution has occurred. This idea may sound somewhat esoteric, but every Internet transaction starts with a DNS name-resolution query. The DNS is a timely and accurate indicator of everything we do online, and it's an entirely unprotected and open protocol. What a rich environment for a network eavesdropper! Little wonder that many service operators, and many nation states for that matter, use the DNS for all kinds of purposes relating to both surveillance and access control.

The intersection of RFC 7258 and the DNS has generated the topic of *DNS Privacy*, complete with an IETF Working Group and a worthy collection of drafts of ideas of how to improve the privacy aspects of the DNS.

The first steps in this activity were to look at the interaction between *end clients* and their chosen recursive *resolver*. This element is a critical one of the larger picture, because it is the only part of the DNS resolution service where the IP address of the end client is contained in the query. Once the query is passed within the DNS infrastructure, the query contains no direct identifying link to the client.

Client Subnet

As an aside it is worth mentioning the *Client Subnet* extension to DNS queries and the tension between privacy and performance levers that are accessible with such end-user information leakage (RFC 7871)^[4].

The rise of *Content Distribution Networks* (CDNs) and multiple points of presence has led to a technique, commonly used by Akamai today as well as some others, where the assumed geolocation of the DNS resolver posing the question is a reasonable facsimile to the location of the end client. The concurrent rise of the use of open DNS resolvers, most notably the **8.8.8.8** service from Google, negated this assumption.

In response to the frustrations on the CDN side of misdirected users and woefully inefficient content delivery, the IETF standardized a mechanism to attach the subnet of the end client to the query, RFC 7871^[4].

The attachment of the client's credentials was made by using the *Extension Mechanisms for DNS* (EDNS)^[17], and the idea was to put the IP address of the end client making the query (or an IP prefix) into the query that both survived recursive resolver hand-offs and could be used as a distinguishing label in local cache lookups to perform content steering via the DNS.

Semantically a bridge is being crossed here. Previously the DNS could be thought of as an invariant distributed database. No matter who posed a name query, the response was always the same. Client Subnet is an overt admission that some folks want the DNS to be inconstant, such that the value of the response may depend on the identity of the querier. More importantly, a major privacy bridge is also being crossed. Previously, authoritative name servers were not exposed to the identity of the original client making the query, because they were masked by the intermediary recursive resolvers. With Client Subnet, the authoritative server is aware of the original client. Interception and eavesdropping undertaken at the server end will enjoy a richer view of the end clients that are expressing some level of interest in the names served by this authoritative server.

Perhaps in deference to RFC 7258 it should be noted that the IETF appeared to be reluctant to reference it when specifying this Client Subnet extension, but nevertheless the organization ended up doing it! I quote here Section 2 of RFC 7871, which is a good description of the level of compromise and discomfort that lies just beneath the surface of this DNS privacy debate in the IETF:

“If we were just beginning to design this mechanism, and not documenting existing protocol, it is unlikely that we would have done things exactly this way.

The IETF is actively working on enhancing DNS privacy and the reinjection of metadata has been identified as a problematic design pattern.

As noted above however, this document primarily describes existing behavior of a deployed method to further the understanding of the Internet community.

We recommend that the feature be turned off by default in all nameserver software, and that operators only enable it explicitly in those circumstances where it provides a clear benefit for their clients. We also encourage the deployment of means to allow users to make use of the opt-out provided. Finally, we recommend that others avoid techniques that may introduce additional metadata in future work, as it may damage user trust.

Regrettably, support for the opt-out provisions of this specification are currently limited. Only one stub resolver, *getdns*, is known to be able to originate queries with anonymity requested, and as yet no applications are known to be able to indicate that user preference to the stub resolver.”^[4]

DNS over TLS

The *Transport Layer Security* (TLS) protocol can both encrypt the communication between a client and a server and provide some assurance to the client that the server is operated under the authority of the named entity that the client intended to connect to. In much the same manner as TLS is used to protect HTTP sessions and provide some assurance that the service point is an authorized agent of the named service, this protocol can also be used in the DNS context between end users' client stub resolver and their chosen recursive resolver service.

The IETF *DNS PRIVate Exchange* (DPRIVE) Working Group^[12] has worked on *DNS over TLS* (DoT)^[9, 10] and we are now seeing numerous DNS recursive resolver services that support DoT. Resolver code for Unbound, PowerDNS, and Knot exists, and BIND can be configured with TLS use through a *stunnel* configuration. So if you are prepared to set up your own DNS-resolution environment on your device, you can bypass the open DNS-resolution system provided by your ISP and use a DoT service that will hide your DNS queries and responses from your ISP, and any interested onlookers.

However, it has to be said that using DoT constitutes a highly qualified form of privacy. It's not a solution for everyone. Adding DoT support to your platform may require the installation of a third-party app on your device (which may or may not be possible on your device), and in any case the number of users who are willing to alter the DNS configuration of their device is very limited. Even when the packing of the TLS service is quite seamless, such as in Android Pie's DNS privacy option, it probably still will not be broadly used. In Android's case it is an esoteric feature buried a few levels deep in menus, it is not necessarily supported on all Android platforms, and unless you already know about it you will probably never stumble over it when poking around in your device.

But configuring the client is only half the story. Whom are you going to talk to? Which recursive resolvers support client connections using DoT?

It's an important question. While you are stopping others from looking over your shoulder at your online DNS activity, you are still telling your chosen DNS recursive resolver your complete DNS profile. Today, Google, Cloudflare, and Quad9 all provide open DNS resolver servers.

Sharing your secrets with Google may sound a bit like dancing with the devil. Google's advertising platform generates comprehensive user profiles and its ad support systems are certainly expert and capable practitioners of the art of surveillance capitalism!

In their defense, I must note that Google clearly states that it does not use its public DNS service to reap user profile data and it exercises strict controls over access to DNS data, but that itself raises the question of how such unilateral undertakings are enforced within the company. Google does not open itself up for any form of third-party compliance inspection. Although its DNS practice statement is an excellent statement of noble intent, how can a user be assured that Google is thoroughly and completely committed to every detail in the practice statement?

Let's look at it from the user's perspective. When you configure your system to use a third-party open DNS resolver, you may also be leaving aside your local national regulatory framework. It's a mixed package, because you may be circumventing what you might think of as onerous national content controls, including DNS censorship, but at the same time you may also be circumventing any rights and protections you may have under these same national regulatory structures. When you are outside of any national jurisdiction, then who is left to ensure that service providers adhere to their stated practices in providing the service?

It's not just trust in the service provider at the other end of the TLS connection. Even accessing such a privacy-oriented service may present a problem. In its wisdom, the IETF's DPRIVE Working Group standardized DoT over TCP port 853. This port is not port 443 as used by TLS in supporting HTTP. Any network operator can prevent users from applying this DNS overlay service by simply blocking all traffic to TCP port 853.

DNS over TLS represents a specialized service accessible to just a few. It's a service that is readily blocked. It's a service that may prevent surveillance on the wire, but still ends up sharing your DNS activity with the DoT service provider of your choice. You may well still be compromised in terms of assured privacy protection, but does it make you feel better having a choice as to which service operator you choose to expose yourself to?

DNS over HTTPS

What caused all the current fuss in the IETF was a variant of this DoT approach, termed *DNS over Hypertext Transfer Protocol Secure* (DoH).

In terms of the carriage of DNS on the wire there is almost nothing that differs between DoT and DoH. Both take wire format DNS messages, encrypt them using TLS, and use a TCP session between the client and resolver. In protocol terms of packets on the wire the only difference between the two approaches is that DoH uses the same TCP port number as HTTPS, namely port 443. It may sound like a cosmetic change, but two very fundamental differences transcend this simple protocol tweak.

Firstly, DoH is very difficult to detect. It looks like HTTPS traffic and uses the same port as HTTPS traffic. One could make assumptions in the opening TLS handshake where the name of the server is carried in the clear, but work on encrypted *Server Name Indication* (SNI) in TLS 1.3 is proceeding, and it is reasonable to believe that even this small aperture of visibility will be sealed up in the near future. If you also add TLS padding to the mix, then even traffic profile analysis would not necessarily reveal that it is a DNS session within the TLS stream.

If privacy is the goal, then what's to complain about with this picture? Surely DoH offers the end user a package of encryption, mimicry, and obfuscation that hides the DNS to all but the endpoints of the session.

The answer to this question leads to the second fundamental difference between DoT and DoH. We are no longer talking about an esoteric feature knob that requires a knowledgeable, or even fool-hardy, user to turn it on. The DNS session may look like just another HTTPS session to the network, but it also looks like just another HTTPS session to the host platform. In other words, a browser may just turn on DoH all by itself. It's not the user turning it on, nor the platform turning it on, but the browser itself. No special configuration needs to be in place by the platform of the local network to support the operation of DoH. If a browser chooses to use DoH, then there is little that the platform or the network can do to prevent it. If a browser has installed DoH support, then control over the DNS name-resolution function has passed from the user to the browser provider, and rather than being an esoteric function enabled by a handful of users, it becomes a "mainstream" service used by potentially billions of end users. For example, it appears that Google's Chrome browser enjoys a 60% market share of browsers^[5]. If Chrome enabled DoH by default, then what would that mean for the entire DNS? Would it literally disappear from sight?

The second concern is the choice of DoH server. Instead of using a locally configured DNS-resolver service provided by the ISP, DoH switches the situation to use a service configured by the browser. The early implementation of this service in Firefox requires the explicit configuration of a trusted recursive resolver, in a manner similar to the configuration of the DoT server in Android Pie. What if the DoH resolver is configured by the browser by default?

Let's just pause for a second to think about this notion. DoH can place the control of the privacy setting for DNS queries into the hands of the browser, bypassing both the user and the local internet infrastructure, and can do so in a way that intertwines secure web services with secure DNS service. In privacy terms it sounds very enticing.

The downside is that the user's browser is now sharing all of its local activity with the configured DoH server. To put it a different way, what part of "sharing your entire personal profile with the browser-selected DoH server" is consistent with our traditional concepts of personal privacy and informed choice?

Consider a second concern here as well. This ability for a browser and a DoH resolver to combine and thereby effectively dominate the Internet namespace is a legitimate concern. Few companies are in such a position, but there are few companies left in the Internet ecosystem. A very small number of digital behemoths inhabits the core of the Internet, and these entities could potentially take advantage of such an opportunity, were it offered to them. Google is the dominant provider of the platform in Android, the browser in Chrome, and the DNS resolver in the 8.8.8.8 service. Would this scenario be a case of a single corporate entity being in a position of overarching control of the entire namespace of the Internet? Netflix already fielded an app that used its own DNS resolution mechanism independent of the platform upon which the app was running. What if the Facebook app included DoH? What if Apple's iOS used a DoH-resolution mechanism to bypass local DNS resolution and steer all DNS queries from Apple's platforms to a set of Apple-operated name resolvers?

We'll find out some answers to these questions in the near future. On April 9, 2019, Mozilla announced its plan to enable DoH by default in the Firefox browser^[6], committing to an earlier informal description of its plans that were outlined by Mozilla's Eric Rescorla at the end of March 2019^[7].

To place this announcement into a broader perspective, it should be noted that the market share of Mozilla's Firefox browser, while large, is by no means dominant. The StatCounter site reported a market share of 4.69% for Firefox in March 2019^[5], so these moves by Mozilla are not intrinsically all that significant in terms of the profile of the larger Internet and the average Internet user. A major concern with this announcement is that the move by the Firefox browser to make DoH the default means of DNS name resolution is a precursor for similar changes to the Chrome browser. Chrome is definitely the dominant browser in today's Internet ecosystem, with some 62.63% market share according to StatCounter. If Chrome were to use a default setting that pushed all its DNS name-resolution activities to a Chrome-selected DoH server, then the implications for the DNS are very significant.

Will the other browsers follow Mozilla's lead with DoH enabled by default? The experience so far would support a "yes" answer. Browser vendors have been enthusiastic to integrate changes to their platform that decrease page load times, and they are equally keen to integrate changes that protect the browser activity against various forms of surveillance.

DoH does not necessarily make DNS resolution quicker, although it does put the browser in more control over its use of the DNS and allows the browser to control its own local DNS cache. But, of course, DoH plugs a critical DNS information leak in the current browser architecture. Third-party observers can infer browser activity by looking at the browser DNS query stream. DoH prevents any such observation in both the user's platform and the local network. So "yes" is a likely answer to this question.

Can such positions be regulated? How can we be assured that transactions that now have disappeared from sight, and from any meaningful form of oversight, are still conducted with all due integrity? We have already seen many national regimes struggle with very real questions concerning the limitations of imposing constraints on the actions of these entities. Have the concerns of the U.S. Supreme Court's Louis Brandeis in the first half of the twentieth century over the rise of industrial and financial behemoths that in his view were too big to effectively regulate at all come full circle?

What Does DoH Mean?

Here is the core of the collective angst and disquiet in the IETF when considering the implications of DoH and the "centrality" of Internet infrastructure.

We are attempting to actively withhold the DNS from the traditional forms of inspection and interception using access carriers and wire-based mechanisms. In so doing we are looking to counter what was perceived as a state-based surveillance operation that had assumed too much capability.

But in the case of the DNS have we over-achieved? In withholding our DNS secrets from one party, have we instead handed the entire plate to another? Have we now provided the private surveillance framework with a whole new trove of personal data to mine by ruthlessly exploiting the DNS in a manner that is entirely out of sight? When the browsers and even the apps direct their name queries through encrypted channels to resolvers operated by the same browser and app providers, then have we dealt a body blow to any efforts to safeguard personal privacy on the Internet?

At least RFC 7871 on Client Subnet included an admonition to operators to turn it off and a tacit apology for specifying a tool that had serious issues relating to erosion of user privacy in the DNS infrastructure. The DoH specification in RFC 8484^[11] contains no such considerations. It fails to mention the security and privacy issues if a browser invisibly co-opted the name-resolution function and passed all its DNS traffic in a secure encrypted tunnel to a cooperating resolver using DoH that faithfully mimics conventional content transactions. It fails to mention the risks of increasing the "centrality" of the Internet when the DNS name resolution is forcibly sucked into the browser and application space and then concealed behind a veil of strong encryption.

It's incredibly challenging to make the case that DoH enhances personal privacy. It probably doesn't. It's easier to sustain a case that DoH has the potential to change the parties whom you bring into your trust circle by virtue of their being privy to your private profile, and not necessarily in a good way. In and of itself such a substitution of trust should not necessarily be of concern. But now it's your browser that can make the decision as to whom you are trusting with your personal data, not you. And the parties who are looking to be your DoH trust partner are the same parties who have a direct and overbearing interest in selling you to the highest bidding advertiser.

Privacy Undertakings

These open DNS providers appear to have a clear view of user concerns over personal privacy. Their privacy policies implicitly acknowledge that the DNS query stream could be used to provide insights into the personal profile of users and assert that they have no such intent to do so. Such noble intentions to operate a free public service and refrain from any form of monetization of the service are entirely laudable.

However, from an historical perspective these undertakings appear to be unrealistic and unsustainable. We should remember the events of a century ago with Theodore Vail and the *Kingsbury Commitment* in 1913 in the United States. His key commitment was a profession of noble intent to enrich the public space. AT&T was to be an "enlightened monopoly" that served the public in close cooperation with the state while at the same time serving the interests of AT&T shareholders. His view of the telephone service as a privately operated public utility is, to quote Tim Wu in his treatise on Vail and AT&T, "...at once the most sympathetic and scariest element of his vision. Vail saw no harm in, and indeed believed in, giants, so long as they be friendly giants. He believed power should be beneficently concentrated, and that with great power came great responsibility."^[8]

As we observe the aggregation of this critical part of the Internet infrastructure in the centralization of the DNS, it cannot be ignored that these grand statements of respect for the public interest and undertakings that safeguard personal privacy sound scarily similar to the espoused public benefactor vision of AT&T in 1913 as it embarked on a course of establishing a national monopoly. But it is perhaps not today's operators and today's commitments that should concern us, but where this condition may lead. Again, quoting Tim Wu: "[Theodore Vail] presents us therefore with a challenging figure: an unabashed monopolist, but a benign one, who lived up to his own ideals of enlightened despotism. The fault in this arrangement therefore lay not so much with Theodore Vail as with the men who would succeed him."^[8]

Perhaps the same is true of these current undertakings relating to protection of personal privacy and their perception of the greater public interest.

Over time these earnest undertakings in the provision of free services may well be eroded by the inevitable pressures that every private enterprise is prone to, namely those of paying the bills and maximizing shareholder value. After the DNS is placed under an all-encompassing shroud of deep encryption, then both good and dark deeds will be both indistinguishable and undetectable.

It appears that the original disquiet on the part of the IETF was not that state-sponsored intelligence agencies collected intelligence, because, after all, that is their role, but a perception that the public accountability of some of these agencies had, in the IETF's view, failed. It is ironic that the IETF's response appears to literally hand the keys to an encrypted DNS over to a handful of private sector entities that appear to have no enduring public accountability whatsoever.

Improving Routing Security

by Andrei Robachevsky, *The Internet Society*

Not a single day goes by without dozens of incidents affecting the routing system of the Internet. Route hijacking, route leaks, IP address spoofing, and other harmful activities can lead to *Denial of Service* (DoS) attacks, traffic inspection and surveillance, lost revenue, reputational damage, and more.

According to our analysis based on BGPStream^[0] data, the following numbers indicate the scale of the problem along with the comparison to data from 2017:

- In 2017, there were 12,600 (a 9.6% decrease) incidents (either outages or attacks such as route leaks and hijacks). Figure 1 shows the number of routing incidents by type in 2018.
- Although the overall number of incidents was reduced, the ratio of outages vs. routing security incidents remained unchanged — 62/38.
- About 4.4% (a decrease of 1%) of all Autonomous Systems on the Internet were affected.
- 2,737 (a decrease of 12%) Autonomous Systems experienced at least one routing incident.
- 1,294 (a 17% decrease!) networks were responsible for 4,739 routing incidents (a 10.6% decrease).

Figure 1: Routing incidents by type in 2018; almost 40% of all incidents were due to routing security issues.

Looking further at the dynamics of the evolution of routing security from the perspective of affected networks (Figure 2), we can see that Bangladesh, mainland China, and Hong Kong appear to be the most vulnerable, with up to 30% of all networks affected by a routing mishap. We can also see positive dynamics in countries like Brazil, India, and Iran, where the percentage of “victimized” networks decreased significantly.

Figure 2: Changes in the percentage of affected networks in a country. Top-10 most affected countries.

Let's look at networks whose configuration mistakes or intentional acts caused these incidents. In absolute numbers, 36% of all “culprits” operate in the US, Brazil, and Russia, but if we normalize this number by the total number of networks in a country, mainland China and Hong Kong are at the top (see Figure 3). On a positive side, the situation has improved in most of the top-10 countries with the highest number of culprits. For instance, in Brazil the number of misbehaving networks has been cut by more than half.

Figure 3: Changes in the percentage of networks in a country responsible for a routing incident, top 10 with most incidents detected.

Why Is Routing Security Hard?

Despite the positive trend, it is too early to celebrate victory; vulnerabilities still exist, and too many networks are not applying required controls to prevent incidents from happening. What is holding the networks from resolving this problem once and forever?

There are several reasons. In the Internet, as a decentralized system, the overall level of routing security depends on the individual actions of all network operators, and incidents in most cases are impossible to address by your own operator. The economics favor insecurity, as the impacts of routing incidents are often felt by others and not by the culprit, and security has not yet emerged as a market differentiator. To put it another way—the controls that are necessary to reduce routing incidents, and that the operator should apply, improve the overall security, and to a much lesser extent they offer protection to their own networks. In other words, the security of your network is in the hands of other network operators, with whom you may not have any relation-ship. Therefore, addressing security issues in the Internet routing system requires a collective action.

Another challenge is related to the fact that security in general is not a state, but a process. Implementing security requires a systemic approach, and that is why corporate security relies on frameworks and established processes. How is it possible to apply such a systemic approach in a decentralized system with more than 60K independent networks?

MANRS^[1], *Mutually Agreed Norms for Routing Security*, attempts to address both challenges.

How MANRS Can Help

MANRS, a global initiative driven by network operators and *Internet Exchange Points* (IXPs) all over the globe and supported by the Internet Society, outlines simple but concrete actions that different types of network operators should take. The actions are limited in scope, and backed up by a growing community they have a good chance to become true norms of security in network operations.

Norms are often seen as possible solutions to a so-called *Collective Action Problem*. The name of this social phenomenon, known for centuries, was coined by Mancur Olson in 1965 in his book *The Logic of Collective Action*^[2]. Not really a problem in small communities, it becomes a real challenge as the number of entities grows, resulting in the failure to cooperate because of conflicting interests, despite a clear common benefit. That phenomenon is exactly what we observe in the area of routing security in the Internet.

Let's look at a set of actions that MANRS offers. Four actions are defined for *Internet Service Providers* (ISPs):

- *Action 1. Filtering:* Ensure the correctness of your own routing announcements and of announcements from your customers to adjacent networks with prefix and *Autonomous System (AS)-path granularity*.
- *Action 2. Anti-spoofing:* Enable source address validation for at least single-homed stub customer networks, your own end users, and infrastructure.
- *Action 3. Coordination:* Maintain globally accessible up-to-date contact information.
- *Action 4. Global Validation:* Publish your routing policy, including the intended announcements, so others can validate routing information on a global scale.

These actions represent a minimum baseline that yields significant improvements to the routing system with relatively little effort from individual players. The actions also provide a global reference that other initiatives or corporate improvement projects can use as a starting building block. This process can help focus various efforts in the area of routing security for steady and continuous improvement on a global scale.

Another aspect of MANRS is related to the interdependency and the fact that only a collective solution is possible. Not only does MANRS serve as a recommendation of what to do, but it also builds a community of security-minded operators committed to the common cause. The community is crucial in reinforcing the baseline and transforming it into norms of operational behavior.

Network operators join MANRS not out of pure altruism. Many understand that a stable and secure communication fabric is an essential component for their growing business. Many of the operators that joined MANRS were already implementing good routing security and even exceeding the requirements of the actions. However, MANRS, as a global reference point, provides them an opportunity to signal their security posture to customers and regulators. Moreover, the growing MANRS community is a clear demonstration that the industry is taking action to address these complex security issues.

IXPs Onboard

ISPs are not the only players that affect routing security. For instance, IXPs form local communities of ISPs with a common operational objective. They are in an excellent position to support the reciprocity of network protection that routing security requires and create a “safe neighborhood” at the exchange. To take advantage of the impact IXPs can have in the area of routing security, the MANRS community set the goal to get IXPs on board.

But IXPs are not exactly ISPs. And since MANRS membership requires demonstration of commitment with a tangible contribution, the community has created a related but separate set of MANRS actions for participating IXPs:

- *Action 1. Prevent propagation of incorrect routing information:* This mandatory action requires IXPs to implement filtering of route announcements at the Route Server based on routing information data (*Internet Routing Registry* [IRR] and/or *Resource Public Key Infrastructure* [RPKI]). A Route Server is a proxy network used to facilitate multilateral peering between the operators. Instead of setting up multiple *Border Gateway Protocol* (BGP) peering sessions with various operators at the exchange, an operator can peer with only the Route Server to accomplish this goal.
- *Action 2. Promote MANRS to the IXP membership:* IXPs joining MANRS are expected to provide encouragement or assistance for their members to implement MANRS actions.
- *Action 3. Protect the peering platform:* This action requires that the IXP have a published policy of traffic not allowed on the peering fabric and perform filtering of such traffic.
- *Action 4. Facilitate global operational communication and coordination among its members by providing necessary mailing lists and member directories.*
- *Action 5. Provide monitoring and debugging tools, such as the Looking Glass (LG)^[3]:* BGP LG servers are computers on the Internet running one of a variety of publicly available Looking Glass software implementations. A LG server is accessed remotely for the purpose of viewing routing information. Essentially, the server acts as a limited, read-only portal to routers of whatever organization is running the LG server. Typically, publicly accessible LG servers are run by ISPs or *Network Operations Centers* (NOCs).

Membership Growth

MANRS has seen a steady growth of its membership since its launch in November 2014. At the time of this writing, 130 operators cover more than 250 ASNs. Since the launch of the IXP Programme^[4] in April 2018, the number of participating IXPs has reached 30 (Figure 4).

MANRS needs partners to scale up adoption. IXPs are a great example of such collaboration. MANRS also partners with organizations such as APNIC, *Latin America and Caribbean Network Information Centre* (LACNIC), *Latin American and Caribbean Internet Exchange Association* (LAC-IX), the *Brazilian Network Information Center* (NIC.BR), Internet2, GÉANT, and RedCLARA to reach out to regional communities to grow the MANRS membership.

Figure 4: MANRS membership growth, ISPs.

Education and training play a very important role helping to lower the threshold for adoption. Based on the “Implementation Guide” developed by the community, MANRS Online Training^[5] contains six modules to help engineers understand the implementation details of the actions. These online modules can be completed either individually or as part of a moderated class, earning a certificate of completion from the Internet Society.

Next step in the capacity-building program is the release of the online hands-on lab; its development is being finalized.

In the area of capacity building, MANRS partners with training organizations such as the *Network Startup Resource Center* (NSRC) and the *Asia Pacific Network Information Centre* (APNIC)—reaching out to hundreds of network engineers.

As the awareness grows, more and more organizations are evaluating their readiness for MANRS actions, making necessary adjustments and joining the effort. The capacity-building efforts help networks that lack necessary expertise to implement the actions quickly.

It is our collective responsibility as participants of the Internet global routing system to ensure the reliability and security of the Internet. Help us make the Internet a safer place. Only together can we protect the core.

ANDREI ROBACHEVSKY is the Senior Technology Programme Manager for the Internet Society. Andrei’s primary area of interest is security and resilience of the Internet infrastructure. This work is based on active engagement with the operator, research, and policy communities. Prior to joining ISOC, Andrei was Chief Technical Officer of the RIPE NCC, leading the development of the company’s IT strategy, external and internal IT services, and work of the engineering departments. He was responsible for the deployment of DNSSEC for the reverse DNS tree and deployment of anycast instances of the K-root DNS server. Andrei brings to the Internet Society more than 10 years of experience in the Internet technical community. For more than a decade he has been actively following Regional Internet Registry (RIR) and Internet Engineering Task Force (IETF) activities. He was Chair of the Number Resource Organization’s (NRO) Engineering Coordination Group (ECG), which is responsible for various technical inter-RIR activities and projects. In 2010–2012 Andrei was a member of the Internet Architecture Board (IAB). Andrei is based in Amsterdam, The Netherlands. E-mail: robachevsky@isoc.org

ISOC Signs Letter Opposing GCHQ Proposal for Weakening Encryption

In late 2018, The British *Government Communications Headquarters* (GCHQ) published an essay^[1] on *Lawfare* outlining its principles for “exceptional” or “lawful” access to encrypted information, alongside a proposed use case—the “ghost proposal.” (Generally, when people speak of lawful or exceptional access they refer to some means of allowing law enforcement the ability to lawfully access the content of encrypted communications and encrypted data in an unencrypted form. For example, by asking companies to have the technical ability to access encrypted content.)

The GCHQ proposal would add a silent (or ghost) user to end-to-end encrypted messaging services, such as *WhatsApp*, and allow the government to listen in to ongoing encrypted conversations secretly for law enforcement or national security purposes. The *Internet Society* is pleased to add its name to an open letter^[2] outlining the dangers that this proposal, and techniques like it, pose to the Internet and to users everywhere.

All exceptional or lawful access proposals put users, the economy, the services we depend on and the Internet itself at greater risk to security threats. GCHQ’s “ghost proposal” is no exception. As stated in the open letter, the ghost proposal would:

“...introduce potential unintentional vulnerabilities, and increase risks that communications systems could be abused or misused ... [and] mean that users cannot trust that their communications are secure.”

Protected communications are a matter of security. Whether they are used to keep critical infrastructure running, safeguard our financial information, or keep personal information from those who would use it to do us harm, protected communications keep us all safe. All of these rely on encryption and other digital security tools.

The ISOC is proud to add its voice to a diverse group of stakeholders from civil society, industry and academia calling on GCHQ to abandon the ghost proposal and avoid any alternate approaches that would similarly threaten digital security and human rights. We must strengthen, not weaken encryption. By whatever name, any point of entry to a secure service is a weakness.

ICANN Publishes Updated Domain Name Marketplace Indicators

The *Internet Corporation for Names and Numbers* (ICANN) recently announced publication of the first wave of the *Domain Name Marketplace Indicators* report, which presents statistics related to *generic top-level domains* (gTLDs) and *country code top-level domains* (ccTLDs).^[1]

This report is an evolution of the previous *gTLD Marketplace Health Index* report (Beta), which was first published in July 2016 with twice annual reports through June 2018. This report includes expanded coverage to include ccTLD data. ICANN plans to further expand its coverage of shortlisted indicators and continue to publish these statistics twice a year to track progress against its goal of supporting the evolution of the domain name marketplace to be robust, stable and trusted.

A community Advisory Panel worked with ICANN to refine these indicators in preparation for publishing this version. Concurrent to the release of these Version 1.0 marketplace indicators, ICANN org will continue to work with the community and the Advisory Panel to evaluate additional enhancements that might be incorporated into this initiative in the future.

ICANN's mission is to help ensure a stable, secure and unified global Internet. To reach another person on the Internet, you need to type an address—a name or a number—into your computer or other device. That address must be unique so computers know where to find each other. ICANN helps coordinate and support these unique identifiers across the world. ICANN was formed in 1998 as a not-for-profit public-benefit corporation with a community of participants from all over the world.

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

“A major design feature of the *Internet Protocol* (IP) is its ability to run over a variety of underlying network technologies. If you look through the *Request For Comments* (RFC) document series, you will find numerous specifications of the form “IP over xxx,” where “xxx” is anything from Ethernet to X.25, Frame Relay, Bluetooth, WiFi, and even “Avian Carriers” (pigeons), the latter being one of the more famous April Fools RFCs. Because each of these technologies has different capabilities in terms of how much data can be carried in a “packet” or datagram, IP employs the concept of *fragmentation* and *reassembly* in cases where the originating datagram is larger than what the underlying network medium can support.”

That paragraph is a quote from our June 2016 issue (Volume 19, No. 2) in which Geoff Huston described various aspects of IPv4 and IPv6 fragmentation. In this issue he explains how the *Transmission Control Protocol* (TCP) and its concept of a *Maximum Segment Size* (MSS) might interact with IP fragmentation even if this interaction is technically a “layer violation.” His article presents measurement data on TCP MSS handshakes recorded by APNIC in August 2019.

The Internet has its origins in the *Advanced Research Projects Agency Network* (ARPANET), which began operation just over 50 years ago, in October 1969, with only two nodes. We asked Vint Cerf, one of the “Fathers of the Internet,” to reflect on this milestone.

As always, we welcome your feedback and suggestions on anything you read in this journal. Letters to the Editor may be edited for clarity and length and can be sent to ipj@protocoljournal.org. Please make sure your subscription details are accurate. In this issue you will also find a summary of our Privacy Policy.

MSS Values of TCP

by Geoff Huston, APNIC

The *Transmission Control Protocol* (TCP) *Maximum Segment Size* (MSS) has been under some examination in recent months because an operating system vulnerability related to the Linux implementation of TCP occurred; it is described in CVE-2019-11477, 11478, and 11479^[1]. One of the effective work-arounds to avoid this problem is to block all TCP connection attempts that use a MSS value of 500 or lower.

What is the impact of such a TCP filter policy? What is being used as MSS values? How will a drop filter of TCP sessions with an MSS value of 500 or lower affect the Internet user base? In the *Asia-Pacific Network Information Centre* (APNIC) measurement platform we have assembled a large collection of recorded TCP handshakes, each of which contains a record of the TCP MSS exchange. Let's look at the MSS settings.

The TCP MSS Parameter

The MSS parameter is a part of the *Options* field in the TCP initial handshake that specifies the largest amount of data that a TCP speaker can receive in a single TCP segment^[2]. The MSS relates to the TCP input buffer size within the implementation as packets are passed from the IP module to the TCP module. Each direction of TCP traffic uses its own MSS value, as this value is receiver-specified. The two ends don't have to agree on a common value because it acts as a constraint on the sender to send TCP segments no larger than this MSS value. But of course smaller TCP segments can always be sent. This MSS value can vary between the forward and reverse directions of a TCP data flow.

The MSS value does not count the TCP header or the IP header. The received IP datagram containing a TCP segment may be self-contained within a single packet, or it may be reconstructed from several fragmented pieces.

Because IP packet fragmentation is an IP-level issue, TCP should not directly concern itself with IP fragmentation in any case. In theory. In practice, a judicious setting of TCP MSS sizes that attempts to avoid sending TCP packets that incur IP-level packet fragmentation should be avoided!

Conventionally, the platform rather than the application sets the MSS value for a connection and the setting is applied to all TCP connections. But many operating system platforms provide a hook in the connection *Application Programming Interface* (API) for an application to specify the MSS value for a connection (such as the TCP_MAXSEG socket option).

What Is a “Good” MSS Value?

Getting the MSS value “just right” is important. While in theory the IP and TCP layers are largely independent, the practical reality is quite the opposite. Too high a value can lead to inefficient and even wedged TCP sessions due to issues with mishandling of IP fragmentation. The problem is that the sender may perform TCP segmentation by using the received MSS value as its guide and the resultant TCP packet is then far larger than the outgoing IP interface *Maximum Transmission Unit* (MTU) size, entailing the sender to perform IP-level fragmentation on the TCP packet.

It’s also worth remembering that many of the TCP congestion control protocols use a rate acceleration based on an increase in the sending rate of 1 MSS of data per round-trip-time interval. Larger MSS values imply a faster rate of acceleration in such protocols, while smaller MSS values will lead to inefficiencies and may stall the sender, potentially leading to some congestion issues within the sender. The IPv4 packet contains a 16-bit packet identification number, implying that in order to avoid fragmentation reassembly issues not more than 65,536 IP packets should be in flight at any point in time.

Therefore, the combination of very small MSS values, long-held TCP sessions, and long-delay bandwidth network paths is certainly inefficient, but it should not necessarily represent any form of attack vector if the implementation of TCP is suitably robust. The recent security notices point to some platform vulnerabilities within the sender that are exposed by low MSS values.

What guidance is there in the RFCs on setting the TCP MSS value?

RFC 791^[3] provides IP MTU guidance, stating that:

"All hosts must be prepared to accept datagrams of up to 576 octets (whether they arrive whole or in fragments). It is recommended that hosts only send datagrams larger than 576 octets if they have assurance that the destination is prepared to accept the larger datagrams."

Given that IP has no explicit MTU signalling capability, this explicit recommendation of obtaining assurance of the receiver’s preparedness to accept larger IP datagrams presumably refers to the TCP MSS value.

RFC 879^[4] provided quite explicit guidance about the TCP MSS value:

"THE TCP MAXIMUM SEGMENT SIZE IS THE IP MAXIMUM DATAGRAM SIZE MINUS FORTY. The default IP Maximum Datagram Size is 576. The default TCP Maximum Segment Size is 536."

These documents were written prior to the specification of IPv6 of course, and in RFC 2460^[5] the following guidance was given for IPv6:

"When using TCP over IPv6, the MSS must be computed as the maximum packet size minus 60 octets."

It also states that:

"IPv6 requires that every link in the internet have an MTU of 1280 octets or greater."

Taken together, RFC 2460 asserts that for TCP over IPv6 the MSS value would be expected to be 1,220 or greater.

These days the now-ancient Ethernet packet-framing specification still dominates the networking environment (although the old thick yellow coaxial cables and even the *Carrier Sense Multiple Access/Collision Detection* [CSMA/CD] 10-Mbps common bus protocol were both consigned to the networking section of silicon heaven years ago!). Thus the most common IP packet MTU is 1,500 octets.

Further clarification was provided in RFC 6691^[6], "TCP Options and Maximum Segment Size," (published in July 2012):

"When calculating the value to put in the TCP MSS option, the MTU value SHOULD be decreased by only the size of the fixed IP and TCP headers and SHOULD NOT be decreased to account for any possible IP or TCP options; conversely, the sender MUST reduce the TCP data length to account for any IP or TCP options that it is including in the packets that it sends. [...] the goal is to avoid IP-level fragmentation of TCP packets."

That information implies that the most common anticipated TCP MSS values would correspond to a 1,500-octet MTU in both IPv4 and IPv6, further implying that we should see a MSS value of 1,460 in IPv4 and 1,440 in IPv6.

How well does practice line up with the theory?

Measuring TCP MSS Values

We looked at the MSS sizes in the HTTP(S) sessions offered by clients who connected to servers with our measurement as part of our large measurement program into IPv6 deployment. We collected all TCP handshakes that occurred in August 2019 and recorded the MSS values from the SYN packets received from the client systems.

We saw some 3B TCP sessions over this period, and after we removed the duplicate entries for multiple TCP sessions from the same end-point within a similar timeframe with a common MSS value, we were left with some 551M unique TCP sessions.

Surprisingly enough, 202 endpoints offered an MSS value of 0, and 284 endpoints offered a value of 1. To put this data into perspective, this count of 486 endpoints represents 0.0001% (slightly less than 1 per million) of all observed TCP sessions. Small MSS values exist, but they are very much a rarity in the larger population of the Internet. A total of 20,488 sessions were opened with MSS values of 500 or lower (0.004%).

At the other end of the range of observed MSS values, three sessions used a value of 65,516 (the IPv4 maximum MTU minus 40). If we categorise any MSS value greater than 1,460 as some form of jumbo MSS, then we observed that 68,278 sessions used jumbo MSS values, or 0.012% of all TCP sessions.

As a side note, the network industry has never reached a clear agreement on exactly what a *jumbo frame* size should be. A value of 9,216 octets has been commonly quoted, as has the Internet2-defined value of 9,000 octets. The lack of agreement within the *Institute of Electrical and Electronics Engineers* (IEEE) on a single definition of a jumbo frame is not entirely unique, as many media-level protocols have used what could only be described in retrospect as idiosyncratic maximum MTU values. IEEE 802.5 *Token Ring* used an MTU of up to 4,464 octets, *Fiber Distributed Data Interface* (FDDI) used 4,532 octets, and IEEE 802.11 used 7,935 octets. Perhaps this diversity in media-based MTU values is not all that surprising, and what is perhaps more surprising is a current rough consensus of a commonly assumed MTU of 1,500 octets in the Internet, irrespective of the underlying media capabilities.

Table 1 shows the most common observed MSS values.

Table 1: Most Common MSS Values

Rank	MSS	Ratio	Rank	MSS	Ratio
1	1,460	17.6%	14	1,390	0.8%
2	1,400	16.4%	15	1,358	0.7%
3	1,370	11.3%	16	1,368	0.6%
4	1,452	8.7%	17	1,388	0.6%
5	1,440	8.3%	18	1,350	0.5%
6	1,360	6.9%	19	1,394	0.4%
7	1,412	5.1%	20	1,312	0.4%
8	1,300	4.3%	21	1,220	0.4%
9	1,380	3.7%	22	1,362	0.3%
10	1,420	3.5%	23	1,240	0.3%
11	1,432	1.8%	24	1,414	0.3%
12	1,410	1.3%	25	1,344	0.3%
13	1,340	1.3%			

The 1,460 value appears to correlate with a 1,500-octet MTU and a 40-octet IPv4 and TCP packet header. If the MSS value is calculated from the interface MTU size less the size of the IP and TCP headers, then we would expect the IPv6 MSS sizes to be 20 bytes less than the IPv4 MSS sizes.

We can separate the TCP MSS values used in IPv4 and IPv6, as shown in Table 2.

Table 2: Most Common MSS Values in IPv4 and IPv6

IPv4			IPv6	
Rank	MSS	Ratio	MSS	Ratio
1	1,460	17.6%	1,370	28.1%
2	1,400	16.4%	1,440	20.5%
3	1,370	11.3%	1,432	7.8%
4	1,452	8.7%	1,300	6.2%
5	1,440	8.3%	1,400	5.2%
6	1,360	6.9%	1,380	4.7%

24	1,414	0.3%	1,140	0.2%
25	1,344	0.3%	1,330	0.1%

The 1,370 value in IPv6 is somewhat unusual, as it corresponds to a MTU of 1,430 octets. It appears to be a common situation to use a 1,430-octet MTU in hosts, presumably as such a value (and any MTU value less than 1,460 octets) would minimise both the risks of IP fragmentation and path MTU issues that may arise from path element encapsulation that could be encountered when using IPv6.

If one takes the 1,460 MSS value in IPv4 and the 1,440 MSS value in IPv6 as an indicator of an underlying 1,500 MTU size, then relatively more endpoints are using a 1,500 MTU in IPv6 than in IPv4. (17.6% in IPv4 vs 20.5% in IPv6). In IPv6 there is a stronger consensus to use a single, smaller MSS value of 1,370 (28.1%) than there is in IPv4, where there is significant use of both 1,400 (16.4%) and 1,370 (11.3%) as MSS values.

The range of observed MSS values between 1,300 and 1,440 in both IPv4 and IPv6 points to the existence of a common action of constraining the IP MTU size in order to circumvent the possibility of IP fragmentation in both IPv4 and IPv6. I described the problem in 2009 in “A Tale of Two Protocols: IPv4, IPv6, MTUs and Fragmentation,”^[7] and pointed out why a reduced MTU setting would be a reasonable response to this problem.

We also saw the MSS value of 536 in 38,359 cases, 38,245 of which were in IPv4 and 14 in IPv6, a value that appears to be derived from an assumed interface MTU of 576 octets and a 20-octet IPv4 packet header and 20-octet TCP header.

Oddly enough, the MSS value of 512 is more prevalent than that of 536, observed in 319,612 cases in IPv4 and not observed at all in IPv6.

While there is no particular media type that uses an MTU of 1,280 (which is the minimum unfragmented packet MTU size in IPv6), we had observed a minor clustering of MSS values at 1,220, with 1,892,966 IPv6 samples using this MSS value. Oddly enough, there were 7,268,197 cases of a 1,300-byte MSS value in IPv6.

Figure 1 on the following page shows the overall distribution of observed IPv4 MSS sizes.

Figure 1: Cumulative Distribution
of TCP MSS Values

Incidence of Low MSS Values

Where might we see hosts with low (less than 500) MSS values?

In IPv4 almost half of all such systems are located in Germany and the Netherlands. Adding the data from systems offering small MSS values from France, South Korea, Bangladesh, Indonesia, Pakistan, and Brazil to the set encompasses some 90% of all hosts with MSS values less than 500. In the case of IPv6, more than half of the low MSS values are from hosts located in Germany, and 90% of all such hosts are located in Germany, Indonesia, the United States, Canada, Malaysia, and Brazil.

In terms of origin network in IPv4, the networks that contain the most hosts with observed low MSS values are operated by a large web-hosting enterprise. In IPv6 the majority of instances originate from a research centre in Germany. It may be that this high incidence of these very low MSS values in these networks could be due to some bug or operational misconfiguration in web-hosting equipment, or an unintentional configuration choice made by a client of this virtual system hosting service.

Incidence of High MSS Values

And where are hosts that use large TCP MSS values (values greater than 1,460)?

In IPv4 the United States contains 21% of all such hosts, and the somewhat diverse collection of India, Russia, and Ireland also each host some 4 to 6% of the total count of such hosts. The picture alters with IPv6, with half of all such hosts located in Japan and a little under one-quarter located in the United States.

At the network level the Amazon *Autonomous System Numbers* (ASNs) were most commonly found to be hosting high MSS-valued TCP stacks in IPv4, while the Japanese *Internet Service Providers* (ISPs) KDDI and NTT's OCN and Comcast in the United States were hosting high-valued MSS hosts in IPv6.

It appears that while some form of hosting or cloud system generates a large MSS value in IPv4, some form of configuration of ISP server product might be the cause of this behaviour in IPv6.

Incidence of Adjusted MSS Values

We can make the supposition that an MSS value of between 1,260 and 1,440 has been the result of a deliberate adjustment of the host MTU value in order to reduce the risk of packet fragmentation and path MTU black holes.

A path MTU black hole occurs when a server emits a packet that is too large for a network path element on the path to the receiver and, in the case of IPv4, either the *Don't Fragment* bit of the packet is set or the packet is an IPv6 packet, and the return path to the server is blocking *Internet Control Message Protocol* (ICMP) messages for some reason.

At this point the connection will stall. The sender is waiting for either an ACK of the data sequence number in the dropped packet or an ICMP packet to indicate that there is an MTU problem. The ACK will never arrive as the packet has been dropped and the ICMP message has been blocked within the network.

The server will timeout and retransmit the large packet, to no effect. It may do so indefinitely unless some local overall session timeout is in effect, or TCP keepalives are in use.

The client has no outstanding data, so it will not retransmit and will just hang, waiting for a packet that will never arrive. TCP keepalives may identify this hung state and kill the hung TCP session.

We see these adjusted MSS values in those locations with a high IPv6 deployment volume—including India, the United States, Japan, and Vietnam.

What Values Should Be Used for TCP MSS?

A decade ago, the best advice around was to use a down-adjusted MSS value such as 1,300, 1,380, or even 1,400. The reason was to avoid path MTU issues, particularly when using IPv6, and the reason why path MTU issues were encountered in IPv6 was the prevalent use of IPv6-in-IPv4 encapsulation tunnels in IP transit paths and the widespread practice of firewall filtering of ICMPv6 *Packet Too Big* messages.

I'm not sure that ICMP filtering has improved or worsened in the last decade, but what has improved markedly is the use of "native" IPv6 transit paths in the Internet.

While it was probably foolhardy to use a 1,500 MTU and a 1,440 MSS with IPv6 a decade ago, it appears now to be not quite so foolhardy. Of course, not every tunnel has been removed and not every potential path MTU issue has been eliminated from the network, not every ICMPv6 filter has been removed, and not every fragment discard rule has been purged from firewalls, and they will probably never be completely purged. In relative terms the situation is better than it was a decade ago, and the expectation of encountering MTU-related problems is far lower than it was when a MSS based on a 1,500-octet MTU setting was used.

But there are still outstanding issues here, and a more reliable service can be staged using a slightly reduced local MTU and MSS setting. If we used a 1,480-octet MTU and corresponding TCP MSS values of 1,420 in IPv4 and 1,400 in IPv6, we could reasonably anticipate that the resultant TCP service would be adequately reliable.

As for the CVE mitigation advice to refuse a connection attempt when the remote-end MSS value is 500 or lower, I'd say that's good advice. It seems that the low MSS values are the result of some form of misconfiguration or error, and rather than attempting to mask over the error and persisting with an essentially broken TCP connection that is prone to generating a packet deluge, the best option is to just say "no" at the outset. If we all do that, then the misconfiguration will be quickly identified and fixed, rather than being silently masked over.

Looking Back on 50 Years of the Internet Era

by Vint Cerf, Internet Pioneer

It isn't possible in a short essay to really cover 50 years of the evolution of the Internet. Books have been written on the subject. We have just celebrated the October 29, 1969, milestone that linked an XDS Sigma-7 computer at the *University of California, Los Angeles* (UCLA) to a time-shared SDS 940 computer at *Stanford Research Institute* (SRI). At that time, there were only two nodes of the planned *Advanced Research Projects Agency Network* (ARPANET)^[0], but two more at *University of California, Santa Barbara* (UCSB) and at *University of Utah, Salt Lake City* were added by the end of the year. What I think is most interesting about the ARPANET part of the Internet saga is the trailblazing that project did in heterogeneous computer networking. It was among the first networks to use *packet switching* as the communications mechanism. Some historians might reasonably argue that the US *Semi-Automated Ground Environment* (SAGE) system developed in the 1950s and in operation until the 1980s and the US *AUTODIN* message switching system also developed in the late 1950s and 1960s both represented then state-of-the-art, wide-area computer communications. These systems were closer in spirit to automated store-and-forward teletype/telegraph messaging services than to the subsequent packet switching of the ARPANET, the French *Cyclades/Cigale* experimental network, and the UK National Physical Laboratory local-area network.

The heterogeneous computers (called *hosts*) of the ARPANET were interconnected to each other through a subnet of identical *Interface Message Processors* (IMPs) that were, in turn, interconnected by dedicated 50 kbps telephone circuits.

Figure 1: The ARPANET in December 1969^[4]

The ARPANET project launched a documentation series called *Request for Comments* (RFCs)^[1] that continues to this day to document the protocols of the Internet.

To coordinate the development of the host-to-host protocols and other applications, a *Network Working Group* (NWG) was established. This concept influenced the creation of an *International Network Working Group* (INWG) that became Working Group 6.1 of Technical Committee 6 of the *International Federation of Information Processing* (IFIP) and also influenced the creation of the *Internet Configuration Control Board* that morphed into the *Internet Architecture Board* (IAB), which gave rise to the *Internet Engineering and Research Taskforces* (IETF and IRTF), all of which are still active today.

A spirit of open sharing and cooperation permeated the participants and organizations that were involved in the ARPANET project and that also influenced the early developers of the Internet and the World Wide Web—which emerged in the early 1990s as the most popular application of the system. Even in today’s competitive environment, we find the engineers of the Internet cooperating to deal with a plethora of malicious attacks against the infrastructure and applications of the Internet and to fashion new protocols to support a growing collection of applications.

As the protocol experiments and research unfolded on the ARPANET, the concept of protocol layering emerged and strongly influenced both the Internet design and the development of the *Open Systems Interconnection* (OSI) Model for computer networking. The layering concepts also influenced the basic Internet architecture in the form of encapsulation and decapsulation of Internet packets in the frames and packet payloads of lower-level protocols in the underlying networks of the Internet. Gateways received Internet packets in the payloads of lower layers, extracted them, decided where to route them, encapsulated them in the appropriate payloads of the next packet network, and sent them on their way.

Electronic messaging, which had been developed in the course of implementing time-shared computer systems, was extended as networked electronic mail in the early years of the ARPANET to work across the network among the cooperating hosts. A *File Transfer Protocol* (FTP)^[2] and a remote-access *telecommunications network* (TELNET)^[3] protocol were among the early applications of the ARPANET and were eventually translated into the Internet.

A look back to the early years of the ARPANET shows that we owe much to those pioneering researchers and engineers who blazed trails into terra incognita for the rest of us to follow and extend. Even today, there is still an enormous frontier of unexplored conceptual space waiting to be discovered. As we collectively struggle to deal with emergent challenges of misinformation, disinformation, denial-of-service attacks, and fragmentation of the Internet, I still remain hopeful that the utility of willing global collaboration will inform the Internet governance policies under consideration around the world and bend them towards positive and fruitful outcomes.

VINTON G. CERF is vice president and Chief Internet Evangelist for Google. He contributes to global policy development and continued spread of the Internet. Widely known as one of the “Fathers of the Internet,” Cerf is the co-designer of the TCP/IP protocols and the architecture of the Internet. He has served in executive positions at MCI, the Corporation for National Research Initiatives and the Defense Advanced Research Projects Agency and on the faculty of Stanford University.

Vint Cerf served as chairman of the board of the *Internet Corporation for Assigned Names and Numbers* (ICANN) from 2000–2007 and has been a Visiting Scientist at the Jet Propulsion Laboratory since 1998. Cerf served as founding president of the *Internet Society* (ISOC) from 1992–1995. Cerf is a Foreign Member of the British Royal Society and Swedish Academy of Engineering, and Fellow of IEEE, ACM, and American Association for the Advancement of Science, the American Academy of Arts and Sciences, the International Engineering Consortium, the Computer History Museum, the British Computer Society, the Worshipful Company of Information Technologists, the Worshipful Company of Stationers and a member of the National Academy of Engineering. He currently serves as Past President of the Association for Computing Machinery, Past Chairman of the *American Registry for Internet Numbers* (ARIN) and completed a term as Chairman of the Visiting Committee on Advanced Technology for the US National Institute of Standards and Technology. President Obama appointed him to the National Science Board in 2012.

Cerf is a recipient of numerous awards and commendations in connection with his work on the Internet, including the US *Presidential Medal of Freedom*, US *National Medal of Technology*, the *Queen Elizabeth Prize for Engineering*, the *Prince of Asturias Award*, the *Tunisian National Medal of Science*, the *Japan Prize*, the *Charles Stark Draper* award, the *ACM Turing Award*, Officer of the Legion d’Honneur and 29 honorary degrees. In December 1994, *People* magazine identified Cerf as one of that year’s “25 Most Intriguing People.” In 2012, he was inducted to the *Internet Hall of Fame*. E-mail: vint@google.com

Book Review

Confessions of a Crypto Millionaire

Confessions of a Crypto Millionaire: My Unlikely Escape from Corporate America, by Dan Conway, Zealot Publishing, September 2019, ISBN-13: 978-1733171700.

You probably have read your fill of business books. Author tries to make it big, leverages tons of his money and time, hires the wrong people, fires them, then goes it alone before striking it rich and motoring off into the sunset in some expensive car. Dan Conway's *Confessions of a Crypto Millionaire* is not one of these books. Most business books offer just enough advice to fill a chapter, maybe two. Conway has a lot more to say about his obsession and investments in cryptocurrency, in particular *Ethereum*. Over a period of several years, he used his home mortgage equity loan and borrowed additional funds because he believed blockchain held the future model for decentralized corporations and the way that we will all work together. He ended up cashing out \$14M ahead. It is his obsession that drives the book's narrative, along with the crazy up-and-down valuation of Ether, where you can gain and lose millions in a matter of minutes.

What isn't in this book is also notable: sordid tales of wretched excess of "tech-bros partying on yachts" or trashing expensive Vegas hotel suites. Conway is a father of three, and still married to their mother.

Conway's confessions make a refreshing tale about his fighting his demons, his addictions (alcohol and pills), his insecurities, and his almost always-on self-destructive alter-ego he calls his "Flip Side." This side rears its ugly head during client presentations where he fumbles and fails and during periods of self-doubt when he tries to reassure himself his huge bet on Ether isn't about to land him in the poor house.

"The book forced me to make sense of how my addictive personality played a part in my undoubtedly reckless crypto investments," he told me via an e-mail interview. He is part visionary, buying Ether at a time and at a level few people had the courage, vision, or just dumb luck to do. "It took everything admirable and loathsome about me to make the plunge into Ether. The loathsome part includes my addictive personality. While betting everything was an extreme risk, all risk requires insight, courage, and maybe a little recklessness." He hopes his story will get others to think about how they formulate their own risk taking.

Conway begins his story "working for the man," doing marketing and public relations for large corporations, one of whom he calls Acme. He wasn't a good fit as the organization man to be sure. And since his windfall with Ether, he is unlikely to return to corporate America "unless we suffer a financial catastrophe."

He still believes that the decentralized blockchain can disrupt the traditional corporate power structure and has a lot of merit as an organizing principle. One example he cites is the MakeDAO, where ordinary folks can originate loans and handle other financial transactions without any financial institutional limits. It could pay off; it could fall flat: that is the challenge of cryptocurrency.

One aspect of his book is dealing very honestly with two situations: first, with his addictions. “This undoubtedly played a part in my reckless crypto investments, and writing the book helped force me to make sense of it all.”

Second, the book also describes how his financial windfall changed his family dynamics and the relationships with his circle of friends. Even though Conway lived in Silicon Valley, he was very firmly rooted in the middle class before he made it big with Ether. He writes:

“Crypto was suddenly like an overexposed celebrity, and everyone was rooting for it to fail,” but then realizes, “one of the bittersweet feelings about making a bunch of money is that you can’t bring your (less fortunate) friends with you.” That takes some adjustment, both for him and his family. Still, don’t be too sad: Now he takes long exotic vacations, buys his kids “name-brand clothes” instead of Sears knock-offs, and does car pool duty with a vengeance. “It’s absolutely nice to have the car-ride conversations rather than pinning all parent/child bonding on the “how was your day?” question when everyone is exhausted.” True that.

Conway is committed to Ethereum because of its disruptive ability to change the way companies operate, the way companies get Venture Capital funding (the parts about the ICO shysters alone are worth reading), and the way the early pioneers—which Conway counts as himself—had to try to separate the criminals from the legit businesses. This book is well worth reading, even if your own exposure to bitcoin and other cryptocurrencies is minimal.

Read Any Good Books Lately?

Then why not share your thoughts with the readers of IPJ? We accept reviews of new titles, as well as some of the “networking classics.” In some cases, we may be able to get a publisher to send you a book for review if you don’t have access to it. For more information, contact us at ipj@protocoljournal.org

Letter to the Editor

Hi Geoff,

I have read the article “DNS Privacy and the IETF,” in the latest issue of *Internet Protocol Journal* (Volume 22, No. 2, July 2019). Thank you for the excellent insights.

I am intrigued about the discussion of a world where apps would control the resolver. I am wondering how these apps would work in an IPv6-only world where the *Internet Service Provider* (ISP) does *Carrier Grade Network Address Translation* (CGNAT). If a DoH server responds with only an A record to say `ipv4google.com`, how does the handset make the connection? Or perhaps I misunderstand CGNAT—in reality the Internet-facing device/router has an RFC 1918 address and a global IPv6 address—IPv4 connectivity would use *Network Address and Port Translation* (NAPT) from the ISP public pool, whereas IPv6 connectivity can pass through without issue.

Thanks,

— Naveen Nathan, naveen@lastninja.net

The author responds:

Great question. Some transition mechanisms “crossed the beams” and relied on a DNS resolver that had knowledge of the transition mechanism and deliberately lied in their responses in order to steer the end host’s traffic to a protocol translator/encapsulator. Obviously if the application selected a DoH resolver that was not part of the local environment and was unaware of the need to provide NAT64 responses to these hosts, then the application would be unable to communicate.

It leads to the interesting outcome where the host (non-DoH) would look just fine and certain applications when going to certain remote services would fail. I have some sympathy for the help desk staff trying to identify and solve this problem.

Evidently some plans for DoH use involve application testing the existing configured DNS resolver for DoH capability and turning on DoH only in that case; that is, encapsulate in HTTP only the first DNS “hop” from the stub resolver to the recursive resolver. This solution would certainly avoid the NAT64 issue but would not really prevent the “my ISP is spying on my DNS transactions and possibly using this data in ways I am unaware of” scenario.

More generally, the more we adorn the network infrastructure and the more we add elements that create dependencies on other elements in novel ways, the more fragile the network becomes. The end point is a network that only barely functions and resists any modification—however slight—as the modification causes it to fail. It’s an odd situation to get to when the original concepts behind the Internet were thoughts about creating a level of resiliency of the network as a service that exceeded the resiliency of any component of the network system.

Regards,

— Geoff Huston, gih@apnic.net

Postel Service Award Presented to Alain Aina

The Internet Society, a global nonprofit dedicated to ensuring the open development, evolution, and use of the Internet, recently presented the prestigious *Jonathan B. Postel Service Award* to Alain Aina, who serves as the chief technology officer of the *West and Central Africa Research and Education Network* (WACREN).

Aina has been building a Regional Research and Education Network to interconnect *National Research and Education Networks* (NRENs) in the region and connect them to the global Research and Education Network. He wants the world to see the work of Africa's premier researchers and carve out its spot in the academic world—in a way that would be impossible without the resources of this new network and community. He also contributes to *AfricaConnect2*, a project that supports the development of high-capacity networks for research and education across Africa, by building on existing networks in Eastern, Northern, and Southern Africa to connect to West and Central Africa's WACREN.

Photo by Minzayar Oo © IETF LLC 2019.

Aina fell into this work after graduating in the early 90s with a degree in electrical engineering and in the maintenance and analysis of computer systems. He was hired to be a technical seller for a company in the Togolese Republic, which had a branch in Benin, where he is from. The owner of the company had recently returned home from the United States and was anxious about computing and internet-working. He noticed Aina's talent and added him to the technical team, where he ended up building the first *Bulletin Board System* (BBS) in the area.

“People used the modem to dial in, then people on the same server could talk to each other,” he said. “Then we decided to put in the first e-mail gateway, connecting to someone in Accra and later in Montreal twice a day to drop mail and download mail. But the cost was so high, it was not sustainable. The delegation of the country-code TLD in 1996 changed the paradigm for the e-mail service and we were proud to demonstrate the first local web server and intranet.”

By the mid-90s there wasn’t a lot of support for people working on Internet access and connection, but there was ever-growing interest and demand. This meant that Aina and his colleagues often worked around the clock to set up networks and services in communities, then trained the local population on how to use what they had made.

“The Internet became so popular that the demand was suddenly so high, and it was putting pressure on us,” he said.

It was about this time that Aina started collaborating with the *Network Startup Resource Center* (NSRC), where he now serves as a part-time network engineer and trainer. He later launched the first full IP services in the Togolese Republic and then in other countries in West Africa.

“At that time, most of the world did not believe that Africa could have the Internet and play a role. When you’d go to places, you’d have to train people,” Aina said. “Training materials were rare. We were lucky to have some books and some knowledgeable friends far away. The people you trained only knew you, so if something broke they called you to fix it.”

Aina helped build large parts of the Internet ecosystem throughout Africa, setting up networks, contributing to the creation of the regional Internet registry and the network operator group, and building ccTLD registries. He also started a consulting firm and became active in the private sector.

He eventually started attending *Internet Society* (ISOC) network technology workshops and getting involved with the organization in other ways. From 2011 to 2014, he served as a trustee for the organization. Active in the Internet community, he is also involved with ICANN, the *African Network Information Centre* (AFRINIC), the *African Network Operators Group* (AFNOG), and other organizations. He helped found AFNOG, where he’s been an instructor since 2000, and he is one of the founders of AFRINIC, where he’s served in several roles, including acting chief technology officer, acting chief executive officer, and director of research and innovation. Aina is a key technical resource for the DNS community, including *Africa Top Level Domains Organization* (AFTLD). A big part of his life has been Internet related, but he feels there is still so much more to do for Africa.

Mr. Aina was selected by an international award committee comprised of former Postel award winners. The committee placed particular emphasis on candidates who have supported and enabled others in addition to their own contributions. The award was presented to Mr. Aina in recognition of his leadership in pioneering the Internet in Africa and building technical communities that helped connect countless others across the continent and beyond. Aina helped build large parts of the Internet ecosystem throughout Africa, setting up networks, contributing to the creation of the regional Internet registry and the network operator group, and building ccTLD registries.

“This award encourages me to continue the work, to grow and help others spread the Internet continent-wide, and to help break down barriers for the engineers and scientists in Africa,” Aina said. “I feel happy and honored to be recognized for this work.”

The Postel Award was established by the Internet Society to honor individuals or organizations that, like Jon Postel, have made outstanding contributions to the data communications community. The award is focused on sustained and substantial technical contributions, service to the community, and leadership. Andrew Sullivan, President and CEO of the Internet Society presented the award, including a US\$20,000 honorarium and a crystal engraved globe, during the 106th meeting of the *Internet Engineering Task Force* (IETF) held in Singapore, 16–22 November 2019.

ICANN Calls for Full DNSSEC Deployment

The *Internet Corporation for Assigned Names and Numbers* (ICANN) believes that there is an ongoing and significant risk to key parts of the *Domain Name System* (DNS) infrastructure. In the context of increasing reports of malicious activity targeting the DNS infrastructure, ICANN is calling for full deployment of the *Domain Name System Security Extensions* (DNSSEC) across all unsecured domain names. The organization also reaffirms its commitment to engage in collaborative efforts to ensure the security, stability and resiliency of the Internet’s global identifier systems.

As one of many entities engaged in the decentralized management of the Internet, ICANN is specifically responsible for coordinating the top-most level of the DNS to ensure its stable and secure operation and universal resolvability.

On 15 February 2019, in response to reports of attacks against key parts of the DNS infrastructure, ICANN offered a checklist^[1] of recommended security precautions for members of the domain name industry, registries, registrars, resellers, and related others, to proactively take to protect their systems, their customers’ systems and information reachable via the DNS.

Public reports^[2] indicate that there is a pattern of multifaceted attacks utilizing different methodologies. Some of the attacks target the DNS, in which unauthorized changes to the delegation structure of domain names are made, replacing the addresses of intended servers with addresses of machines controlled by the attackers. This particular type of attack, which targets the DNS, only works when DNSSEC is not in use. DNSSEC is a technology developed to protect against such changes by digitally “signing” data to assure its validity. Although DNSSEC cannot solve all forms of attack against the DNS, when it is used, unauthorized modification to DNS information can be detected, and users are blocked from being misdirected.

ICANN has long recognized the importance of DNSSEC and is calling for full deployment of the technology across all domains. Although this will not solve the security problems of the Internet, it aims to assure that Internet users reach their desired online destination by helping to prevent so-called *Man in the Middle* attacks where a user is unknowingly re-directed to a potentially malicious site. DNSSEC complements other technologies, such as *Transport Layer Security* (TLS) (most typically used in HTTPS) that protect the end user/domain communication.

As the coordinator of the top-most level of the DNS, ICANN is in the position to help mitigate and detect DNS-related risks, and to facilitate key discussions together with its partners. The organization believes that all members of the domain name system ecosystem must work together to produce better tools and policies to secure the DNS and other critical operations of the Internet.

The RIPE NCC has run out of IPv4 Addresses

From the RIPE-NCC Website: “Today, at 15:35 (UTC+1) on 25 November 2019, we made our final /22 IPv4 allocation from the last remaining addresses in our available pool. We have now run out of IPv4 addresses. Our announcement will not come as a surprise for network operators—IPv4 run-out has long been anticipated and planned for by the RIPE community. In fact, it is due to the community’s responsible stewardship of these resources that we have been able to provide many thousands of new networks in our service region with /22 allocations after we reached our last /8 in 2012.

Even though we have run out, we will continue to recover IPv4 addresses in the future. These will come from organisations that have gone out of business or are closed, or from networks that return addresses they no longer need. These addresses will be allocated to our members (*Local Internet Registries* [LIRs]) according to their position on a new waiting list that is now active.

While we therefore expect to be allocating IPv4 for some time, these small amounts will not come close to the many millions of addresses that networks in our region need today. Only LIRs that have never received an IPv4 allocation from the RIPE NCC (of any size) may request addresses from the waiting list, and they are only eligible to receive a single /24 allocation. LIRs that have submitted an IPv4 request can see their position on the waiting list in the LIR Portal. A graph is available at <https://www.ripe.net/> that shows the number of requests on the waiting list and the number of days that the LIR at the front of the queue has been waiting.

This event is another step on the path towards global exhaustion of the remaining IPv4 addressing space. In recent years, we have seen the emergence of an IPv4 transfer market and greater use of *Carrier Grade Network Address Translation* (CGNAT) in our region. There are costs and trade-offs with both approaches and neither one solves the underlying problem, which is that there are not enough IPv4 addresses for everyone.

Without wide-scale IPv6 deployment, we risk heading into a future where the growth of our Internet is unnecessarily limited—not by a lack of skilled network engineers, technical equipment or investment—but by a shortage of unique network identifiers. There is still a long way to go, and we call on all stakeholders to play their role in supporting the IPv6 roll-out.

At the RIPE NCC, we are here to support our membership and the wider RIPE community in this work. Aside from allocating the IPv6 resources that will be required, we will continue to provide advice, training, measurements and tools to help network operators as they put their deployment plans into action. We are optimistic and excited to see what the next chapter will bring. So let’s get to work—and together, let’s shape the future of the Internet.”

Check your Subscription Details!

If you have a print subscription to this journal, you will find an expiration date printed on the back cover. For the last couple of years, we have “auto-renewed” your subscription, but now we ask you to log in to our subscription system and perform this simple task yourself. The subscription portal is here: <https://www.ipjsubscription.org/>. This process will ensure that we have your current contact information as well as delivery preference (print edition or download). For any questions, contact us by e-mail at: ipj@protocoljournal.org

Our Privacy Policy

The *General Data Protection Regulation* (GDPR) is a regulation for data protection and privacy for all individual citizens of the *European Union* (EU) and the *European Economic Area* (EEA). Its implementation in May 2018 led many organizations worldwide to post or update privacy statements regarding how they handle information collected in the course of business. Such statements tend to be long and include carefully crafted legal language. We realize that we may need to provide similar language on our website and in the printed edition, but until such a statement has been developed here is an explanation of how we use any information you have supplied relating to your subscription:

- The mailing list for *The Internet Protocol Journal* (IPJ) is entirely “opt in.” We never have and never will use mailing lists from other organizations for any purpose.
- You may unsubscribe at any time using our online subscription system or by contacting us via e-mail. We will honor any request to remove your name and contact information from our database.
- We will use your contact information *only* to communicate with you about your subscription; for example, to inform you that a new issue is available, that your subscription needs to be renewed, or that your printed copy has been returned to us as undeliverable by the postal authorities.
- We will *never* use your contact information for any other purpose or provide the subscription list to any third party other than for the purpose of distributing IPJ by post or by electronic means.
- If you make a donation in support of the journal, your name will be listed on our website and in print unless you tell us otherwise.

Thank You!

Publication of IPJ is made possible by organizations and individuals around the world dedicated to the design, growth, evolution, and operation of the global Internet and private networks built on the Internet Protocol. The following individuals have provided support to IPJ. You can join them by visiting <http://tinyurl.com/IPJ-donate>

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

In mid-February, I traveled to Melbourne, Australia, to attend the *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT). I normally attend around 10 or 12 similar Internet-related events in a year, be they *Network Operator Group* (NOG) conferences, *Regional Internet Registry* (RIR) events, or meetings of *The Internet Engineering Task Force* (IETF). This year, most of these events have either been cancelled or have “gone virtual” as the world tackles the COVID-19 pandemic.

The pandemic has clearly demonstrated the resilience and flexibility of the Internet and the people and organizations that rely on it for work, education, and entertainment. The various lock-downs or shelter-in-place orders have also given many of us an opportunity to take a closer look at some of the underlying technologies of the Internet, as we participate in online events or perhaps read more books and articles. This journal continues to receive many interesting articles on all aspects of networking, and in addition to the normal issues in print (and PDF format), we are also planning to expand our online presence in the near future.

Buffering is a central concept in packet-switched networks. Applications such as streaming audio or video rely on buffers to compensate for the fact that packets do not arrive at a fixed rate or even in a fixed order. Memory buffers are also used within the switches of the network to account for variations in network bandwidth and throughput. In our first article, Geoff Huston discusses network buffers and explains the numerous mechanisms that are used or have been proposed to tackle network congestion.

Previous articles in this journal have discussed various aspects of unsolicited e-mail, commonly referred to as “spam.” This time, John Levine explains recent developments in anti-spam efforts, specifically *Domain-based Message Authentication, Reporting & Conformance* (DMARC) and *Authenticated Received Chain* (ARC).

As always, we welcome your feedback and suggestions on anything you read in this journal. Letters to the Editor may be edited for clarity and length and can be sent to ipj@protocoljournal.org. Please make sure your subscription details are accurate.

You can download IPJ

What's the Right Network Buffer Size?

by Geoff Huston, APNIC

Packet-switched networks need to use memory buffers within the switches of the network. In a simple example, if two packets arrive at a switch at the same time and are destined to the same output port, then one packet needs to wait in a local buffer while the other packet is sent on, assuming that the switch does not want to needlessly discard packets. Not only do these buffers address such timing issues that are associated with multiplexing, they are also useful in smoothing packet bursts and performing rate adaptation that is necessary when packet sources are self-clocked. However, there is a question that has never been answered satisfactorily: What's the "right" size for the memory buffer of a switch? If buffers are generally good and improve data throughput by reducing the incidence of packet drop, then more (or larger) buffers are better, right? Not necessarily, because buffers also add additional delay to packet transit through the network if the packet gets parked into one of more buffers in transit. If you want to provide a low-jitter packet-transit service, then deep buffers in the network are decidedly unfriendly! The result is the rather enigmatic observation that network buffers have to be as big as they need to be, but no bigger.

Buffers in a packet-switched communication network serve at least two purposes. They impose some order on the highly erratic instantaneous packet rates that are inherent when many diverse packet flows are multiplexed into a single common transmission system, and they compensate for the propagation delay inherent in any congestion feedback control signal and the consequent coarseness of response to congestion events by end systems.

The Internet adds an additional dimension to this topic. Most Internet traffic is still controlled by the rate adaptation that various forms of *Transmission Control Protocol* (TCP) congestion-control algorithms use. The overall objective of these rate-control mechanisms is to make *efficient use of the network*, such that no network resource is idle when there is latent demand for more resources, and *fair use of the network*, such that if the network has multiple flows, then each flow will be given a proportionate share of the network resources, relative to the competing resource demands from other flows.

The study of buffer sizing is not one that occurs in isolation. The related areas of study encompass various forms of queueing disciplines that these network elements use, the congestion-control protocols that data senders use, and the mix of traffic on the network. The area also encompasses considerations of hardware design; *Application-Specific Integrated Circuit* (ASIC) chip layouts; and the speed, cost, and power requirements of switch hardware.

The topic of buffer sizing was the subject of a workshop at Stanford University in early December 2019. The workshop drew together academics, researchers, vendors, and operators to look at this topic from their perspectives. It hosted 98 attendees from 12 countries, with 26 from academia and 72 from industry. The following are my notes from this highly stimulating workshop^[0].

Background

In an autonomously managed packet network, packet senders learn from reflections of data that packet receivers provide, in a similar fashion to the way a radar system “learns” from a reflected signal. In a reliable flow-controlled TCP session the receiver sends an ACK packet to acknowledge the receipt of one or more data packets. Each ACK describes how many in-sequence bytes the receiver removed from the network. The sender can use this ACK signal to guide the injection of additional data into the network. One aim of each packet sender is a position of *stability*, where every packet passed into the network is matched against a packet leaving the network. In the TCP context, this behaviour is termed *ACK Pacing*.

While the sender can use ACK pacing to determine a stable sending rate, it cannot readily determine a *fair* and *efficient* sending rate. The unknown factor in this model is that the sender is not aware of the right amount of network resources to claim for the data transaction that would sustain a *fair* and *efficient* outcome. The TCP approach to solve this problem is to use a process of *dynamic discovery* where the sender probes the network by gently increasing sending rates until it receives an indication that the sending rate is too high. It then backs off its sending rate to a point that it believes is lower than the sustainable maximum rate and resumes the probe activity^[1].

This classic model of TCP flow management is termed *Additive Increase, Multiplicative Decrease* (AIMD). The sending rate is increased by a constant amount over each time interval (usually the time to send a packet to the receiver and the receiver to send an acknowledgement packet back to the sender, or a *Round Trip Time* (RTT) interval). In response to a packet-loss event, indicated by *Duplicate ACKs* that suggest the next in-sequence packet has been lost and the receiver considers successive packets to be out of order, the sender decreases the sending rate by a multiplicative ratio. The classic model of TCP uses an additive factor of 1 TCP *Message Segment Size* (MSS)^[9] of data per RTT and a rate halving (divide by 2) in response to a packet loss. The result is a “sawtooth” TCP behaviour^[2] (Figure 1). This control is determined by the sender maintaining a *Congestion Window* value, which is the maximum amount of unacknowledged data that the sender can have. Increasing the sending rate is achieved by increasing this value, and a decrease is achieved by reducing this value. When the value is reduced, then the sender must wait for the amount of unacknowledged data to drop below the new value before sending new data into the network.

Figure 1: TCP AIMD Congestion-Control Behaviour

We can mathematically model this behaviour of rate halving in response to packet loss and linear increase otherwise. If the packet-loss function is assumed to be a random loss function with a probability p , then the data-flow rate is proportional to the inverse square root of the packet-loss probability, as given in following equation (0)^[2]:

$$BW = \frac{MSS}{RTT} \cdot \frac{C}{\sqrt{p}} \quad \text{where } C = \sqrt{\frac{3}{2}} \quad (0)$$

This result implies that the achievable capacity of an AIMD TCP flow is inversely proportional to the square root of the packet-loss probability.

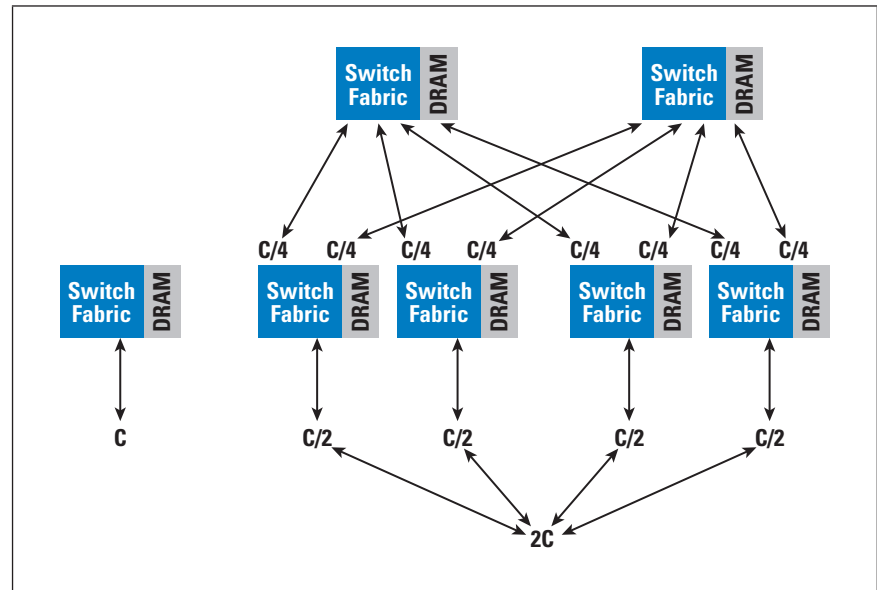

But packet loss is not a random event. If we assume that packet loss is the result of buffer overflow, then we also need to consider buffers and buffer depth in more detail. An informal standard for the Internet is that the buffer size should be equal to the delay-bandwidth product of the link (the derivation of this “rule of thumb” result is explained in the next section).

$$Size = MSS \cdot RTT \quad (1)$$

As network link speeds increase, the associated buffers similarly need to increase in size, based on this engineering rule of thumb. The rapid progression of transmission systems from megabits per second to gigabits per second and the prospect of moving to terabit systems in the near future pose, particular scaling issues for silicon-based switching and buffer systems. As networks increase in scale, the switching scaling factors tend to show multiplicative properties.

For example, if we have a single switch of capacity C and we want to double the effective switching capacity but cannot increase the capacity of the switching chip, then how many switching chips will we need to produce a composite switch of capacity $2C$? The answer is not 2 but 6, as shown in Figure 2. A packet will also need to traverse up to three switch fabrics, so the aggregate buffer size of the path through the switch fabric may triple in size.

Figure 2: Doubling Switch Capacity

Self-clocking packet sources imply that congestion events within the network are inevitable, and any control mechanism that is imposed on these sources requires some form of *feedback* that allows the source to craft an efficient response to congestion events. However, this feedback is constrained by propagation delays and this lag creates some coarseness in the response mechanisms. If the response is too extreme, the sources will over-react to congestion and the network will head into instability with oscillations between periods of intense use and high packet loss and periods of idle operation. If the response is too small, the congestion events will extend over time, leading to protracted periods of operation with full buffers, high lag, and high packet loss.

Robust control algorithms need to be stable for general topologies with multiple constrained resources, and ways of achieving this stability are still the subject of investigation and experimentation. If feedback based on rate mismatch is available, then feedback based on queue size is not all that useful for stabilising long-lived flows. Feedback based on queue size is, however, important for clearing transient overloads.

Over more than three decades of experience with congestion-management systems, we have seen many theories, papers, and experiments.

Clearly, there is no general agreement on a preferred path to take with congestion-control systems. However, a consistent factor here is the network buffer size, and the sizing of these buffers in relation to network capacity. One view, possibly extreme, says that buffers are at the root of all performance issues.

The task of dimensioning buffers in a switching system has implications right down to the design of the ASIC that implements the switch fabric. On-chip memory can be fast, but it is limited in capacity to some 100 MB or less. Larger memory buffers need to be provisioned off-chip, requiring I/O logic to interface to the memory bank, and the speed of the off-chip system is typically slower than on-chip memory. Hybrid systems have to compromise between devoting chip capacity to switching, memory, and external memory interfaces. And layered on top of these design trade-offs is the continuing need to switch at higher speed across larger numbers of ports.

One objective of the Buffer Size Workshop was to continue the conversation about buffers, determine their relationship to congestion control, and improve our understanding about the interdependence among buffer size, queuing control, self-clocking algorithms, network dimensioning, and traffic profiles.

How Big Should a Buffer Be in the Internet?

The single AIMD flow model predicts poor outcomes for flows operating across buffers that are too deep or too shallow. Too deep and the flow's loss response of halving the congestion window does not clear the buffer, and a standing queue forms that contributes to an increased latency imposed in the flow (Figure 3).

Figure 3: Deep Buffers and Rate Halving
Halving Congestion Response

If the buffer is too shallow, then rate halving drops the sending rate below the bottleneck capacity, and the link will be under-used until the additive increase brings the rate up to the link capacity (Figure 4).

Figure 4: Shallow Buffers and Rate Halving Congestion Response

The delay-bandwidth product rule of thumb generates some extremely large queue-capacity requirements in medium-delay, high-capacity systems. A 10-Gbs system using a 100-ms RTT link requires a 125-MB memory pool per port that can read and write at 10 Gbps. A 1-Tbps system would require a 12.5-GB memory pool per port that can read and write at 1 Tbps. A 16-port switch would require 200 GB of high-speed buffer memory using this same design guideline.

Such numbers are challenging for switch designers, and it is reasonable to review the original work to understand the derivation of this provisioning rule.

This model of provisioning the queue to the bandwidth-delay product is derived from a AIMD control algorithm of a single flow using an additive value of 1 segment per RTT and halving the congestion window on packet loss, coupled with the objective of using the buffer to keep the link busy during the period of window deflation.

However, something a little deeper in the oscillation of the AIMD flow-control process affects the selection of the buffer size. In the purely hypothetical situation of a single flow operating across a single switch with a lossless transmission medium, the only source of packet loss is buffer exhaustion. If the switch has no buffer at all, then the AIMD algorithm will operate in a steady state between half capacity and full capacity, leaving approximately one-fourth of the capacity unused by the flow.

The objective is to use a buffer as a reservoir to fill the transmission link while the sender pauses, waiting for the receiver's count of unacknowledged data to fall below the new congestion-window value. If the buffer size is set to the link bandwidth times the link RTT, then the buffer will be drained at the point when the sender's unacknowledged data reaches the congestion-window value and the sender can resume sending.

While this result is from a theoretical analysis of a single flow through a single link, experiments by Villamizar and Song in 1994^[3] pointed to a more general use of this dimensioning guideline in the case of multiple flows across multiple links. The rationale for this experimental observation was a supposition that synchronisation occurs across the dominant TCP flows, and the aggregate behaviour of the elemental flows was similar to a single large flow. This work was the foundation of today's common assumption that buffers in the network should be provisioned at a size equal to the round-trip delay multiplied by the capacity in order to ensure efficient loading of the link; see equation (1).

This supposition has been subsequently questioned. The scenario of a link loaded with a diversity of flows in RTT, duration, and burst profiles implies that synchronisation across such flows is highly unlikely, obviously having implications for buffer-size calculation. If there are two concurrent TCP flows, they have the same RTT, and they resonate in the increase and decrease events, then the buffer requirement will be the same for an efficient use of the network and a fair sharing of the available bandwidth. But if the increase and decrease of the two sessions are exactly out of phase, then a fair and efficient outcome would be created by a buffer size that is three-quarters of the original single flow. The real world typically sees a number of concurrent flows where both the RTT and the phase of the TCP duty cycle all vary. A Stanford TCP research group study in 2004^[4] used the central-limit theorem to point to a radically smaller model of buffer size. You can maintain link efficiency for N desynchronised flows with a buffer that is dimensioned to the size of:

$$Size = \frac{BW \cdot RTT}{\sqrt{N}} \quad (2)$$

This result is radical for high-speed extended latency links in a busy network. The consequences on router design are enormous: “For example, a 1 Tb/s ISP router carrying one TCP flow with an RTT_{min} of 100ms would require 12.5 GB of buffer and off-chip buffering. If it carries 100,000 flows, then the buffer can be safely reduced to less than 40MB, reducing the buffering and worst-case latency by 99.7%. With small buffers, the buffer would comfortably fit on a single chip switch ASIC.”^[5]

Queue Management

The default operation of a queue within a switch is to accept new packets while there is still space in the queue and discard all subsequently arriving packets until the output process has cleared space in the queue. If an incoming packet burst arrives at a switch and the queue capacity is insufficient to hold the burst, then the tail of the burst will be discarded. This tail-drop behaviour can compromise the performance of the flow, because the clocking information for the tail end of the burst has been lost.

One mitigation of this behaviour is *Active Queue Management* (AQM), where the process of queue formation triggers “early” drop. In other words, a packet drop will occur even when there is space in the queue to accept the packet. The ideal outcome of AQM is that packet drop in a large burst will occur inside the burst and the trailing packets following the dropped packet (which are not dropped as there is still space in the queue) will carry a coherent clocking signal in the ACK packet train that allows the flow to repair the loss quickly without losing the implicit clocking signal. Loss-based congestion-control algorithms will react to this packet drop by dropping their congestion-control window size, reducing their sending rate without collapsing the sending rate back to zero.

Drop-based TCP control algorithms react predictably to packet loss. However, the Internet is not entirely homogenous with respect to flow-control algorithms, and we are seeing increasing interest in flow systems that account for variance of the RTT measurements in a flow, or so-called *delay-based* TCP control systems. Delay-based paced control algorithms react differently to queue drop, and a “pure” delay-based flow-control system is indifferent to a loss signal. The question is: Are there AQM functions that can support a mix of congestion-control algorithms? Indeed, is the question of what form of AQM to use a more important question than the size of the underlying buffer?

Explicit Network Feedback

For many years there has been considerable debate between an end-system approach that uses *only* the received ACK stream to infer the network congestion state in the data forwarding direction from a packet loss signal (Figure 5), and an approach that uses some form of *explicit* signalling from the network that can directly inform the source of the network state. Very early efforts in such direct signalling through *Internet Control Message Protocol* (ICMP) *Source Quench* messages were quickly discounted because of the various issues related to its potential for *Denial-of-Service* (DoS) attacks and its inability to authenticate the messages.

The *Explicit Congestion Notification* (ECN) proposal^[6] tried to address the most obvious failing of the earlier approach by placing the congestion signal inside the end-to-end IP packet exchange. Switching elements that were experiencing the onset of local congestion load in their buffers were expected to set a *Congestion Experienced* bit in the IP packet header of packets that were contributing to this load condition. Receivers were expected to translate this bit into the ACK packet header, so that the sender received an explicit congestion signal rather than having to infer congestion from an ACK signal that reflects packet loss (Figure 6).

Figure 5: Loss-Based Congestion-Control Behaviour

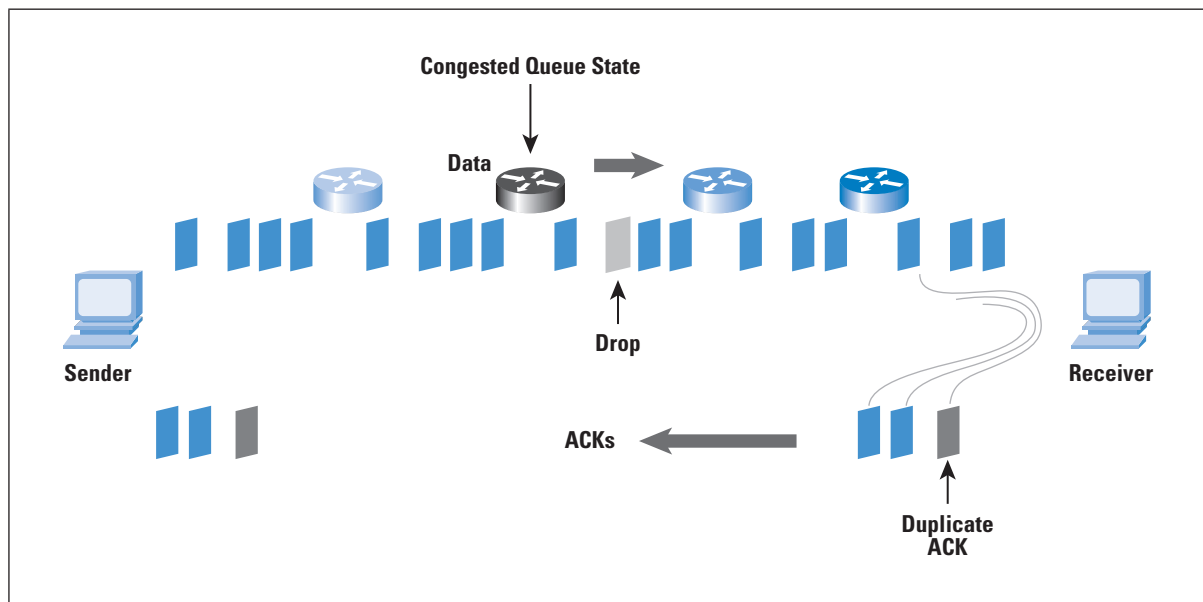

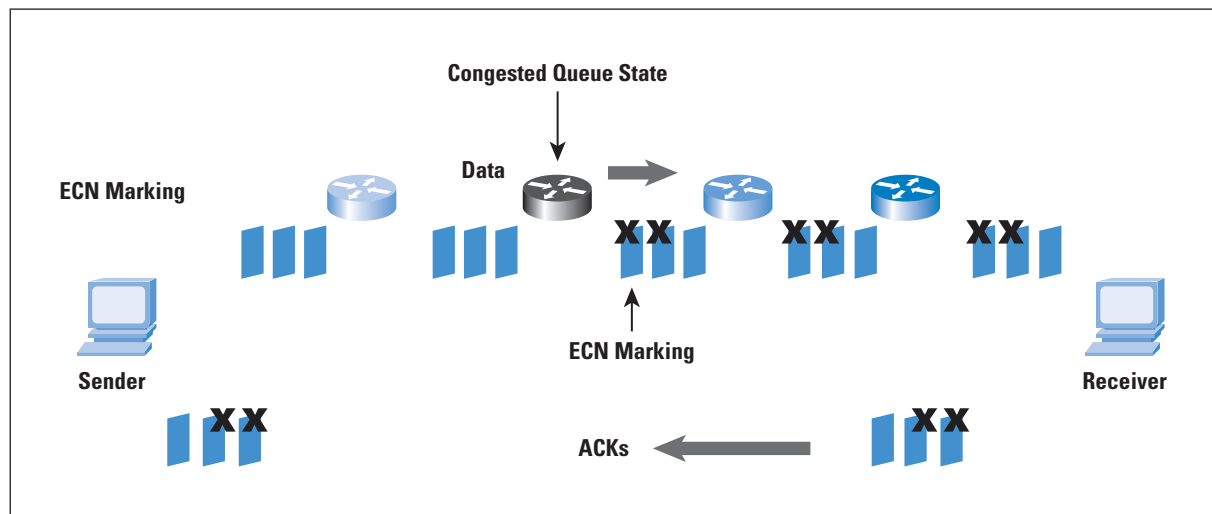

Figure 6: ECN Marking

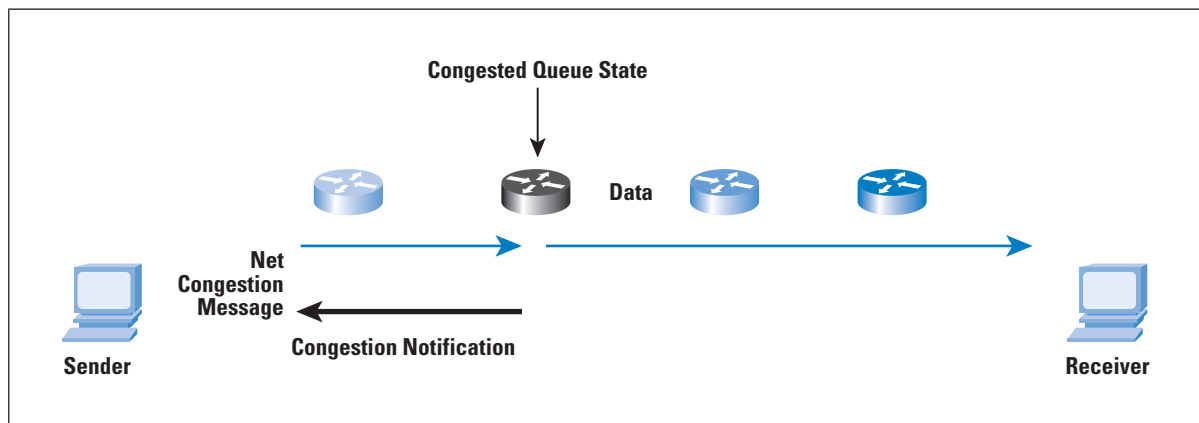

The advantage of ECN is that the sender is not placed in the position of being informed of a congestion condition well after the condition has occurred. Explicit notification allows the sender to be informed of a condition as it is forming, so that it can take action while there is still a coherent ACK pacing signal coming back from the receiver (that is, before packet loss occurs). This measure mimics the intention of delay-based flow systems, but with increased precision assuming that all switches were to perform this congestion marking.

However, ECN is only a single bit marking. Is that enough? Would a richer marking framework facilitate a more precise sender response? What if we had a marking regime that marks based on the distance from the current rate to a desired fair-efficient rate? Or use a larger vector to record the congestion state in multiple queues on the path?

The conclusion from one presentation is that the single-bit marking, while coarse and non-specific, is probably sufficient to moderate self-clocking TCP flows such that they do not place pressure on network buffers, leaving the buffers to deal with short-term bursts from unconstrained sources.

Another presentation at the workshop explored a network-level direct-feedback message, analogous to the ICMP *Packet Too Big* messages in *Path MTU Discovery* (PMTUD). To short-circuit the delays associated with completing the entire round trip, this approach envisages the switch experiencing the onset of congestion to explicitly message the source of this congestion condition (Figure 7).

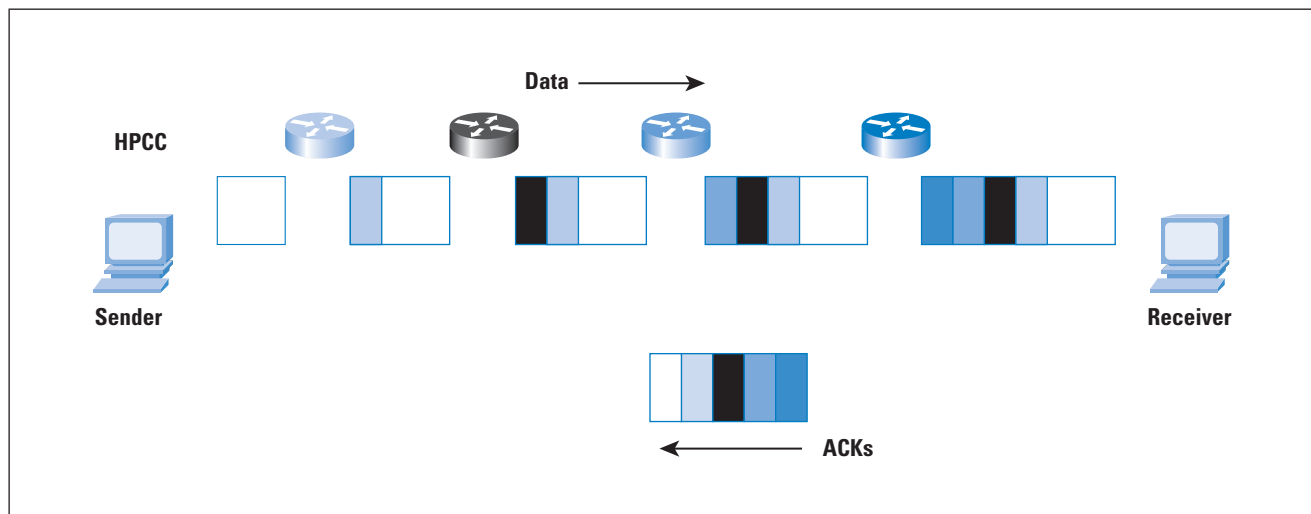

Figure 7: Network-Congestion Signalling

Another presentation looked at the attachment of a detailed telemetry log to each packet in a data-centre application. In the *High-Precision Congestion Control* (HPCC) framework each switch attaches the time, queue length, byte count, and link bandwidth to the data packet. The receiver takes this data and attaches it to the corresponding ACK, so that the sender can form a detailed model of the recent state of path capability. HPCC allows the sender to calculate a fair sending rate and then rapidly converge to this rate, while at the same time bounding the formatting of queues and bounding queuing delays. The domain of application of this approach appears to be the data centre, and the objective is to achieve high speed with bounded delay for *Remote Direct Memory Access* (RDMA)-style applications (Figure 8).

There is a degree of debate between *congestion-based* TCP control and delay-based mechanisms. On the one hand, we hear that delay-based mechanisms can operate the flows at the onset of queue formation in the network. On the other hand, we hear that attempting to set the flow to a fixed delay and operating with fairness to other flows is intrinsically impossible and that we need to operate flows with congestion moderation.

Figure 8: High-Precision Congestion Control

Near and Far Buffers

What is the cost/power trade-off of buffers on-chip and off-chip? And if we are considering off-chip, what do we actually mean, because there are different implementation approaches to off-chip memory. As a general observation, the performance of off-chip memory is not remotely close to what is required by a high-capacity, high-speed switch. This performance is not improving over time because memory speed is not scaling at the same rate as transmission or switch speeds, so the gap in performance between transmission and switching and memory speed is only getting larger over time.

One switch chip fabricator, Broadcom, implements both deep and shallow buffers. On its switch fabric chip Broadcom uses small, fast buffers and wraps the switch fabric with everything it can to reduce the dependency on deep buffers.

Recent operational data at Intel suggests that shallow buffers may be “good enough,” but because of limitations in instrumenting technologies there is insufficient confidence in these results to allow switch chip designs to completely discount external memory interfaces and a local cache and use on-chip memory exclusively. Current switch designs use between 10% and 50% of chip area on memory management. This observation applies to high-capacity, high-speed switches, because at lower capacity and lower speeds there is no such constraint and you can use large pools of off-chip memory (relative to transmission speeds), although some constraint in the amount of memory will likely produce a better outcome in these contexts as well.

The question of future requirements is always present in chip design, given the long times between phrasing requirements and deployment into networks. Where is this situation heading? Memory buffers are not growing as fast as chip bandwidth. Clock speeds are not increasing, and scaling chip bandwidth is currently achieving parallelism rather than increasing the chip clock speed.

While doubling switch capacity may be feasible, contemplating an increase in capacity by factors of 20, 50, or even 100 seem like particularly tough challenges.

Today packet rates are typically achieved with multiple parallel pipelines, and orchestrating such highly parallel mechanisms creates its own complexity in design. No one is yet prepared to call an end to the prodigious outcomes of *Moore's Law* in the semiconductor realm, but it looks like clock speeds are not keeping up, and pin density and even increasing gate density are becoming challenging. Is doubling the number of ports on a switch chip good enough? If a chip has twice the switch bandwidth, does it need twice the on-chip memory capacity? Or less? The answer lies in external factors such as congestion-control algorithms, queue-management disciplines, and delay management.

Hop-by-Hop Flow Control

Hop-by-Hop Flow Control represents a revival of a very early attribute of packet-switched networks, where an end-to-end path is composed of a sequence of flow-controlled hops. Each switching element sends at its line rate into the buffer of the next switch. When a queue forms at the receiver, the hop flow control can pause the flow coming from the adjacent switch and resume it when the queue is cleared. Yes, this process sounds very reminiscent of X.25 and the *Digital Data Communications Message Protocol* (DDCMP) component of DECnet, and it's the opposite of the intent of the end-to-end approach. However, the approach can produce direct back pressure on a bursting source with no packet drop and yield highly efficient use without extensive buffer-induced delays. Essentially the self-clocking nature of the flow is replaced with a network clocking function (Figure 9). Admittedly, this approach is not universally applicable, and it appears to offer a potential match to the intra-data-centre environment where traffic patterns are highly bursty, propagation times are low, paths are short, and volumes and speeds are intense.

Figure 9: Hop-by-Hop Flow Control

Flow-Aware Buffer Management

It appears that the move towards shorter buffers relative to the link speed is inevitable. But how to manage the feedback systems to allow self-clocking data sources to adjust to the shortened buffer space is still an outstanding issue.

One approach starts with a basic traffic characterisation of a relatively small proportion of “elephant flows” (high volume, long duration) mixed with a far higher count of “mice” flows (low volume, short duration). While elephant flows are highly susceptible to congestion signalling, mice flows are not.

If the network could classify all currently active flows into either elephants or mice, then the network could use different queuing regimes for each traffic class. This sorting adds to the cost and complexity of packet switches, and if scaling pressures are a factor in switch design, then it’s not clear that the additional cost of switch complexity would be offset by a far superior efficiency outcome in the switching function.

Assuming that such a flow classification could be achieved dynamically, we can consider differential responses. For short flows, there is little benefit to be gained by any form of explicit congestion control other than placing all such flows into their own queuing regime. For long-lived large flows, we could contemplate an explicit network-congestion signal. It could take the form of an explicit packet back to the network-generated source. The advantage of this approach is that the feedback of excessive sending rate is faster than a full RTT interval, allowing the sender to give a timely response. However, this idea does seem like a reprise of the ill-fated ICMP Source Quench message, and all that was problematical with ICMP Source Quench is probably still an issue in this form of network-congestion notification.

We can exploit this concept of the use of various queue regimes for different flow types in a different way by using a short buffer for long flows in the expectation that the implicit congestion signal of packet drop would allow the long-duration flow to stabilise into the available network resource, while short unregulated bursts could have access to a deeper buffer, allowing effective use of the buffer as a rate-adaptation tool to mitigate the burst.

This concept is taken even further in one project, which used the observation that if a buffer is too deep, then the flow-rate reduction following packet drop will leave a standing queue in the buffer, and if the buffer is too shallow, then the rate reduction will leave a period of an empty queue and an idle transmission system. This observation means that a flow-aware buffer manager could adjust its buffer size following observation of the post-reduction behaviour, reducing the buffer if standing queues form and increasing it if the queue is idle. It’s an interesting approach to fair-queuing flow management, treating the per-flow buffer as an elastic resource that can resize itself to adapt to the congestion-management discipline of the flow.

ISP Network Buffer Profile

P4 is a language used to program the data plane of network devices. The language can express how a switch should process packets (“P4” itself comes from the original paper that introduced the language, *Programming Protocol-independent Packet Processors*^[7].)

Barefoot's *Tofino* is an example of a new class of programmable Ethernet packet switches that are controlled through P4 constructs, and these units can currently handle aggregate capacity of some 12.8 Tbps of data-plane capacity. This capability allows for a measurement regime that can expose packet characteristics at a nanosecond level of granularity. By tapping the packet flow of a high-speed trunk transmission system into and out of a switching element in the network and attaching the taps to a P4 switch unit, it is possible to match the times of ingress and egress of individual packets and generate a per-packet record of queuing delay within the switching element at a nanosecond level of granularity.

This capability provides a new level of insight into burst behaviour in high-speed carriage systems *Internet Service Providers* (ISPs) use. The major observation from an exercise conducted on a large ISP network was that network buffers are lightly used except for “microbursts,” bursts of some 100 microseconds or so, where the queue adds a delay element of more than 10 ms on a 10 GigE port. Further analysis reveals an estimate of packet drop rates if the network buffers were reduced in size, and for this case the analysis revealed that an 18-msec buffer would be able to sustain a packet drop rate of less than 0.005%.

If buffer-congestion behaviours in such ISP networks are, in fact, microbursts, then network measurement tools that operate at the per-minute or even at the per-second level of granularity are simply too crude. P4-based measurements that can resolve behaviours at the nanosecond level offer new insights into buffer behaviours in networks that carry a large volume of diverse flows. Even though the per-flow control cycle of the data-plane flows is of the scale of some milliseconds and longer, the microburst behaviour is that of a load model that exhibits sub-millisecond burstiness. The timescale of end-to-end congestion control operates at a far coarser level than the observed behaviour of congestion within a switch running a conventional traffic load.

This discussion leads to the observation that large-scale systems are creating extremely rapid queue size fluctuations, and it is unrealistic to expect that end-to-end control algorithms can control the queue size. It might be that at best these control algorithms can contribute to influencing the distribution of queue sizes.

Sender Pacing

The Internet can be seen as a process of statistical multiplexing of a collection of self-clocked packet flows where the flows exhibit a high degree of variance and a low level of stability. The reaction to this unconstrained input condition so far is to use large buffers that can absorb the variations in traffic. How large is “large enough” becomes the critical question in such an environment. The work on buffer sizing as being in proportion to the bandwidth-delay product of the transmission elements is an outcome of a process that measures the properties of the control algorithm for traffic flows.

It then derives estimates of buffer sizes that should be capable of carrying such a volume of traffic that it will efficiently and fairly load the transmission system.

The exercise assumes that the buffer dimension is a free parameter in network design, and control algorithms are fixed. Buffer speed inside the network has to double at a cycle of some 2 years, and the buffer size has to double in a similar timeframe. The product of size and speed is a quadrupling every 2 years. The current tactical response to this escalation of buffer requirements due to transmission capacity increases has been to reduce the size of the buffers relative to the transmission capacity. However, this response is not a long-term sustainable solution because such under-provisioned network buffers will impair overall network efficiency in these self-clocking flow regimes.

The future prospects for self-clocked traffic flows are not looking all that bright given that the growth demands for network buffer-based mitigation of unconstrained sender behaviours appears to be in excess of what can be satisfied within constraints of constant unit cost of network infrastructure. Without overall economies of scale where larger service-delivery systems achieve lower unit costs of service delivery, the management of traffic and content assumes a different trajectory that tends to drive towards greater distribution and dispersal rather than continued aggregation and amalgamation. For the large hyper-scaled content enterprises in today's Internet, this outcome is certainly not optimal.

It is a potentially fruitful thought process to consider this topic from an inverted perspective and look at the desirable control-algorithm behaviour that efficiently uses the network transmission resources when the available buffering is highly restricted. This thought process leads to the consideration of "pacing," where the server uses high-precision timers to smooth data flows as they leave the server, attempting to create a stable traffic flow that matches bottleneck capacity on the path. The more accurate this estimation of bottleneck bandwidth, the lower the demand for buffer capacity due to burst adaptation. Residual buffer demand is presumably based on the demands of statistical multiplexing of disjoint flows. Given that the senders are under the control of the service-delivery platforms and there are orders of magnitude fewer high-volume senders than receivers, this form of change is actually far less than the change required by, say, the IPv6 transition.

It is this thinking that lies behind the *Bottleneck Bandwidth and Round-trip Propagation Time* (BBR) protocol work. The sender's flow-control algorithm generates an estimate of the bottleneck bandwidth and the minimum RTT interval, and then paces packet delivery so as to feed traffic into the bottleneck at exactly the bottleneck capacity, which should not involve the formation of a queue at the bottleneck.

The BBR control algorithm periodically probes up to revise its previous bandwidth estimate, and probes down to revise its previous minimum RTT, and accounts for other congestion-formation signals, such as ECN. This probing up and down, or dithering, is not precisely specified in the core BBR algorithm, and these parameters are being revised in the light of deployment experience to determine dithering settings that are both efficient and fair. The expectation is that BBR will not drive the formation of standing queues in the network and will pace the flow at the maximal rate that the network path can fairly sustain.

However, BBR is not the only way to perform flow pacing, and a large number of outstanding questions remain. How does pacing at the sender affect the queue management at the edge close to the client? What are the cross impacts of burst traffic with pacing? How should a pacing-control algorithm react to packet loss? Or to out-of-order packet delivery? Can strict flow pinning still be required for *Equal Cost Multiple Path* (ECMP) routing or does pacing relax such requirements for strict path pinning? Are pacing or self-clocking the only options, or are there other approaches?

One perspective is that we are sitting between two constraint sets. Escalating volume and speed in the core parts of the network implies that bandwidth-delay product model buffer sizing is an unsustainable approach. The scaling back of buffer sizes in the network means that self-clocked protocols will potentially become more unstable and compromise achievable network efficiency and fairness. From this perspective sender pacing looks to be a promising direction to pursue.

Is There a Buffer Sizing Problem?

In the Internet we are currently seeing a diversity of responses to network provisioning. Some network operators use equipment with generous buffers. These buffers are overly generous according to the buffer-bloat argument. Other network operators field equipment with scant buffers that run the risk of starving data sources while leaving idle network capacity.

There is a mix of congestion-control algorithms (CUBIC, NewReno, BBR, *Low Extra Delay Background Transport* [LEDBAT], etc.) and a mix of queue-management regimes (*Controlled Delay* [CoDel], *Random Early Detection* [RED], *Weighted Random Early Detection* [WRED])^[8]. A diversity of deployment environments exists, including mobile networks, Wi-Fi, wired access systems, LANs, and data centres. And there is a mix of parameters of the desired objective here, whether it is some form of fairness, loss, jitter, start-up speed, steady-state throughput, stability, efficiency, or any combination of these factors. It is little wonder that it's challenging to formulate a clear picture of common objectives and to determine what actions are needed to achieve whatever we might want!

There is the assumption that large network buffers absorb imprecision in clocking (timing “slop”) and allow simpler coarse rate-control algorithms to operate effectively without needing high-precision tuning. Small network buffers provide little leeway and tolerance for such approximate approaches. This mistrust of the level of precision of control that end systems exercise is a pervasive view within the networking community, and it could even be characterized as an entrenched view. So entrenched is this view that probably no experimental result could convince the community as a whole that network buffers can be far smaller than they are today, all other factors being equal. This fact is true despite the overwhelming evidence that overly large buffers compromise network performance, a position that has been described as “buffer bloat.” There are other reasons why large buffers are a problem for networks and users. As we scale up the size and speed of the network, large very-high-speed buffers are also increasing in cost. If we are going to admit compromises and trade-offs in network design, is reducing the relative size of the buffer an acceptable trade-off?

And if we want to reduce buffer size and maintain efficient and fair performance, how can we achieve it? One view is that sender pacing can remove much of the pressure on buffers, and self-clocking flows can stabilise without emitting transient bursts that buffers will need to absorb. Another view, one that does not necessarily contradict the first, is that the self-clocking algorithm can operate with higher precision if there were some form of feedback from the network on the state of the network path. This feedback can be as simple as a single bit (ECN) or a complete trace of path element queue state (HPCC).

This topic remains a rich area of unanswered questions. What does it imply when the timescale of buffer-congestion events are orders of magnitude smaller than the timescale of self-clocking flows? Are flows overly reliant on loss signals and too insensitive to delay variation? Can paced delay-based algorithms like BBR coexist with loss-based oscillating algorithms such as CUBIC and NewReno? Would the general adoption of sender pacing change the picture of buffer sizing in the Internet?

How big should buffers be in the network? Or perhaps the opposite is the more practical question: How small can we provision buffers in an increasingly faster and larger network and still achieve efficient and fair outcomes in a variety of deployment environments?

All of these questions are good and legitimate for further research, experimentation, and measurement.

Mail Security with DMARC and ARC

by John Levine

Electronic mail is both one of the most useful services of the Internet and the most frustrating. The best thing about mail is that anyone can send a message to anyone else without prearrangement, while the worst thing about mail is that anyone can send a message to anyone else without prearrangement. As mail became ever more ubiquitous in the 1990s and 2000s, an increasing fraction of it was mail the recipients didn't want. In 2005, Dave Crocker^[1] and John Klensin^[2] wrote articles in this journal about the spam problem. Since then, several of the anti-spam techniques described in Crocker's article have become ubiquitous as the spam problem has become worse.

One can distinguish between *spam*, unsolicited mail sent in bulk, and *phishing*, mail sent to trick the recipient into revealing account credentials or other private information. (Some phishes are sent in bulk, some are sent to specific victims, known as *Spear Phishing*.) Starting in 2007, PayPal, which had long been among the biggest phishing targets, started working with some large consumer mail systems to keep PayPal phishes out of recipient mailboxes. The idea was that the recipient systems could identify genuine e-mail from PayPal, and reject anything else purporting to be from PayPal. In 2012 an industry group started the DMARC project to generalize this technique. In 2015 the *Domain-based Message Authentication, Reporting & Conformance* (DMARC) specification was published as an independent track RFC^[3], and now it is ubiquitous in large mail systems.

DMARC works by tying the address in the RFC 5322^[4] **From:** header of a message to mail authentication, and letting a domain offer policy advice to mail recipients. If a message is successfully validated by *Sender Policy Framework* (SPF) or *DomainKeys Identified Mail* (DKIM), and the domain in that validation matches the one in the **From:** header, the message is DMARC "aligned." Sending mail systems can publish DMARC policy records in the *Domain Name System* (DNS) requesting recipient systems to quarantine (send to the spam folder) or reject unaligned mail. This system works quite well for the original intended application of DMARC, business-to-consumer mail, where the sending organization generally has full control over all mail sent from its domain. It works particularly well for PayPal, where all the mail is some variation of "log into your account to see what's new," so if a few messages are accidentally lost because DMARC miscategorizes a legitimate message it's not a big problem.

Underlying and Previous Work

DMARC depends on two existing mail authentication schemes, *Sender Policy Framework* (SPF)^[5] and DKIM^[6]. SPF does path validation of the domain in the RFC 5321^[7] **MAIL FROM:** address. A domain can publish an SPF record that uses a complex syntax to specify a set of IP addresses.

If the message was sent from one of those addresses, SPF validation passes. (This description is oversimplified; see [5] for the full details.) SPF has the virtue of being easy to implement because it requires no changes to outgoing messages and a single DNS record to implement, but it can describe only a limited subset of the ways that mail is delivered. For the most part it can handle only mail sent directly from sender to recipient, without any forwarding or remailing, and does not deal well with mail sent by third parties on the sender's behalf. While SPF provides a **-all** code that advises recipients to reject mail from the domain if SPF validation fails, most mail systems disregard the advice because the false positive rate is so high.

DKIM does message content validation by adding cryptographic signature headers to a message that the recipient can check using a key in the DNS. Each signature is stored in a **DKIM-Signature** header field that contains several subfields, including the name of the domain that added the signature. If a DKIM signature validates, it means both that the message hasn't been modified since it was signed and that the domain in the signature takes responsibility for the message. Since DKIM validates the contents of the message rather than the path, it is unaffected by forwarding.

DKIM is considerably harder to implement than SPF because it requires modifications to mail software to add the signature headers to each outgoing message. It also requires the signing system to create public/private key pairs, publish the public key in the DNS, and configure the private key into the signing software. DKIM validation fails when a message is modified in transit, such as when a mailing list adds a subject tag or a message footer, and sometimes simply because a *Message Transfer Agent* (MTA) hasn't been configured to add the signature in the first place. (In large enterprises it can be remarkably hard to track down all of the computers sending mail. DMARC helps address this problem, as we will see later.)

DKIM had an optional add-on called *Author Domain Signing Practices* (ADSP)^[8], which was sort of a proto-DMARC. A domain could publish an ADSP record in the DNS saying that if a message with the domain in the **From:** header didn't have a valid DKIM signature from the same domain, recipients should discard the message. ADSP was never deployed beyond experiments, and the *Internet Engineering Task Force* (IETF) has since made it an historic specification.

DMARC Deployment

One of the reasons that previous sender policy approaches like SPF **-all** and ADSP failed is that there is no way to test them other than turning them on to see what happens. For a small domain with one or two mail servers that might be possible, but for a large organization the risk is impossibly high since they rarely have complete knowledge of all of the systems sending their mail and how those systems are configured.

DMARC offers a variety of features to check the alignment of the mail of a domain before publishing any policy advice. It has powerful reporting features that let a domain owner ask other systems to send reports about the mail purporting to be from the domain. Domains invariably ask for reports before publishing any policies, so they can see what mail they send is and isn't aligned. This information lets them fix alignment issues before they do publish policies.

DMARC Validation

When a message arrives, DMARC validation involves first finding a DMARC policy record for the **From:** header domain, then validating SPF and the DKIM signature(s) on the message, and then perhaps doing something to the message. The first step is to find the policy record for the **From:** domain of the message, a DNS TXT record. If that domain is **marketing.mybiz.example**, the first place to look is **_dmarc.marketing.mybiz.example**. If there is a TXT record in DMARC syntax, for example, it starts with **v=DMARC1**; that's the policy record. If not, it looks for a policy record in the "organizational domain."

The DMARC specification is deliberately vague about how to find the organizational domain, but in practice everyone uses the Mozilla *Public Suffix List* (PSL)^[9] where the organizational domain is the superdomain just below the public suffix. In this case if the domain were a typical *Top-Level Domain* (TLD) that accepts registrations at the second level, the organization domain would be **mybiz.example**, so it would look for a TXT record at **_dmarc.mybiz.example**. If there is a TXT record in DMARC syntax, that's the policy record; otherwise there is no policy record for this domain.

The DMARC record is a list of key=value pairs, with rules for checking alignment, what to do with unaligned mail, and where to send aggregate and failure reports. A typical record might be:

```
v=DMARC1; p=none; rua=mailto:dmarc-a@example.net;  
ri=3600; ruf=mailto:dmarc-f@example.net
```

There is no policy (**none**), abuse and failure reports are mailed to the given addresses (**rua** and **ruf**), and the requested report interval is an hour (**ri** is 3,600 seconds.) The point of the second check for the organizational domain is twofold. First, the second check makes it easier to deploy DMARC across a large enterprise, since one DMARC organizational record can cover all of an organization's subdomains. The other is that it covers non-existent subdomains of the organizational domain, for when hostile or buggy mailers send mail purporting to be from such a subdomain.

The next step in validation is to check whether the **From:** header domain is aligned with the SPF identity of the message. The SPF validation process can produce a result of *None*, *Neutral*, *Pass*, *Fail*, *Softfail*, *Temperror*, or *Permerror*. For DMARC alignment, only a *Pass* result is acceptable.

The DMARC policy record can require strict SPF alignment, meaning the **From:** domain and SPF identity have to be the same, or relaxed SPF alignment, meaning they need only be in the same organizational domain. In the previous example, if the **From:** domain were **marketing.mybiz.example**, an SPF identity of **mail.mybiz.example** or just **mybiz.example** would be sufficient for relaxed SPF alignment. Relaxed alignment is the default.

Next, the validator checks for DKIM alignment. For each valid DKIM signature on the message, the validator compares the **From:** domain to the **d=** domain of the signature. The policy record can specify strict or relaxed DKIM alignment, again requiring either an identical signature domain or just one in the same organizational domain. If at least one valid DKIM signature is aligned, the message is DKIM aligned. If the message is either SPF or DKIM aligned, it is DMARC aligned.

If the message is aligned, we're done other than perhaps saving some statistics for later reporting. If it's not aligned, the situation is potentially much more complex if the recipient system opts to follow the policy advice, as most mail systems (at least by mail volume) now do.

The policy record can specify policy advice of **none**, **quarantine**, or **reject**. It can also specify an optional percentage of how often to apply the policy. Advice of **none** means to do whatever the recipient would have done with the message anyway. Advice of **quarantine** means to treat the message extra skeptically, perhaps by filing it in a spam folder or marking it as suspicious. Advice of **reject** asks the recipient to **reject** the message at the end of the *Simple Mail Transfer Protocol* (SMTP) session and not handle it further. If the percentage is less than 100, the advice is to treat that percentage of unaligned mail from the domain according to the advice, and the rest one step less. For example, if the advice were **reject** and the percent was 25, one-fourth of unaligned mail would be rejected and the other three-quarters would be quarantined. (The percent has no effect if the policy is **none**.)

As noted previously, the point of the percentage is to allow domain owners to enable policies gradually, see what happens, and limit the damage from misconfigurations.

DMARC Reporting

DMARC has two powerful reporting features. A domain can ask for daily aggregate reports of what IP addresses have sent mail with the domain in the **From:** header, with details about DMARC alignment and DKIM and SPF validation. Many large mail systems including Google, Yahoo/AOL, Comcast, and Fastmail send aggregate reports.

It is also possible to request copies of messages that fail DMARC validation, but for privacy reasons very few systems do. The only significant mail system in the U.S. that sends failure reports is LinkedIn.

Even for a site that has no plans to publish a DMARC policy, the reports are useful and interesting. They can provide insight into where your mail is actually going, and who else might be sending mail purporting to be from you.

To request each kind of report, the domain policy record includes a tag with a list of *mailto: Uniform Resource Identifiers* (URIs), each with an optional size limit of the maximum message report size the system can handle. The default aggregate report interval is once a day.

Aggregate reports constitute an *Extensible Markup Language* (XML) file attached to an e-mail message in gzip or ZIP compressed form. The XML file includes a section (a “record”) for each sending IP address, with subsections (a “row”) for each combination of authentication results. For example, here’s a section of a report Google sent to my *Smail* system describing mail it received from two IP addresses:

```
<record>
  <row>
    <source_ip>2001:470:1f07:1126:0:43:6f73:7461</source_ip>
    <count>1</count>
    <policy_evaluated>
      <disposition>none</disposition>
      <dkim>pass</dkim>
      <spf>pass</spf>
    </policy_evaluated>
  </row>
  <identifiers>
    <header_from>taugh.com</header_from>
  </identifiers>
  <auth_results>
    <dkim>
      <domain>iecc.com</domain>
      <result>pass</result>
      <selector>k1912</selector>
    </dkim>
    <dkim>
      <domain>taugh.com</domain>
      <result>pass</result>
      <selector>k1912</selector>
    </dkim>
    <spf>
      <domain>taugh.com</domain>
      <result>pass</result>
    </spf>
  </auth_results>
</record>
```

```

<record>
  <row>
    <source_ip>209.85.220.55</source_ip>
    <count>4</count>
    <policy_evaluated>
      <disposition>none</disposition>
      <dkim>fail</dkim>
      <spf>fail</spf>
    </policy_evaluated>
  </row>
  <identifiers>
    <header_from>taugh.com</header_from>
  </identifiers>
  <auth_results>
    <dkim>
      <domain>googlegroups.com</domain>
      <result>pass</result>
      <selector>20161025</selector>
    </dkim>
    <spf>
      <domain>googlegroups.com</domain>
      <result>pass</result>
    </spf>
  </auth_results>
</record>

```

The first record for the IPv6 address reports on a message sent from my mail server. It has a valid SPF and two valid DKIM signatures, one with the **From:** header domain and one for the server domain, so it was DMARC aligned. The second record describes four messages with valid SPF and DKIM signatures, but with SPF and DKIM domains that don't match the **From:** header, so they wouldn't have been DMARC aligned. Since the second group of messages have **googlegroups.com** authentication identifiers, they're probably the same message, modified and remailed to a Google Groups mailing list. [Since I know I sent only one message to the list that day, this message leaks the number of *Gmail* subscribers to the list. I've seen similar leakage for much larger lists; for example, like the one operated by the *North American Network Operators' Group* (NANOG).]

Larger mail systems receive reports with larger numbers of messages and more report sections. The reports are intended to be mechanically handled. Some open source software is available to analyze reports and put summaries in a database^[10]. More often the reports are sent directly to specialist services like *Dmarcian*^[11] or *Agari*^[12] that offer freemium report analysis services, simple analysis for free, or more sophisticated analysis and remediation advice for a fee.

The other kind of report is a failure report. When a message arrives that has the domain address in the **From:** header and fails DMARC validation, the recipient system may (but usually doesn't) send the message back in a failure report. The report is a multipart/report e-mail message containing a structured report section and a full or partial copy of the failing message.

A typical report section follows:

```
Feedback-Type: auth-failure
User-Agent: Lua/1.0
Version: 1.0
Original-Mail-From: nanog-bounces@nanog.org
Original-Rcpt-To: xxx@linkedin.com
Arrival-Date: Thu, 26 Dec 2019 19:22:54 +0000
Message-ID: <20191226191849.6BBF111BA67D@ary.qy>
Authentication-Results: dmarc=fail (p=none; dis=none)header.from=iecc.com
Source-IP: 50.31.151.76
Delivery-Result: delivered
Auth-Failure: dmarc
Reported-Domain: iecc.com
```

The message in a failure report might be a legitimate one that was unaligned when sent, or modified on the way to become unaligned. Or it might be a fraudulent one, either an attempted phish, or just a random spam message where the spamware happened to pick your domain for the fake return address. For this particular report, it's obviously a real message relayed through the NANOG mailing list.

The original failure report included the full address of the recipient, meaning that by looking at the failure reports, anyone who posts to NANOG can see who subscribes to LinkedIn. This kind of data leakage explains why most sites don't send failure reports at all, and most of the ones that do limit what they send, typically including only the headers of a failing message and redacting recipient address details.

Using DMARC Reporting to Prepare for Policy Publication

Before publishing a DMARC policy of **quarantine** or **reject**, domain operators should be confident that as close as possible to 100% of the mail they send is DMARC aligned. They might send unaligned mail if SPF records of a domain do not cover all of the IP addresses that send valid mail, causing SPF validation to fail. Some outgoing *Mail Transfer/Transfer Agents* (MTAs) might have DKIM configured incorrectly or not at all, so there's no aligned DKIM signature. Large organizations often can have MTAs sending mail that the network managers didn't know about; for example, if a department set up its own local server, or contracted with a third-party mail sender.

The data from DMARC reports tells the operator what IP addresses are sending unaligned mail, and generally makes it straightforward to figure out why it's unaligned. Mitigation might involve updating the domain SPF records to include missing MTAs, fixing the DKIM signing configuration in MTAs, or enforcing rules about unapproved mail servers or third-party mail senders. (Many third parties can do DKIM signing with a client's domain, but that requires either sharing the private signing keys(s) or delegating a DNS subtree that the third party can manage.)

After the operator has the mail sufficiently under control, it can gradually turn on sending policies. DMARC provides the quarantine policy as an intermediate step between no policy and reject so there is a chance for recipients to retrieve miscategorized mail. It can also use the percentage parameter in the policy record to apply policies gradually and limit the damage if mistakes occur.

DMARC vs. Discussion Lists

DMARC was originally intended for domains at organizations like banks that send primarily business-to-business and business-to-customer mail, and little or no person-to-person mail. When the organization considers when to publish a DMARC policy, and what policy to publish, it should remember that some fraction of its legitimate mail will arrive unaligned because of intermediate processing that DMARC cannot describe. Since the organization presumably knows what mail it sends, it can weigh the benefits of less phishing versus the cost of lost mail and make a decision that is reasonable for the organization.

In 2014, AOL and Yahoo, two large consumer mail systems, had separate security breaches in which intruders stole copies of millions of their users' address books. The stolen data was quickly sold to spammers, who used it to send spam to AOL and Yahoo users that appeared to be from the recipients' friends. This situation caused an expensive support problem at AOL and Yahoo as users complained about the spam and asked why their friends were spamming them. First AOL, and then Yahoo, "solved" the problem by quickly publishing DMARC **p=reject** policies that told every mail system that implements DMARC to reject any AOL or Yahoo mail that didn't come directly from AOL or Yahoo. This decision was very different from the ones made by organizations described previously. In this case the benefit of the policy was to mitigate the cost of an operational failure, with little if any benefit for most of their users, while creating major problems for their discussion list users.

A small but important part of the mail from users of any consumer mail system is unaligned yet legitimate mail that recipients want. That happens typically because the mail is routed indirectly from the sending user to the ultimate recipients. A particular point of contention is e-mail discussion lists where the normal actions of list managers make most of the mail unaligned. This situation can cause non-receipt of mail sent to subscribers on mail systems that enforce DMARC policies on incoming mail, and it can also cause removal of subscribers from lists because of bounces caused by DMARC failures. (Yahoo was aware of the mailing list issues but decided to publish **p=reject** anyway, according to someone who was there at the time.) Another source of unaligned mail is third-party mailing services. A small organization like an athletic club or scout troop often has an announcement list where the return address on the announcements is the personal address of the organization's secretary, who may use AOL or Yahoo.

A variety of proposed workarounds have been made for the problems that DMARC causes to mailing lists, none of which are very satisfactory. Initially, the easiest approach was to tell people sending mail from addresses with DMARC policies to subscribe from another address. That approach stopped being practical when AOL and Yahoo flipped the switch.

Since then, mailing list software has taken a range of approaches to ensure that the messages the list sends out are aligned. In a few cases, lists tried to turn off any features that would modify messages in ways that would invalidate DKIM signatures, hoping that DKIM signatures on incoming messages would remain valid when resent from the list. This idea didn't work very well, partly because remailed messages weren't SPF aligned (the list uses its own envelope address for bounce management), and users want the changes that lists make, such as adding subject line tags to identify the list.

Mailing lists have settled on two general anti-DMARC approaches^[13]. The most common is to put the list address into the **From:** header so the list can add a DKIM signature with its own domain and make the message DMARC aligned. For example, if the incoming message included:

```
From: Steve C <steve@aol.com>
To: nodule@lists.example.com
```

The list might rewrite it as:

```
From: Steve C via the nodule list <nodule@lists.example.com>
To: somelist@lists.example.com
Reply-To: Steve <steve@aol.com>
```

The rewritten **From:** header usually includes the author's address comment and the list name. The author's actual address is placed in a **Reply-To:** header, or occasionally a **Cc:** header. This approach allows DMARC alignment, since the list can add a lists.example.com DKIM signature, but makes mail from the list harder to handle. Mail user agents treat **Reply-To:** in different ways, leading to confusion about whether someone is replying to the author of a message, or to the list, or both. Adding to the confusion, some lists only rewrite the headers for messages in author domains that publish a DMARC policy, so messages from the same list have different headers.

Another approach is to rewrite the **From:** header to replace the problematic author address with one that is DMARC aligned but still represents the author. For example, my mailing lists would rewrite the headers in the previous example like this, changing the author address only by adding a local domain suffix:

```
From: Steve C <steve@aol.com.dmarc.fail>
To: nodule@lists.example.com
```

The domain **dmarc.fail** is a real domain I registered. (It was available.) I publish an MX record for ***.dmarc.fail**, to catch any mail sent to rewritten addresses. The rewritten message as sent by the mailing lists has a **dmarc.fail** DKIM signature, so it's properly DMARC aligned. When the list software rewrites an address, it creates a forwarding entry for the rewritten address that redirects back to the original address. The forwarding entries are deleted after a few days so that replies to the author sent shortly after the original message go back to the author, but the forwarding is limited, so it's not a useful vector to relay third-party spam.

This technique works fairly well. Since only the **From:** header is changed, there's no effect on **Reply-To:** or other mail behavior, and the author's identity is easy to recognize. Other systems have implemented the same idea in perhaps less passive-aggressive ways. The IETF's working mailing lists rewrite the address into the local part; for example:

From: Steve C <steve=40aol.com@lists.ietf.org>

The commercial LISTSERV mailing list service rewrites the address into an opaque local address and puts the real address in **Reply-To:**

From: Steve C <00000006b01fa96f-dmarc-request@lists.example.com>
Reply-To: Steve C <steve@aol.com>, Nodule list <nodule@lists.example.com>

The primary disadvantage of the address rewriting is that it requires access to the local mail system of the list to manage the set of temporary forwarding addresses, rather than doing it entirely inside the list software.

The other anti-DMARC approach that some lists take is message wrapping, enclosing the message as a *Multi-Purpose Internet Mail Extensions* (MIME) part within an outer message from the list. Most mailing lists have a MIME digest option, to send the day's messages as a set of MIME parts within a single daily message, so this process in effect turns each message into a one-message digest. The outer message typically has the list address in the **From:** header, while the inner message is unmodified.

Technically, this approach should work well, because it uses existing well-standardized features of RFC 5322 mail. Having done some experiments to see how workable it is, I found that in practice it works very badly because mail user agents treat MIME attached messages as an afterthought. While the inner message is typically displayed legibly, it is often not possible to reply to the inner message without clumsy extra steps, or in some cases at all, and multipart messages or those with attachments are handled inconsistently. The IETF experimented with several varieties of MIME wrapping before deciding that rewriting the **From:** header was the best of a bad lot.

While all of these approaches allow mailing lists to send DMARC-aligned mail, none of them are very satisfactory, and none let mailing lists work as well as they did before DMARC.

ARC

While the amount of mail that large providers get from mailing lists is small, on the order of 1% to 2% of the non-spam total, it is mail that the recipients care about deeply. After years of complaints, several large mail providers developed *Authenticated Received Chain* (ARC) to help them handle wanted but unaligned user mail.

An obvious way to handle unaligned mail from mailing lists would be to whitelist them. Large mail systems have a pretty good idea of where the lists are (the number of mailing list hosts worldwide is probably only about 10,000), so they could just accept the mail from the lists that they know their users want. The problem with this concept is that mailing lists don't do a very good job of spam filtering, and spam leaks through them all the time.

In particular, most lists check only that the address in the **From:** header is subscribed to the list before forwarding a message. If a subscriber's account is compromised and starts sending spam, any message sent to a list will generally get forwarded to the list. Even without an account being compromised, if a stolen address book happens to contain your address and the address of a list to which you subscribe, spamware can forge mail from you to the list, and again the list will forward it. I've seen this happen multiple times, and it is quite frustrating since the person whose address is being forged can't do anything about it.

The goal of ARC is to add a "chain of custody" to a message that shows what happened to it each time it was forwarded. This technique lets the ultimate recipient system retroactively make spam filtering decisions based on what happened to the message at the forwarding systems.

ARC builds on existing mail technology. It adapts the *Authentication-Results* (A-R) header^[14] that many mail systems apply to incoming messages that records the authentication status of the message at the time an MTA received the message. Here is a typical A-R header that my MTA applied to an incoming message from Apple's **me.com**:

```
Authentication-Results: iecc.com; spf=pass spf.mailfrom=xxx@me.com
spf.helo=mr85p00im-hyfv06011401.me.com smtp.remote-ip="17.58.23.191";
dkim=pass header.d=me.com header.s=1alhai header.a=rsa-sha256;
dmarc=pass header.from=me.com (p=quarantine, pct=100)
```

The first field is the name of the system that added the header, followed by groups of authentication results, in this case for SPF, DKIM, and DMARC. Each group includes the result and relevant items like the envelope **MAIL FROM** and sending IP for SPF. All of the fields are optional other than the system name, and they are added only for the kinds of authentication the system checked. ARC combines a modified A-R header and two DKIM-like signature headers into an *ARC seal*, which is intended to describe the passage of a message through a system such as a mailing list manager. A single message may have multiple ARC seals if it has passed through multiple forwarding systems.

Each seal is numbered, starting with 1 for the first seal applied. Each header in an ARC seal has an `i=` clause to indicate which seal it's part of.

The headers in an ARC seal look like this:

```
ARC-Message-Signature: i=1; a=rsa-sha256; d=microsoft.com; s=abcd; h=From:Date:...
ARC-Authentication-Results: i=1; mx.microsoft.com 1; spf=pass ...; dkim=pass ...
ARC-Seal: i=1; a=rsa-sha256; s=abcd; d=microsoft.com; cv=none; b=j7M/jt9eVP...
```

The *ARC-Message-Signature* (AMS) is almost identical to a DKIM signature, with the added `i=` field. It is intended to cover the usual headers and body of the message, at the time the message was sent from the signing system. If the system makes changes to the message, the AMS is applied after those changes. When a message is received, the most recent AMS signature will be valid unless an intermediate system has modified the message since the ARC seal was applied and not added a seal of its own.

The *ARC-Authentication-Results* (AAR) header reports the authentication status at the time the sealing system received the message; that is, before any modifications reflected in the AMS.

The *ARC-Seal* header is a DKIM-like signature that covers only the three headers in the ARC seal, to validate the seal itself. It also indicates whether the chain of ARC seals in the message was intact when the message was sealed, using the `cv=` (chain value) field. If this seal is the first one, the chain value is “none” for no previous seal. For any subsequent seal, the chain value is “pass” if the previous seal was valid (the DKIM-like signatures validated) and the previous seal had `cv=none` or `cv=pass`. Otherwise the chain value is “fail.”

If a mail system receives a message from a trustworthy source with a valid ARC chain, it can use the information in the ARC seals to make exceptions to its DMARC policy. As a simple example, assume a message that is not DMARC aligned arrives, but it has a valid chain of ARC seals. In one of the seals, an AAR header shows that the message was DMARC aligned (`dmARC=pass`) and the **header.from** domain was the same as the one currently in the message. That means the lack of alignment is due to changes made by the forwarding system. If the forwarding system is considered trustworthy, for example, a host that hosts discussion lists, the receiving system can decide to deliver the message. More complicated analysis is possible, but I expect this sort of analysis looking for typical mailing list operations is likely to be the most common. Since malicious systems can add fake ARC seals, this analysis makes sense only for mail from trust-worthy sources. Identifying sources trustworthy enough to apply ARC exceptions may be a problem for mail systems too small to develop reliable data on hosts that send mail to them. There are some efforts to provide shared lists of reputable mailing list hosts that will likely be good enough, since the number of active list hosts is not large and changes slowly.

At this point the implementation of ARC has started, but it is not yet common enough to let mailing lists stop doing anti-DMARC header munging. *Python* and *Perl* libraries for DKIM have both added ARC support^[15]. The Sympa 6.2 mailing list manager has ARC support, as does GNU Mailman 3.1, but not Mailman 2.x.

Large mail systems including Google's *Gmail* and Microsoft's **outlook.com** have some ARC support, and both *Gmail* and **outlook.com** put ARC seals on forwarded and mailing list mail, but neither is yet using it for mail filtering other than experimentally. Few mailing lists yet add ARC seals, partly because of the lack of ARC support in the list software they currently use, and partly because the list managers are unaware of ARC.

Conclusions

DMARC started as a relatively simple technique to deter phishing of high-profile commercial domains such as those of banks and payment providers. Consumer mail systems AOL and Yahoo then repurposed it to deal with spam forging their users' addresses. While this repurposing largely solved the spam forgery problem of mail systems, it caused severe collateral damage to e-mail discussion lists. While many lists have tried to work around the DMARC problems, all of the workarounds have drawbacks that make them ultimately unsatisfactory. To help undo the DMARC damage, a group of large mail providers invented ARC, which makes it somewhat possible to examine the history of a message and see how a message that is not DMARC aligned got that way.

The ongoing evolution of DMARC, mailing lists, and ARC is yet another round of security measures with unexpected consequences. With any luck, ARC will be the end of this sequence of effect, side-effect, and counter-effect, but we won't know until ARC is more widely deployed, hopefully in a few years.

Letter to the Editor

Ole,

I enjoyed reading Geoff Huston's article "MSS Values of TCP," (*The Internet Protocol Journal*, Volume 22, No. 3, December 2019). I had not been familiar with the variation of *Maximum Segment Size* (MSS) values that are used in the broad Internet.

I have never run into a client or server device that has been unable to operate with greater than a 576-byte *Maximum Transmission Unit* (MTU). Even the early Intel 8088-based MS DOS PCs in the 1980s with 3Com 3c501 *Network Interface Cards* (NICs) could handle 1500-byte MTU. In modern times only a tiny fraction of our tens of thousands of connected hosts are capable of Ethernet Jumbo packets (SAN nodes replicating data between data centers; our routers along just those paths are configured for 9,216-byte MTU).

Geoff touched only briefly on encapsulation influencing resulting TCP MSS values. Our *Wide-Area Network* (WAN) connections between our office locations use *Internet Protocol Security* (IPsec) tunnels, and we also use IPsec tunnels between our office locations and our virtual routers inside the Amazon *Virtual Private Cloud* (VPC). In addition to those, we have some *Generic Routing Encapsulation* (GRE) tunnel connections with some information providers and partners (Zscaler is an example). With the recent availability of low-cost high-speed Layer 2 connections between some sites, we have been implementing *Media Access Control security* [MACsec] (lower router resource consumption than IPsec). We also are beginning to use *Virtual Extensible LAN* (VXLAN) between our two data centers. With all of these encapsulations in our network, we've been avoiding IP fragmentation of TCP packets by configuring TCP `adjust-mss` on our Cisco routers. We also use `adjust-mss` on our Wireless LAN Controllers.

We still face plenty of *User Datagram Protocol* (UDP) packets from video devices that would need to be fragmented if attached with default configuration. When our IT group controls such devices, we configure their MTU to fit within our IPsec tunnels.

Regards, —Richard Berke, Richard.Berke@troweprice.com

The author responds: Richard,

Thanks for your comments about MSS sizes and the related topic of MTU selection.

We need to go back to the 1970s to find some variation from the current ubiquity of the 1,500-octet MTU that dominates today's communications, and very little of that early network environment has survived. However, we can piece together some of the thinking behind the original design of the Internet Protocol and the selection of MTU and MSS values.

Smaller packet sizes made packets less susceptible to bit-error-rate corruption and could reduce jitter (which was a major consideration behind the design of *Asynchronous Transfer Mode* (ATM) cells), but at the same time smaller packets had a reduced payload efficiency. Various mainframe vendors tuned their network products to match their intended deployment environment, including the choice of supported packet sizes.

As a “network of networks,” the Internet was envisaged to work across various permutations of networks, all with differing MTU sizes. The fragmentation model of IP Version 4 came from this approach, where an IP router was permitted to fragment a packet if it was too large for the next network.

IP Version 4 permitted IP packets between 20 and 65,535 octets in size. While in a strict sense the minimum MTU is 20 octets, that is without any payload at all. A 21-octet MTU would make some level of progress in sending a payload, albeit extremely inefficiently.

Where does 576 octets come from? IP hosts were not required to accept the entire protocol-permitted range of packet sizes. The specification required IP hosts to reassemble and accept IP packets up to 576 octets in size. Why 576? It is such an odd number. I could understand a value of 532, 542, 572, or even 592 octets, all based on a 512-octet payload and various permutations of minimum or maximum IP headers and optionally including a TCP header. However, I can’t get to 576 octets that way, so I don’t have any credible explanation as to why this value was chosen.

By the time we were designing IPv6 in the early 1990s the thinking had changed, and fragmentation was frowned upon. It was slow and insecure, and the experts advised its avoidance wherever possible. What should the minimum unfragmented MTU be for IPv6? Ethernet framing was ubiquitous by this time, so a 1,500-octet MTU size seemed like a good first answer. But the Internet had a new aspect by then: it was no longer a “network of networks” but was the base substrate network upon which other networks were overlaid. Various other headers, including IP-in-IP, were being added. So, we needed to specify a universal minimum unfragmented IPv6 packet size that would be relevant in many kinds of IP-in-IP contexts. The value of 1,280 octets as the new minimum unfragmentable packet size was chosen for IPv6. Why 1,280? I understand that this number was chosen because it’s the sum of 1,024 and 256.

My view is that the marginal loss of payload efficiency is small enough that for the public Internet a 1,220-octet MTU can be used with some confidence that it will not encounter MTU mismatch issues.

Regards,

—Geoff Huston, gih@apnic.net

Keeping the DNS Secure During the Coronavirus Pandemic

The Internet's value in bringing people together has never been more apparent than it is now. While most of us are under some form of "stay at home" order in an effort to slow the spread of the coronavirus, the Internet provides us with a lifeline. It brings us information and entertainment, allows some of us to continue our work and education, and brings us what we need most at times of isolation—social connections.

The role of the *Internet Corporation for Assigned Names and Numbers* (ICANN) community, Board, and organization in maintaining a secure, stable, and unified Internet has always been important, but at this time, when reliance on the Internet has skyrocketed, our collective role has become all the more vital. ICANN's mission frames our concern about cybercriminals who are exploiting the pandemic by perpetrating scams and victimizing Internet users. Some are selling phony cures, treatments, and vaccines. Some are using domain names as part of their efforts to prey on people at this time when many are experiencing anxiety, fear, and loneliness. The U.S. *Federal Trade Commission* reports that it has fielded more than 7,800 coronavirus-related complaints. The agency noted that U.S. consumers alone have collectively lost more than U.S. \$5 million.

Of course, ICANN cannot involve itself in content issues, both because of our Bylaws as well as practically, but that does not mean we are unaware or unconcerned about those who are using the *Domain Name System* (DNS) to victimize others. It is this concern that prompted me to contact the registries and registrars thanking them for their efforts and actions aimed at helping to mitigate and minimize the abusive domain names being used to maliciously take advantage of the coronavirus pandemic. For example, the *Registrar Stakeholder Group*^[1] has posted a useful guide, entitled "Registrar approaches to the COVID-19 Crisis" that provides a number of steps and resources the registrar community can use in their efforts.

Many of our contracted parties already support a *Framework to Address Abuse*,^[2] which deals with DNS abuse and website content abuse. I continue to commend them for making this commitment to protect the DNS from those who would maliciously exploit domain names. In my correspondence to the registries and registrars, I expressed ICANN org's appreciation for their work during the pandemic.

Additionally, I'm pleased to tell you that ICANN org has joined registries, registrars, security experts, law enforcement, Internet engineers, and others, in the COVID-19 *Cyber Threat Coalition* (CTC)^[3]. The CTC's mission is to, "operate the largest professional-quality threat lab in the history of cybersecurity out of donated cloud infrastructure and with rapidly assembled teams of diverse, cross-geography, cross-industry threat researchers."

I am proud that so many in the Internet ecosystem are joining together during this crisis to stop those who prey on the desperate. We will continue to keep you advised of our engagement efforts to mitigate the misuse of domain names during these critical times.

—Göran Marby, *President and Chief Executive Officer, ICANN*

Global Encryption Coalition Formed

Encryption is a critical technology that helps keep people, their information, and communications private and secure. However, some governments and organisations are pushing to weaken encryption, which would create a dangerous precedent that compromises the security of billions of people around the world. Actions in one country that undermine encryption threaten us all.

As a global coalition, we call on governments and the private sector to reject efforts to undermine encryption and pursue policies that enhance, strengthen and promote use of strong encryption to protect people everywhere. We also support and encourage the efforts of companies to protect their customers by deploying strong encryption on their services and on their platforms.

The mission of the *Global Encryption Coalition* is to promote and defend encryption in key countries and multilateral gatherings where it is under threat. It also supports efforts by companies to offer encrypted services to their users.

With a steering committee led by the *Center for Democracy and Technology* (CDT), *Global Partners Digital* (GPD) and the *Internet Society* (ISOC), the Global Encryption Coalition is composed of national coalitions, civil society groups, corporations, academics, and technologists around the world who agree to support its founding statement.

APNIC Launches Networking from Home Events

With most Asia Pacific economies forced into various states of lockdown to minimize COVID-19 infections, *Network Operator Group* (NOG) meetings and other technical events in the region have either been cancelled or postponed. NOGs are a great forum for network engineers to share experience with their peers, work out solutions to common technical problems, and build the strong relationships that help the Internet operate. There are 22 NOGs in the APNIC region, but sadly that means a lot of events have been cancelled in 2020.

Networking from Home is a new virtual event initiative to provide a place for technical folk in the region to share their experience and expertise with their peers, just like they would at a NOG event.

There will be four free online events—one each held in the time zones of South East Asia, South Asia, East Asia, and Oceania—and they will be a digestible 2.5 hours long. Presentations will be short and punchy and interaction is encouraged! APNIC’s Geoff Huston will deliver a different keynote at each event, and he will be supported by a range of great speakers suggested by the NOG communities.

If you have a great presentation in mind, get in touch with the Program Committees for the events. For more information, visit: <https://nfh.apnic.net/>

Check your Subscription Details!

If you have a print subscription to this journal, you will find an expiration date printed on the back cover. For the last couple of years, we have “auto-renewed” your subscription, but now we ask you to log in to our subscription system and perform this simple task yourself. The subscription portal is here: <https://www.ipjsubscription.org/> This process will ensure that we have your current contact information, as well as delivery preference (print edition or download). For any questions, contact us by e-mail at: ipj@protocoljournal.org

Our Privacy Policy

The *General Data Protection Regulation* (GDPR) is a regulation for data protection and privacy for all individual citizens of the *European Union* (EU) and the *European Economic Area* (EEA). Its implementation in May 2018 led many organizations worldwide to post or update privacy statements regarding how they handle information collected in the course of business. Such statements tend to be long and include carefully crafted legal language. We realize that we may need to provide similar language on our website and in the printed edition, but until such a statement has been developed here is an explanation of how we use any information you have supplied relating to your subscription:

- The mailing list for *The Internet Protocol Journal* (IPJ) is entirely “opt in.” We never have and never will use mailing lists from other organizations for any purpose.
- You may unsubscribe at any time using our online subscription system or by contacting us via e-mail. We will honor any request to remove your name and contact information from our database.
- We will use your contact information only to communicate with you about your subscription; for example, to inform you that a new issue is available, that your subscription needs to be renewed, or that your printed copy has been returned to us as undeliverable by the postal authorities.
- We will never use your contact information for any other purpose or provide the subscription list to any third party other than for the purpose of distributing IPJ by post or by electronic means.
- If you make a donation in support of the journal, your name will be listed on our website and in print unless you tell us otherwise.

Thank You!

Publication of IPJ is made possible by organizations and individuals around the world dedicated to the design, growth, evolution, and operation of the global Internet and private networks built on the Internet Protocol. The following individuals have provided support to IPJ. You can join them by visiting <http://tinyurl.com/IPJ-donate>

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

In June 2013 we published an article entitled “Optimizing Link-State Protocols for Data Center Networks.” In that article, Alvaro Retana and Russ White wrote: “With the advent of cloud computing, the pendulum has swung from focusing on wide-area or global network design toward a focus on *Data Center* network design. Many of the lessons we have learned in the global design space will be relearned in the data center space before the pendulum returns and wide-area design comes back to the fore.” In this issue, Russ White and Melchior Aelmans examine the use of link-state alternatives to the *Border Gateway Protocol* (BGP) in data center designs. One such alternative, *Routing in Fat Trees* (RIFT), will be explored further in an upcoming article in this journal, so please make sure your subscription details are up-to-date.

The depletion of the IPv4 address space and transition to IPv6 has been covered in numerous articles in IPJ over more than two decades. It was initially believed that “everyone” would implement IPv6 by the time the *Regional Internet Registries* (RIRs) ran out of addresses, but such predictions have proven to be too optimistic for a variety of reasons. The demand for public IPv4 address space has led to an “aftermarket,” whereby blocks of addresses can be purchased (or leased) through the use of address brokers. We asked David Strom to explore this market in more detail, and he approached this assignment by deciding to sell his own Class C address block.

We are excited to bring you another book review, this time on the topic of information security. Please send us your suggestions for networking-related books that we should have reviewed.

Publication of *The Internet Protocol Journal* is made possible by the generous support of numerous individuals and organizations. Please consider making a donation or getting your company to sign up for a sponsorship.

As always, we welcome your feedback and suggestions on anything you read in this journal. Letters to the Editor may be edited for clarity and length and can be sent to ipj@protocoljournal.org

Recent Developments in Link State on Data-Center Fabrics

by Russ White and Melchior Aelmans, Juniper Networks

Since the initial publication of the drafts resulting in RFC 7938^[0], the *Border Gateway Protocol* (BGP)^[10] has been the default choice for *Data-Center* (DC) fabrics, assumed by most controllers, intent-based systems, training courses in DC fabrics, and implementers. Recent activity in the *Internet Engineering Task Force* (IETF) and implementers suggests using link-state protocols in DC fabrics. This article explores why this move towards link-state protocols on DC fabrics is taking place, and then considers three specific avenues to link state on DC fabrics: *Distributed* (or localized) *Optimized Flooding in Intermediate System-to-Intermediate System Protocol* (IS-IS)^[1], centralized calculation of optimal flooding trees^[2, 3], and *Routing in Fat Trees* (RIFT)^[4].

The arguments presented in this article are legitimate reasons not to use BGP for the DC fabric underlay and show that options other than BGP are available. Readers might (incorrectly) conclude the authors believe BGP should never be used as the routing protocol for a DC fabric overlay—but that is not true. To make a case for link-state protocols in DC fabric underlays, an extensive examination of the positive and negative aspects of BGP—and the other available protocols—is essential. Ultimately, it is up to individual operators to decide which protocol is “the best” for their application, a decision based on business and operational—as well as technical—reasons.

Defining Terms

Defining terms is often considered pedantic, and therefore often overlooked. But as the networking world spreads to wholly virtual environments, definitions quickly become blurry and local. In this article, two distinct terms that might be used differently in other contexts are used. The first is the *underlay*. For this article, the underlay is the physical infrastructure, control plane, and telemetry; it provides basic connectivity, including IPv4, IPv6, and *Multiprotocol Label Switching* (MPLS), edge-to-edge in the fabric. The *overlay*, on the other hand, provides virtual topologies which tunnel traffic edge-to-edge through fabric-side interfaces and devices. In other words, the overlay consists of tunnels with head- and tail-ends on *Top of Rack* (ToR, or *leaf*) switches or servers attached to the fabric and the control planes that provide reachability through those tunnels.

In other words, underlay control planes do not carry overlay reachability, overlay control planes do not carry underlay reachability, and underlay devices (other than where they terminate an overlay tunnel) do not switch based on overlay destinations. If this explanation sounds vaguely like the *Exterior Gateway Protocol* (EGP) versus *Interior Gateway Protocol* (IGP) split in a traditional transit provider network, that is because it is—just like the EGP/IGP split in a conventional transit network.

The underlay/overlay distinction might be confusing in some discussions because people who work entirely within cloud services may well consider the set of tunnels built between virtual machines or containers the overlay, and everything under these tunnels the underlay—even if the network has two layers of tunnels. There is no set of standard terms for the situation where a bottom layer provides connectivity based on the physical fabric topology, a collection of virtual networks on top of that used to create logical topologies, and another set of virtual networks within those logical topologies formed by the applications running over the network. Overlay tends to end up being used for both the “middle layer” and the “upper layer,” hence the importance of defining the terms as they are used here.

Two other terms of importance here are *autonomic* and *automatable*. Confusion around these terms arises from the use of *Zero Touch Provisioning* (ZTP), used to mean the configuration of a device that does not need manual configuration to deploy. While both automated and autonomic networks are ZTP, there is still a difference between the two concepts. The closer a protocol comes to not needing any configuration at all, whether that configuration is automated or not, the closer the protocol is to being autonomic. While autonomic and automatable protocols appear similar, there are differences. The automation system must still be managed and maintained, there are still interfaces to integrate and manage, etc. Autonomic control planes may (or may not) be more complex, at least under the surface, than automatable ones; regardless, they are not the same thing.

It is rare for a protocol to be fully automated or fully autonomic; these two are a continuum rather than a binary space. For instance, BGP is not autonomic by design but can be modified to allow BGP speakers to discover one another and form a peering relationship automatically. In other cases, it might be possible to derive information, such as the IS-IS system ID, automatically, but doing so might make troubleshooting and maintenance more difficult—so automatic assignment might be possible, but not always desirable. Individual operators may have different optimal positions along the automatable-to-autonomic continuum.

Given autonomic to automatable is a spectrum of options, why would you choose to move towards autonomic operation? After an automation system is put in place to support the network, it may not seem to make much difference.

In a sense, moving from automatable to autonomic is simply shifting complexity from one place in the network to another. Moving configuration from the automation system to the protocol moves complexity from the automation system to the protocol as well. The one vital difference is each piece of complexity moved from the automation system to the protocol is one less interface to manage, one less piece of state the automation system must build and keep track of, etc.

Complex automation systems can be difficult to create and manage. Even in fully automated networks, research shows a major portion of network failures are caused by configuration failures.^[5] Deducing the amount of state the automation system, and the humans supporting the automation system, is managing can be justified by reducing the number of places mistakes can happen. The more the protocol can figure out on its own, the less you must figure out how to configure.

This article assumes *spine-and-leaf* (or leaf-and-spine!) fabrics. A *Clos*^[14] is a three-stage fabric, while a five-stage fabric wired in the most common way is called a *butterfly*. Butterfly fabrics are illustrated in two ways; “as-wired” with the leaves on both the top and bottom of the diagram and “folded” with the leaves arrayed at the bottom of the diagram.^[6]

The number of stages in a spine-and-leaf fabric denotes the maximum number of switches a packet is forwarded through when crossing from edge to edge. A spine-and-leaf fabric may have multiple spines; a three-stage fabric has one spine, while a five-stage fabric has three spine stages. The inner or top-most tier (depending on how the fabric is drawn) is considered the *Top of Fabric* (ToF) or the fabric layer. In a five-stage fabric, the “middle tier” is called either the *Top of Pod* (ToP) or the *spine*. The level or tier denotes the distance from the edge, with the ToR or leaf nodes being considered T0, the “middle” stage T1, and the fabric or ToF stage T2.

BGP in the Underlay

For the last 10 to 15 years, BGP has been the “underlay protocol of choice” for DC fabrics. While the reasons for using BGP in the underlay have been outlined in several places through the years, including RFC 7938^[0], it is useful to recap and explore some of these reasons as background.

First, BGP is widely implemented; virtually every routing vendor and every open-source routing stack such as *Free Range Routing* (FRRouting) has a fairly complete and well-tested BGP implementation. You can be confident that no matter whose hardware and software you choose, BGP will be supported—and the implementation is likely to be mature, interoperable with other implementations, and running in production in a lot of networks.

Second, BGP was—at least at one time—conceived of as one of the most straightforward routing protocols to understand and implement well. The logic of path-vector is reasonably easy to implement correctly, and the underlying transport mechanism, the *Transmission Control Protocol* (TCP), is built into every operating system already.

Third, BGP is widely deployed, and hence well understood by operators. Operators consider it easier to hire someone who knows BGP than one who knows any other protocol, and it is easy to find tooling for operating BGP in the open-source community.

There is a bit of irony in this point as 10 years ago it was almost impossible to find engineers with solid BGP experience; the advent of BGP on large-scale data-center fabrics has become something of a “self-fulfilling prophecy” in this regard.

Fourth, where scale is of concern, the perception is BGP outshines every other protocol. After all, “BGP runs the global Internet,” and you cannot ask for a better proof point of scalability than that. The initial implementations of BGP on large-scale DC fabrics originally tried various IGP, and found they could not scale to the size required.

Fifth, BGP has extensive prefix-filtering, route-tagging, and traffic-engineering capabilities. No other protocol, other than perhaps *Enhanced Interior Gateway Routing Protocol* (EIGRP) (!), can match the ability of BGP to control route flow.

Sixth, you can use BGP for both the underlay and the overlay in a single network. In theory, this possibility makes the configuration simpler. The normal configuration when using BGP for both is to configure the underlay using *External BGP* (eBGP) peering and the overlay as *Interior BGP* (iBGP) peering.

With all these advantages, why would you decide to move away from using BGP in both the underlay and overlay?

Challenging BGP in the Underlay

There are, however, counterpoints to many of the advantages of using BGP as the underlay protocol listed previously. Beginning with the second one—BGP is one of the simplest routing stacks to implement. With the advent of multiple address families, the *Resource Public Key Infrastructure* (RPKI), *Ethernet VPN* (EVPN), *Virtual Private LAN Service* (VPLS), MPLS traffic engineering, *BGP Link-State* (BGP-LS), and the many other features that have been “piled into” BGP across the last 20 years, BGP implementations have exploded in complexity. BGP may be the most complex protocol to implement among all the routed control planes today.

Using BGP as a singular DC fabric protocol, both overlay and underlay, is one factor causing the increasing complexity of BGP implementations. The ability to peer on unnumbered interfaces, the ability to accept any peer with any *Autonomous System* (AS) number, the ability to accept routes without any filters implemented, and many other changes must be made to make BGP work correctly in a DC fabric. It is easy enough to create a single knob that turns on a group of features at once. It is not so easy to hide the increased complexity—and the higher chance of a defect in the code or a misconfiguration of some kind—resulting from these kinds of changes. BGP is strongly automatable, but it will take massive work to make it autonomic. Is pushing that work into code used at critical points throughout the Internet a good idea?

At some point, the routing community needs to decide if it is wise to make one protocol the “protocol to end all protocols.” Is a single solution the right answer for all problems? Or is it better to move back towards developing multiple parallel protocols to support different purposes? This criticism may not apply to operators building their private implementation of BGP for use on their DC fabrics—but these kinds of implementations are uncommon.

A second related issue is the amount of specialized configuration required to allow BGP to converge quickly on the kinds of dense topologies used for DC fabrics. Figure 1 illustrates the design.

Figure 1: A Small Butterfly Fabric

Note that in this diagram, A and E are ToR switches or leaf nodes, B and D are spines, and C is either the superspine or fabric. Dashed boxes around a set of devices indicate the pods. How BGP converges depends on the kind of topology change. In the case of a single router or link failure, BGP can converge almost as quickly as an IGP, given the failure timers are tuned correctly, BFD and other underlying mechanisms are in use, etc. The case of a withdrawal from the edge of the network, however, is much different.

In the case of a withdrawal, BGP converges by hunting across available paths, starting from the shortest and ending in the longest. This hunt does not happen because of the way BGP is designed, but rather because of the timing of processing and forwarding updates. To prevent loops, a BGP speaker must process an update locally, modifying the routing table before it can forward the update to its peers. Longer paths just take longer than shorter ones for withdrawals to traverse. This withdrawal behavior can be a problem in at least two situations: when a workload is moved from one location on the fabric to another, and when an anycast address representing a service instance is removed from the fabric.

In these cases, the slow convergence time of BGP can impact applications running on the fabric.

Controlling the impact of the hunt is fairly easy. The key is to reduce the length of the paths through which BGP must “search.” The easiest way to do it is to block the reflection of updates and withdrawals through the network. For instance, E1 in Figure 1 should not reflect any withdrawals or updates to any of its peers in row D, and D1 should not reflect any updates or withdrawals to any of its peers in row C. There are many ways to accomplish these stipulations, but a common method is to create filters on the routers at rows A and E, the leaf nodes or ToR switches, so only BGP updates with an empty AS path (^\$) are permitted, and to place all the routers at the spine routers (such as B and D) within a single pod in the same AS.

With these changes, BGP is essentially converted into “Fancy *Routing Information Protocol* (RIP),” and you can reduce the time required to withdraw a route (or move it from one place to another in the fabric) to about 1 minute in large-scale fabrics. It is possible to modify BGP to converge more quickly, but doing that returns the discussion to the first argument discussed previously—is creating a single protocol to solve all problems really the right answer? When is the complexity of the BGP code “complex enough” to start considering other options?

Let’s examine two other considerations before moving on to examining link-state protocols in DC fabric underlays. One of the advantages listed for BGP is that it has many different policy options, such as route filtering and tagging. If the underlay is really designed to provide undifferentiated IP connectivity, these policies do not seem like much of a real advantage. Policy, such as route tagging and filtering, should be moved to the overlay—which is most likely going to be BGP anyway.

A final point is that transit providers separate infrastructure and customer routes to split these two kinds of information into different failure domains. One misunderstanding about failure domains is they must be “absolute” and “complete,” where the two failure domains are completely decoupled at every point, if they are effective. They are not, however, always effective because it is likely impossible to build networks out of completely decoupled failure domains. Instead, it is a matter of tradeoffs. How much gain is there in separating these two kinds of information in this way, versus how difficult is it to separate these two kinds of information, and how much deoptimization is likely to occur?

In a DC fabric, separating the infrastructure routes of the underlay from the “customer” routes in the overlay is a legitimate way to form two different failure domains. These two failure domains might be somewhat tightly coupled, but they are still two different failure domains.

Separating the routes this way also creates multiple administrative domains, leaving open the possibility of allowing “customers,” or workload processes, to control some aspects of the reachability information in the overlay without the risk of causing problems in the basic IP connectivity the underlay provides.^[7]

Link State in the Underlay

Link-state protocols, like BGP, are also widely implemented and understood. Every commercial routing stack and many open-source routing stacks—including an implementation of *Open Shortest Path First* (OSPF) or IS-IS—are mature, well tested, and widely deployed. However, most of these implementations are not optimized for use on DC fabrics. This section considers the positive aspects of using a link-state protocol on a DC fabric, some of the challenges operators face when deploying standard link-state protocols on DC fabrics, and realistic expectations for scale when using these unmodified implementations. The following sections address modified link-state protocols currently being designed and implemented, and the probable scaling characteristics of these implementations.

The first advantage link-state protocols have over BGP in DC fabrics is convergence speed—but the irony is link-state protocols are at their fastest where BGP is at its slowest, and vice versa. Link-state protocols are most challenged at scale during initial convergence because of the density of the topology through which flooding must take place. Considering the network in Figure 1, shown previously; when E1 originates a new *Link State Update* (LSU)—whether a *Label Switched Path* (LSP) fragment in IS-IS or a *Link-State Advertisement* (LSA) in *Open Shortest Path First* (OSPF)^[11,12], it sends the update to every router in row D. Every router in row D, in turn, sends the LSU to every router in row E, which then sends the LSU to every router in row D. The number of copies each fabric device receives depends primarily on timing, but in topologies of around 2,600 fabric devices, each one was observed receiving more than 40 copies of each LSU. Nonetheless, unmodified link-state protocols converge at their worst as fast or faster than BGP up to some scale, where scale includes both the number of devices (nodes in the *Shortest Path Tree*, or SPT) and the number of reachable destinations. To what scale? The number will vary, but 1,000 (or more) fabric devices with a 100,000 reachable destinations are not unreasonable within a single flooding domain (or area in OSPF terms) based on prior large-scale deployments. Optimizations will increase these numbers somewhat—though to what degree depends on many factors.

Where link-state protocols converge much faster than BGP is when a reachable destination either moves from one place on the fabric to another or is disconnected from the fabric entirely. From the perspective of IS-IS, any reachable destination changes are just changes in leaf connectivity, meaning the destination can just be removed from the SPT without running *Shortest Path First* (SPF). This process is called a *partial SPF*; it is extremely fast and requires minimal processing on each of the fabric devices.

The second advantage link-state protocols have over BGP in DC fabrics is topology *visibility*. Link-state protocols require each device to maintain a full view of the topology, which must be synchronized with every other router in the network (or rather flooding domain); this process is called the *Link State Database* (LSDB). To obtain a copy of the LSDB, you need only to connect to one (or two, if you are concerned with resilience) router connected to the fabric. This kind of information is useful for traffic engineering and traffic steering. Further, periodic snapshots of the network topology from the perspective of the control plane can be a useful mine of telemetry information.

The first challenge for link-state protocols in the DC fabric is scaling, mainly related to flooding. We will consider several ways to reduce the number of LSUs each device receives in the following sections, so we don't consider them here. Another problem often cited in this area is the impression that link-state protocols can drop or fail to deliver LSUs—that flooding is periodic, rather than reliable, and the period is long enough to allow significant problems to develop. All link-state protocols, however, use reliable transport to deliver flooded packets. For instance, IS-IS tracks whether each neighbor has received an LSU through acknowledgments and retransmits LSUs until they are acknowledged. IS-IS can also send a description of the entire database periodically to ensure a neighbor's LSDB is correctly synchronized. OSPF has similar mechanisms.

Two other challenges link-state protocols face are scaling the number of reachable destinations and the time required to run the SPF algorithm used to calculate the set of loop-free paths. Faster processors combined with well-designed and well-tested implementations of SPF, along with optimizations such as partial SPF, have largely mitigated these concerns up to much larger scales than many engineers realize. Link-state protocols will never scale to the same levels as BGP, but they will scale enough to support a large proportion of the DC fabrics operators will build.

This article considers three proposed methods to control flooding designed to allow link-state protocols to support dense large-scale topologies. The first is *Distributed Optimized Flooding* (distopt-flood), arguably the least complex of the three options. The second is a centralized flooding controller, and the third is *Routing in Fat Trees* (RIFT), which is essentially a modified link-state protocol designed specifically for spine-and-leaf fabrics.

Distributed Optimized Flooding

Distoptflood outlines two optimizations to flooding, both of which work across all topologies and do not require a centralized controller of any kind. The first optimization is selecting a reduced set of reflooders^[8] when flooding an LSP (or fragment—LSP is used interchangeably with LSPF fragment in these explanations) by doing the following:

- Set all link metrics to 1.
- Calculate the shortest path tree.
- Group nodes with a cost of 2 by directly connected neighbors (nodes reachable with a cost of 1) through which they are reachable.
- Select a set of directly connected neighbors that can reach all nodes with a cost of 2.
- Remove any directly connected neighbors that are on the shortest path towards the origin of the change.

Figure 2 illustrates the flooding optimizations in a Clos fabric, while Figure 3 illustrates flooding optimizations in a Butterfly fabric.

Figure 2: Distributed Optimized Flooding in a Clos Fabric

In the three-stage Clos (Figure 2), some change happens at C1; for instance, some network that was connected to C1 is disconnected. C1 calculates its two-hop neighborhood and determines it needs only to designate one of its neighbors, B1 through B8, as a reflooder. Let's assume it chooses B1 as the reflooder. C1 will send the LSP to C1 normally, and send the LSP to B2 through B8 using a link-local packet; these neighbors will receive the LSP and process it, but will not flood the changed LSP to their neighbors (they will not, in IS-IS terms, set their *Send-Receive* flag).

B1 will discover all of its neighbors can reach the same set of neighbors, and hence will select one connected neighbor as a reflooder; say B1 selects A1 as its reflooder. B1 will send the updated LSP to A1 through A8 and C2 through C8 using a link-local packet, so each of these routers will receive and process the change, but not reflood it. A1 will receive and process the update, but building its optimized flooding set will discover every one of its connected neighbors is on the shortest path towards the origin of the change, which is C1, so it will not reflood the update to any neighbors.

After about a second, each of the reflooders will send a *Complete Sequence Number Packet* (CSNP), which contains a description (or digest) of the local LSDB. If an IS notices a mismatch between its local LSDB and a neighbor's LSDB, it can send a *Partial Sequence Number Packet* (PSNP) requesting the retransmission of the missing information.

Figure 3 illustrates a slightly more complex five-stage spine-and-leaf fabric; while there is no “official” name for this configuration, it is often called a *Butterfly*.

Figure 3: Distributed Optimized Flooding in a Butterfly Fabric

Once again, let's assume a change occurs at E1, such as losing connectivity to a network (or reachable destination). In stage 1, E1 will build an LSP and calculate a set of reflooders that can reach its entire two-hop neighborhood—which is all of its neighbors in this case (D1 through D4). D1 through D4 will build a set of reflooders, which will include one of the two routers they are connected to in row C (C1 through C8). In stage 2, the selected reflooders in row C (C1, C3, C5, and C7) will determine a set of reflooders, which will be one spine router in each pod (such as A1, A5, and D5 for C1). The result: A1 through A8 and E5 through E8 will receive four copies of the changed LSP. None of the row A or row E routers will reflood the change because all their neighbors are on the shortest path back to E1, which originated the change. Depending on the timing of flooding, the number of copies of the changed LSP routers in rows A and E will likely be less than four.

A virtual testbed of around 2,600 routers configured as a butterfly showed this optimization decreased the number of LSPs each router received by a factor of 10 and doubled the initial convergence speed with more than 100,000 routes.

Because IS-IS runs over Ethernet natively and you can calculate the local system ID from an attached *Media Access Control* (MAC) (or Ethernet ID) address, you can run a modified IS-IS fabric with virtually no configuration on the fabric devices. You can assign locally calculated IPv6 addresses to the loopback address of each device, and use link-local IPv6 addresses to forward IPv6 traffic across the fabric. Forwarding IPv4 traffic would, of course, require an address plan and some form of automated configuration for loopback addresses. Fully autonomic configuration of this kind, however, can make troubleshooting issues and tracing flows through the fabric difficult. Therefore, current implementations do not include fully autonomic operations, so you must configure the system ID and the loopback address on each device.

A more controversial point is that using a control plane that runs natively at Layer 2 could improve security somewhat. A host that has been taken over or “pwned” by an attacker could not use the IP capabilities of the host to attack the operation of the fabric itself. Whether this feature results in an improvement in security is left to the reader (and operator!) to consider more deeply.

Centrally Calculated Optimal Flooding Trees

Centralized flooding management requires several modifications to link-state protocols, explained in “Dynamic Flooding on Dense Graphs”^[2]—a framework describing the changes required rather than a specific implementation. Rather than approaching the problem of optimally flooding information through a dense topology using local calculations, you can calculate a *flooding leader*, which then distributes an optimal flooding tree to all nodes in the fabric. Individual nodes would normally flood only along the designated tree, and then “by request” to resolve any flooding issues or to add links temporarily without impacting the flooding topology.

Each flooding domain (area in OSPF terms) must have a flooding leader; the draft suggests OSPF can elect this leader in much the same way as the *Designated Router* (DR) or a *Designated Intermediate System* (DIS) in IS-IS, both of which are used to reduce the amount of flooding required to synchronize a set of routers connected to a single broadcast link. While a single leader per flooding domain is required, the draft suggests each flooding domain should have multiple candidates, so the failure of the flooding leader does not cause an outage. This setup would be similar to the way OSPF elects a *Backup DR* (BDR) first, promotes the BDR to the DR role, and then elects a new BDR. In this way, a new flooding leader can “listen in” and be ready to take over the role of flooding leader if failure occurs.

A new *Type Length Value* (TLV) is added to IS-IS to enable the election of an area leader. An IS advertising this TLV is considered in the area leader election on all devices in the flooding domain. Rather than specifying the algorithm used to elect the flooding leader, an algorithm field is used to indicate how the flooding leader should be elected. Perhaps the simplest algorithm would be to elect the device with the highest (or lowest) priority, as advertised in the new TLV, and select among multiple advertisers with the same priority using the system ID (in the case of IS-IS).

When elected, the flooding leader calculates an optimal flooding topology. The flooding leader does not need any special information here; it already has a full view of the topology of the flooding domain through the synchronization of LSDBs required by normal link-state protocol operation. The precise calculation used is not specific in the draft, but a simple one might be to just use the shortest path tree as calculated by the flooding leader as the optimal flooding tree. The flooding tree does not need to be optimal from every point in the topology; it is not used to forward traffic, only to reduce flooding. The flooding tree also does not need to be perfect. A single device receiving two copies of a flooded link-state change might be less than optimal, but it will not cause routing loops or other significant network problems. In the same way, if a device fails to receive some new link-state information, the result might be suboptimal traffic flow. The normal flooding processes in OSPF and IS-IS will eventually catch the error (generally on the order of seconds) and fix the problem. Some optimizations, such as choosing only one link from a set of parallel links, and handling multiple nodes connected to a shared multi-access link, are considered in some detail.

After the topology is calculated, it must be advertised to the network devices in the flooding domain. IS-IS advertises it using a new TLV that is similar to the way link-states are already advertised. Each TLV contains a series of system IDs through which the flooding path passes. Similar additions to the OSPF protocol are described as well.

What “Dynamic Flooding on Dense Graphs”^[2] provides is a framework for a solution to flooding inefficiencies in link-state protocols, rather than a solution. In fact, you can advertise the use of distributed optimized flooding within a network by using the mechanisms in this draft. One specific algorithm for computing a dynamic flooding topology is described in “An Algorithm for Computing Dynamic Flooding Topologies”^[3] in this way:

“The proposed algorithm constructs a subgraph composed of small overlapping cycles. The base graph is denoted by $G(V, E)$, where V is the set of all reachable nodes in this area, and E is the set of edges. The subgraph to be computed is denoted by $G'(\{\}, \{\})$, which starts with an empty set of nodes and an empty set of edges.”

It is beyond the scope of this article to describe the precise way this algorithm operates or proposed alternatives.

RIFT

Routing in Fat Trees (RIFT) is a recent addition to this list, combining link-state and distance-vector concepts. Link-state-like operation is retained as information is transmitted up the fabric towards the ToF, while distance-vector-like operation carries reachability and topology information towards the edges of the fabric, the leaves.

Work on this new protocol started in IETF when the RIFT working group charter was approved in February 2018. The charter states:

“The Routing in Fat Trees (RIFT) protocol addresses the demands of routing in Clos and Fat-Tree networks via a mixture of both link-state and distance-vector techniques colloquially described as ‘link-state towards the spine and distance vector towards the leaves.’ RIFT uses this hybrid approach to focus on networks with regular topologies with a high degree of connectivity, a defined directionality, and large scale.”

The working group was chartered to create a protocol that will:

- Deal with automatic construction of fat-tree topologies based on detection of links.
- Minimize the amount of routing state held at each topology level.
- Automatically prune topology distribution exchanges to a sufficient subset of links.
- Support automatic disaggregation of prefixes on link and node failures to prevent black-holing and suboptimal routing.
- Allow traffic steering and rerouting policies.
- Provide mechanisms to synchronize a limited key-value data-store that can be used after protocol convergence.

According to the charter: “It is important that nodes participating in the protocol should need only very light configuration and should be able to join a network as leaf nodes simply by connecting to the network using the default configuration. The protocol must support IPv6 and should also support IPv4.”

Basic Operations

As briefly described earlier, RIFT combines concepts from both link-state and distance-vector protocols. A *Topology Information Element* (TIE) is used to carry topology and reachability information; it is like an OSPF LSA or IS-IS LSP. Figure 4 illustrates the advertisement of reachability and topology information in RIFT.

In Figure 4, E1, a ToR, advertises **2001:db8:3e8:100::/64** and its connections to D1–4 to D1–4. D1–4, in turn, refloods this information towards C1–8.

Rather than flooding the TIEs received from E1 back down the fabric, however, C1–8 advertises the minimal amount of reachability possible (normally this route would be a single default route) and their full set of neighbors to D5–8 and B1–8. When this process is completed:

- E2 will know about any locally connected destinations, four potential default routes from D1–4, and all the neighbors of D1–4 (the two-hop neighborhood for each connected neighbor).
- D5 will know about the neighbors and destinations connected to E5–8, the C1 two-hop neighborhood, the C2 two-hop neighborhood, and two possible default routes from C1 and C2.
- C4 will know about the destinations and neighbors reachable from all devices in rows A and E, and the neighbors connected to devices in rows B and D.

Using this information, the routers in row C can calculate a full SPT to discover the best path to each destination in the network. Routers in rows B and D will forward any traffic destined within the pod based on local information learned from the ToR switches, and all other traffic towards the default route learned from the ToF (row C). ToR switches will forward traffic using the default route learned from the spine stage above them, rows B and D.

Figure 4: RIFT Operation in a Butterfly Fabric

Automatic Disaggregation

In normal circumstances, devices other than those in the ToF stage rely on the default route to forward packets towards the ToF, while more specific routes are available to forward packets towards the ToR switches. What happens, however, if the C3→D2 link fails? B2, B6, and D6 will continue forwarding traffic towards C3 based on the default route being advertised in the TIE flooded by C3, but C3 will no longer have a route by which it can reach `2001:db8:3e8:100::/64`—so this traffic will be dropped at C3.

To resolve this problem, RIFT can use the two-hop neighbors advertised to all routers to automatically determine when there is a failed link and push the required routes along with the default route down the fabric. In this case, C4 can determine D3 should have an adjacency with D2, but the adjacency does not exist. Because of the failed adjacency, C4 can flood reachability to `2001:db8:3e8:100::/64` alongside the default route it is already sending to all its neighbors. This more specific route will draw any traffic destined to the `100::/64` route, so C3 no longer receives this traffic. The default route will continue to draw traffic towards C3 for the other destinations it can still reach.

Other RIFT Features

When ToF fabric switches are configured, fabric devices running RIFT can compute their fabric location and largely self-configure (there are exceptions for devices requiring Layer 2 support and leaf nodes in the topology). This self-configuration includes the use of IPv6 *Neighbor Discovery* (ND)^[13] to determine local IPv6 addresses, so no addressing plan or distribution protocols are required for pure IPv6 operation. If native IPv4 forwarding is required in the underlay, those addresses must be managed and configured in some way.

RIFT also offers the ability to perform unequal-cost load balancing from the ToR towards the ToF. Since each node has only the default route, and the stages closer to the ToF have more complete routing information, it is not possible for the ToR to cause a routing loop by choosing one possible path over another, or unequally sharing traffic along its available links.

Conclusion

BGP has been and will continue to be an important option for DC fabric underlays for many years to come. BGP may eventually offer some of the interesting features link-state protocols already offer, such as faster convergence and closer-to-autonomic deployment. On the other hand, some features of a link-state protocol, such as the ability to get a complete view of the entire topology from a single place—pulling a copy of the LSDB—are going to be very difficult to replicate in BGP, and the BGP convergence speed is always likely to lag behind a link-state protocol.

Table 1 summarizes many of the differences between the options outlined here.

Table 1: Differences Between Modified BGP, Modified IS-IS, and RIFT

Feature	BGP (Modified for DC Fabrics)	IS-IS (Modified for DC Fabrics)	RIFT
Peer Discovery	Partial	Yes	Yes
Automatic Tier Calculation	No	Potentially	Yes
Mis-Cabling Detection	No	Capability in progress	Yes
Fabric Addressing	Loopback address, peering; can be reduced with protocol modifications; can be automated	System ID, loopback address; can be automated or locally calculated	ToF state and others; can be automated
Aggregation; Default only on ToR and Below	Manually configured	No	Yes
Scales to Underlay Routing on Host	Yes	Depends on fabric size and implementation	Yes
High <i>Equal-Cost Multi-Path</i> (ECMP) Fanout Support	Yes	Yes	Yes
Unequal-Cost Load Sharing	Yes (in some implementations)	No	Yes
Full View of Topology	No	Yes	Yes (in the ToF)
Carry Opaque Configuration Data	No (can carry opaque information through Communities)	No (can carry opaque information through Tags)	Yes
Drain Node without Disruption	Yes	Yes	Yes
Automatic Disaggregation	No	No	Yes
Fast Convergence Speed	Partial (Depends on event type)	Yes	Yes
Security Includes Origin Validation and Replay Protection	Origin validation could be implemented, but heavy weight; no replay protection	No	Yes
Initial Implementation	Simple	Moderate	Complex
Overlay Support	Assumes single protocol (eBGP underlay, iBGP/eVPN overlay)	Assumes eVPN overlay	Supports eVPN overlay, can operate pure Layer 3 fabric with no overlay to the workload
Support for General Topologies (not just DC fabrics)	Yes	Yes	No

Link-state protocols offer a different set of tradeoffs than BGP does; operators would do well to consider the link-state options described here as strong alternatives to using BGP for DC fabrics underlays.

- [6] “Folded” unfortunately has two distinct meanings in spine-and-leaf networks. The original spine-and-leaf design, the Clos, was considered unidirectional, in that circuit setup proceeded in one direction through the fabric, and the resulting fabrics were nonblocking. Using a spine-and-leaf for bidirectional packet-switched traffic “folds” the fabric. However, folding also means drawing the fabric with the topmost tier at the top of the diagram and all the leaves along the bottom of the diagram.
- [7] Note that in some implementations of BGP, the iBGP and eBGP I/O paths are handled separately, making iBGP and eBGP either closer to, or fully, two separate failure domains. You should consider this point when determining which implementation to deploy in a DC fabric when BGP is used as the underlay protocol.
- [8] The “first flood” to build an initial LSDB on which the two-hop neighborhood can be calculated is performed in the normal way; there is no optimization of this initial flood of topology information.

MELCHIOR AELMANS is Lead Engineer Cloud Providers at Juniper Networks, where he has been working with many operators on the design, security, and evolution of their networks. He has over 15 years of experience in various operations, engineering, and sales engineering positions with cloud providers, data centers, and service providers. Before joining Juniper Networks, he worked with eBay, LGI, KPN, etc. Melchior enjoys evangelizing and discussing routing protocols, routing security, and internet routing and peering. He also participates in IETF and RIPE and is a board member at the NLNOG foundation. E-mail: melchior@aelmans.eu

So You Want to Sell Your IPv4 Address Block?

by David Strom

If your company owns a block of IPv4 addresses and is interested in selling it, or if your company wants to purchase additional addresses, now may be the best time to do so. As readers of *The Internet Protocol Journal* (IPJ) are well aware, the number of available IPv4 addresses has been steadily dwindling, to the point now that many of the *Regional Internet Registries* (RIRs) are no longer assigning them. It may be a good time to look at the used-address marketplace. This arena could be a new corner of the Internet for you, so this article can help you understand what is going on and prepare you to do business in it.

For sellers, a good reason to sell address blocks is to make money and get some use out of an old corporate asset. If your company has acquired other businesses, particularly ones that have assets from the early Internet pioneers, chances are you might already have at least one range that is gathering dust, or is underused. Think of this idea of selling blocks as similar to how your company might decide to sell or release its unused real estate. “Many companies have millions of unused IP addresses,” said Vincentas Grinius of Heficed, an address leasing vendor. “They have been holding on to them for future growth or to save as a strategic asset.” Now might also be a good time to sell since prices are starting to level off, according to several brokers that I spoke to (of course, they have a vested self-interest), and the practice is becoming more accepted.

If you’re a buyer, it is also a good time for you, as a way to extend the life of your enterprise IPv4 equipment for a few more years. It is particularly true if your business has resisted a full IPv6 deployment or you can’t easily upgrade your legacy endpoints.

Until recently, the used-address marketplace hasn’t had the best of reputations. Many of us imagine that getting a used-address block from a broker is like buying a cheap used car. Grinius told me that used addresses used to be thought of “as akin to *Hustler* magazine, something folks were ashamed of having in their possession.” But things have gotten more legitimate: in addition to the used-car metaphor, you should also add the digital equivalence of a title insurance company and an accident reporting service like Carfax to establish more of a trusted exchange among buyer, broker, and seller.

Certainly the used-address market is thriving and quite competitive: now we have dozens of block brokers and at least three block lessors (IPv4 Market Group, Prefix Broker, and Heficed) that have solid business operations to help match buyers and sellers.

I have owned my own Class C block since 1993, and it seemed like an opportune time to sell it when IPJ’s editor asked me to write about the used IPv4 marketplace.

So let's first review the history of the IPv4 address depletion and how RIRs work in terms of address allocation before we get into the specifics of how the broker/resale space works. Along the way I will offer my own comments about my experience in selling my own block, and what I learned that can help you decide whether you want to become a buyer, a seller, or a lessor of your own block.

Address Transfer Reference Library

Perhaps the best source of information about IPv4 address depletion, myths (such as changing out customer routers is easy and ISPs still have plenty of IPv4 addresses) and tools about IPv6 transition are available in the back issues of IPJ itself, including articles that Geoff Huston of the *Asia Pacific Network Information Centre* (APNIC) wrote. Following is a guide to the most useful pieces, in IPJ and elsewhere. Note that I shared my thoughts with Huston prior to publication, and have woven in some of his remarks in this summary.

- An IPJ June 2003^[1] article reviews the early stages of IPv6 and includes some early myth busting by Huston, such as IPv6 has innately better security, *Quality of Service* (QoS), and mobility support. In one article, Huston says that “With a continuation of current policies it would appear that IPv4 address space will be available for many years yet.” He was right, just perhaps not in the way that he originally intended. In a recent e-mail, Huston told me, “At the time there was a common expectation that the adoption of IPv6 was meant to complete before the IPv4 pool had exhausted itself.”
- Four years later in an IPJ September 2007^[2] article, Huston talks directly about the state of IPv4 address depletion, and has models that (accurately as it turned out) predicted full depletion by 2011. At that time, address exhaustion was pretty much inevitable. In the article, Huston stated that IPv6 didn't have a very compelling business case and that the use of *Network Address Translation* (NAT) in IPv4 is far easier, a claim you could still make today.
- An IPJ March 2011 special issue on the IPv6 transition^[3] includes commentary on *World IPv6 Day* held June 2011 and a history of the address exhaustion of IPv4. “The stock of [IPv4] addresses is facing imminent depletion,” Huston wrote in that issue. By then, APNIC had exhausted its IPv4 address pool. “Most of the actors in the Internet are unsure about what needs to be done [to make the v6 transition], from the largest of the service providers down to individual end users,” he wrote. That issue is worth reviewing because it has a lot more helpful information about making the IPv6 transition.
- A December 2019 presentation by Huston about IPv6 is also worth reading^[4] He discusses current pricing trends on block sales and predicts that by the time we run out of IPv4 addresses we will have outgrown IPv6: “We didn't need it back when it was first proposed and we still don't need it now.”

Huston mentioned in a recent e-mail to me that it has been “nine years after the initial exhaustion point and IPv6 is still used by less than a quarter of the Internet and IPv4 remains the mainstay of the Internet. It was easier for the industry to change the entire architecture of the Internet than it was to universally adopt a new IP protocol.”

- A nice historical review of the development of RIRs is available in the December 2001 IPJ.^[5] It covers *Classless Inter-Domain Routing* (CIDR), subnetting, and supernetting.
- A white paper from Eric Bais^[6] has loads of practical advice for address transfer, written from the perspective of a broker in the *Réseaux IP Européens* (RIPE) region who both sells and leases blocks.

Historical Review

I first wrote about the depletion of the IPv4 address space when I was editor-in-chief of *Network Computing* magazine back in the early 1990s. Alas, that article is no longer accessible online. I remember it vividly because it got an amusing comment from my father, who never really understood technology but thought it would be funny if I were to leave my job and become an address broker. Needless to say, it was just a passing but prescient thought.

Back in these early days of the commercial Internet, Jon Postel personally and manually assigned IP address ranges. Usually he did it within moments of receiving an e-mail request, and that is how I got my /24 block. Obviously it didn’t scale after the Internet caught on. One of the first to sound the alarm was Frank Solensky, who published his predictions for various run-out dates in 1990 during the 18th meeting of the *Internet Engineering Task Force* (IETF).^[7] See Figure 1.

Figure 1: Solensky’s Original Estimates of Address Exhaustion

<u>Depletion Dates</u>	
• Assigned Class “B” network numbers	Mar. 11, 1994
• NIC “connected” Class B network numbers	Apr. 26, 1996
• NSFnet address space *	Oct. 19, 1997
• Assigned Class “A-B” network numbers	Feb. 17, 1998
• NIC “connected” Class A-B network numbers	Mar. 27, 2000
• BBN snapshots *	May 4, 2002
* all types: may be earlier if network class address consumption is not equal	

The basic “Goldilocks” issue is that for the average business looking to get online, 250 addresses for a class C block is too little and 65,000 addresses for a class B block is too many. Numerous technical approaches have been proposed, including classless addressing (RFC 1918^[8]), NAT, elimination of assigning static addresses to dial-up users, and changes to routing protocols. But the real solution was inventing IPv6 to increase the overall address space. During the early 1990s, the larger blocks of A and B ranges were already being rationed, given that Postel by then had previously assigned many of these blocks.

While the IPv4 addresses were being depleted, three of the RIRs were created through RFC 1366^[9], modified by RFC 1466 in 1993^[10], and further refined a few years later in RFC 2050^[11]. Now there are five of them:

- *African Network Information Centre* (AFRINIC) serving Africa
- *Asia Pacific Network Information Centre* (APNIC) serving parts of Asia and the Pacific region
- *American Registry for Internet Numbers* (ARIN) serving North America and parts of the Caribbean
- *Latin America and Caribbean Network Information Centre* (LACNIC) serving Latin America and parts of the Caribbean
- *Réseaux IP Européens Network Coordination Centre* (RIPE NCC) serving Europe, parts of central Asia, and the Middle East

By February 2011, the last remaining common blocks of IPv4 addresses were fully allocated to the RIRs. In an article in IPJ, Raúl Echeberría, Chairman of the *Number Resource Organization* (NRO), the umbrella organization of the five RIRs, was quoted as saying, “It’s only a matter of time before the RIRs and ISPs must start denying requests for IPv4 address space.”^[3] Today almost every block is assigned to some entity. AFRINIC has the most available, and APNIC has a few smaller blocks left. RIPE made its last /22 block assignment in November 2019.^[12]

The Rise of the Used-Address Marketplace and RIR Supervision

Perhaps the origin event for the used-address market was when Microsoft purchased Nortel’s inventory of more than 600,000 individual IPv4 addresses for US\$7.5M in 2011. (Well, that isn’t a completely accurate statement, but it does appear that Nortel’s address pool was the main corporate asset.) Since then, tens of millions of addresses have been transferred^[13] per year, as you can see in Figure 2.

In the last decade, the RIRs have played an increasing role in these transfers. In the references I have the direct links to the current transfer policies for each registry.^[14] Note that some RIRs have more precision and transparency about their process, along with higher thresholds, than others to prove existing ownership of an address block.

Figure 2: Address transfers from 2020 statistics compiled by Geoff Huston

But this system wasn't perfect by any means: block ownership questions weren't easily resolved within a single registry, organization records were full of stale data or listed businesses that were no longer operating entities, and spammers could pollute address blocks by clouding any resale opportunities. Also, many address blocks (such as the one that I owned) pre-date the establishment of RIRs, what they call "legacy resources." How the RIRs deal with these assignments is a challenge, particularly as businesses are no longer around, and tracing the lineage from the original Postel assignment to a current stakeholder can involve some detective work. The question is, who should do the detecting? That isn't a simple question to answer, as you'll see.

Part of the problem was WHOIS itself, the primary domain and block ownership query tool. However, WHOIS is far from perfect. First, its responses differ depending on the data being queried, the RIR in charge of that block, and whether the block owner has provided accurate and up-to-date information or deliberately hidden these details.

But another part of the problem is that the Internet community has made changes to the display of information from WHOIS queries. Changes were necessary because of privacy concerns (from various changes to regulations around the world) and from spammers abusing WHOIS to drive legitimate business owners into hiding their details. I have placed the links to the different RIR WHOIS pages in the reference section if you want to compare them.^[15]

If you were to examine my own /24 block before I began writing this article, you would see:

Organization: David Strom, Inc. (DAVIDS-3)
RegDate: 1993-05-21
Updated: 1996-04-18

The address used for my DAVIDS-3 organization is a New York corporation that is no longer in business. And the point of contact listed is an engineer at an ISP that I used to register the block that is also no longer in business. My challenge: I had to prove that the David Strom Inc. that did business in New York was the same David Strom Inc. that is now doing business in Missouri. Other than finding the plane ticket that I used in my move, I wasn't sure what else I could do to document the "asset transfer" that ARIN was going to eventually ask for.

Thus began my own journey to correct this information and get it ready for resale. The process involved spending a lot of time studying the various transfer webpages at ARIN, calling their transfer hotline several times for clarifications on their process, and paying a \$300 transfer fee to start the process. ARIN staff promises a 48-hour turnaround to answer e-mails, and that can stretch out the time to prepare your block if you have a lot of back-and-forth interactions, as I did.

Enter the Block Broker

This discussion brings us to the modern era (say after 2012) and the IP block-broker marketplace. The goal was to try to make it easier for these transfers, and at the same time improve trust among all parties. As I said earlier, we now have many block brokers doing business. The broker's service (for either selling or leasing a block) is somewhat similar and involves these basic steps:

1. You need to register your business with the broker, a process that involves just answering a few basic questions and creating a login ID so you can interact with them via their various web-based forms and forums and e-mail.
2. Next, if you are a seller, you sign a mutual *Non-Disclosure Agreement* and then list your block that you want to sell. Some brokers have a variety of sales methods, including open and closed auctions and the ability to "buy now." If you are a buyer, you can start browsing the blocks that are available on the open auctions, and participate in the auction. If you have ever bought or sold any physical object via an online auction, you should be familiar with this process.

3. After you select a buyer for a particular block, you request the funds and place them in escrow, and then close the auction.
4. The broker's support team arranges for the transfer with the relevant RIR(s). As a buyer, you will then pay the fees directly to the RIR(s) for the transfer. Each RIR has a different way to calculate fees, ranging from free for RIPE to thousands of dollars, depending on the size of the block. (See Figure 3.)

Figure 3: The Different Fees Each RIR Charges for Transferring Addresses

RIR	Transfer Fee Amount
ARIN	\$300 USD
RIPE	\$0 USD
APNIC	20% of the annual fee for the # of IPv4 addresses being transferred
LACNIC	Initial payment of \$200 USD Smaller than a /19 - \$1,000 USD /19 and larger - \$1,500 USD
AFRINIC	Smaller than /22 - \$0 USD /22 to /20 - \$1,750 USD /20 to /18 - \$2,000 USD

5. Finally, the transaction closes and the block control and the funds released from escrow, minus any commission from the broker, are transferred to the buyer or leaser. Here is where things get interesting. The commissions aren't transparent: you have to get far enough down the process before you can find out what they are; the brokers set up the process this way deliberately so you can't shop around for lower fees. Still, there is a place for brokers, since "nothing is more frustrating than trying to get paid in a country of which you don't know the legal system nor have local representation. Using an escrow makes things easier for all parties involved," says Eric Bais of Prefix Broker.^[6]

One other caveat for block leases: the lessor and lessee have a more intimate and longer-term relationship than if you are buying and selling the block outright, because ultimately the "landlord" business is still responsible for the reputation of the folks who are using your IP addresses. In other words, renting out your space also carries a certain risk to the lessor: just like rentals in the physical space, owners (or landlords) are responsible for their property. If you have a bad tenant who trashes your space, your reputation will suffer. This reality places a bigger burden of trust on the broker to ensure a proper tenant.

Three RIRs list brokers on their websites. They all have somewhat different contact information and number of brokers:

- APNIC has 22 listings^[16], with contact names and phone and skype numbers.
- RIPE has 76 listings^[17], with links to their contact webpages.
- ARIN has 29 listings^[18], with contact names and phones and the date the broker registered with ARIN.

All of these RIRs try hard to indicate that their listings are not a recommendation, just awareness of their businesses. RIPE says its listing, for example, is of brokers who have agreed to conduct their business honorably, but no one checks on the brokers after they are listed to see if they have actually lived up to their promise. That is worth remembering. As the old saying goes, “on the Internet, no one knows if you are a dog.”

If you are starting out in the used marketplace as I was, I recommend that you examine these RIR webpages carefully. Just having these lists of brokers is nice, but if you are going to sell or buy a used block you will find it frustrating to find the right broker for your situation. The biggest issue is that there are no fixed rules for buying, selling, and leasing used addresses. Unlike the used-car industry, there is no overall supervision or agreement on what constitutes the *quality* of an asset. As you can see from the five-step process cited previously, uncertainties and potential problems can arise at every step.

One other thing worth mentioning should be obvious but isn't: The only entities that can play are businesses. If you own a block as an individual, you will first have to transfer ownership to a business to proceed. You notice my ownership is my S-corporation (with my name; that helped me in the transfer process from my New York corporation to my Missouri corporation). Had I initially registered for my block as an individual, I might have had to work harder to prove my identity.

Important Caveats for the Transfer Process

Following are some of the complicating factors to watch out for as you begin your own transfer journey:

First, choosing whether to buy or lease a block can be tricky, and it depends on how many addresses you need and for what purpose. More details will follow, but you need to make this very basic decision before doing anything else, and often you won't have as much data as you might like.

Unlike the used-car industry, there aren't any generally accepted practices or guides to making a tradeoff between buying and leasing. Of course, one aspect is the overall cost, and to estimate it you have to know your time horizon. If you are a buyer, do you need the block for a few years or a few months? Can you eventually migrate the endpoints to IPv6 using these addresses?

If you are a seller, do you want to dispose of the block and make a quick addition to boost your current year's balance sheet, or do you want to invest in a steady rental income over time? As a renter, you are also betting on a particular price curve over the terms of the lease that may or may not materialize. Now imagine that you are having this conversation with your Chief Financial Officer, who may or may not understand the various subtleties about the used-address marketplace.

You should base part of your choice of whether to rent or buy on the size of the block involved. Some brokers specialize in larger blocks and some won't sell or lease anything less than a /24, for example. "If you are selling a large block (say a /16 or larger) you would need to use a broker who can be an effective intermediary with the larger buyers," said Geoff Huston in an e-mail to me. Again, knowing that your broker has listed prior transactions can help you make a more informed decision. Not all brokers have pricing transparency, and many brokers are more circumspect about pricing.

IPv4.Global is one that does list their own prior auction sale data^[19], for example. Another broker, IPv4 Market Group, has assembled the overall pricing chart shown in Figure 4 from March 2019^[23]. There is no way to independently verify this information, but at least these examples show you how the market has evolved over the past decade.

Figure 4: IP Address Block Pricing Trends over Time

In early January 2020, /24s were selling at around US\$20–24 per IP address, or US\$5,000–6,000 for the entire block. Rental prices varied from 20 cents to US\$1.20 per month per address, meaning at best a 2-year payback and at worst a 10-year payback when compared to sales. I decided to sell my block: I wanted the cash, and didn't like the idea of being a landlord of my block any more than I liked being a physical landlord of an apartment that I once owned. You'll also want to ensure that the RIR that is responsible for your block recognizes the broker you eventually choose.

Second, there is no guarantee that any of these brokers is reputable and will actually deliver the goods, or even if the RIR listings and contacts for the broker are still accurate. There is no easy way to vet their operations, or even agree on overall metrics to be used as part of the vetting process. Unless you know them personally, or know someone who does, chances are the names of the brokers on the RIR lists will require additional research for you to decide whom you should use to sell your block. You can look to see their registration data with ARIN, if ARIN controls your block.

One possible vetting strategy is to inquire how the broker is involved in the various Internet governance committees in your region, or at least examine their posted attendee lists. The hypothesis for this strategy is that broker representatives who attend IETF, RIR, and network operator meetings such as The *North American Network Operators' Group* (NANOG)^[20] are more reliable than those that have never been to any of these meetings. (For example, PrefixBroker.com claims on their website that they helped author the RIPE transfer rules.)

IPv4 Market Group has a list of questions^[21] to ask a potential broker, including if they will represent only one side of the transaction (most handle both buyer and seller) and if they have appropriate legal and insurance coverage. I found that a useful starting point.

Some brokers are also involved (either as other lines of business at their own company or as a subsidiary of a larger corporation) in other network- and Internet-related businesses, such as hosting and cloud services, while others operate in real estate development and intellectual property litigation. That may be relevant, or it could cloud your evaluation if the quality of these other businesses differs from that of the brokerage.

One of the reasons I went with IPv4.Global/Heficed was because of their transparency in terms of showing me the active auctions and past sales of their blocks right on their web homepage, and they e-mailed me periodically with the active and closed auctions.

Third is how you vet the other party in your transaction. In other words, if you are a seller, what process do you use to know your buyer, and vice-versa?

You might want to consider longer-term contracts for rentals (such as 3 years) for stability and also to minimize the movement of their tenants. “I would be somewhat worried if the broker did not undertake some diligence steps directly to validate the credentials of the seller,” said Huston in an e-mail to me.

The final part of the transfer process is to understand the condition of the actual address block itself. There is no guarantee that a used block isn’t tainted with spammers or used for other less-than-legal activities. “There are no established standards of conduct, little transparency, and even less accountability,” wrote Marc Lindsey in 2018 for a blog post on *CircleID*.^[13] “Many participants in the market struggle to define, from a legal perspective, what is being bought and sold.” He also has several suggestions on vetting the other party in the transaction that are worth reviewing.

Most brokers will state that they examine prior ownership of their blocks to ensure they are spam-free and to eliminate the potential of being used for other shady dealings. The trick is understanding what tools they use to convince you of this claim. For example, some brokers require you to check the blacklists (such as those maintained at Cisco Talos, Hetrixtools.com, and IP-score.com) on your own to ensure that your block isn’t listed there. IPv4 Market Group offers a blacklist cleaning service^[22] that examines 90 blacklists. While charges vary, to give you an idea, they quoted me \$2,000 as part of their selling services for my /24 block. IPv4.Global checks 20 different blacklists as part of their services.

However, identifying whether a block is on a blacklist and removing it from a list are two different matters. If it is listed, you will have to work on removal from the blacklists before you can lease it. According to Geoff, “Once an address is blacklisted it’s exceptionally hard to get it unlisted.” None of the brokers will give you a firm price on cleansing a block, because it depends on how many blacklists it appears on.

So what happened to my sale? It took 10 days to auction off my block. I worked with ARIN to transfer my ownership to my current corporation, and paid them a second fee of \$125 for dealing with my legacy ownership. I then worked with my broker to finalize the sale. The overall elapsed time from beginning to end was 1 month, including about a week of elapsed time to conduct the initial research and select the broker.

Summary

If all that seems like a lot of work to you, then perhaps you just want to steer clear of the used marketplace for now. But if you like the challenge of doing the research, you could be a hero at your company for taking this task on. Expect the entire process to take several months from start to finish, allowing for time to get your ownership in order (if you have a legacy block), navigate the legal and other corporate approvals, research your broker, and then actually execute the transaction.

DAVID STROM has written several articles for IPJ, most recently on fileless malware in 2018. He was the founding editor-in-chief for *Network Computing* (USA) magazine and ran overall editorial operations for Tom’s Hardware.com. He is the author of two books on computing, including one as co-author with Marshall T. Rose on Internet messaging. He lives in St. Louis and can be reached at: david@strom.com or Twitter [@dstrom](https://twitter.com/dstrom).

In Memoriam: Yngvar Lundh

by Ole Jacobsen, *The Internet Protocol Journal*

Yngvar Gundro Lundh (March 19, 1932 – August 15, 2020) was my friend, mentor, and boss at the *Norwegian Defence Research Establishment* (NDRE). I first met Yngvar around 1976 when I was still in high school working on a report about computers and society. I worked at NDRE in Yngvar's micro-computer group through my military service and later during summer vacations while at university. Yngvar was the person who introduced me to the wonders of computers, and most of all to networking. NDRE had access to the first ARPANET connection outside of the United States. It was through this link (a *TeleType* connected to the NORSAR-TIP itself connected at 9.6 kbit/s to the ARPANET via satellite) that I met many friends in the US, ultimately leading to my employment at the Network Information Center at SRI International in 1984.

Yngvar played a major role in fostering technology development in Norway through his work at NDRE, as professor of informatics at the University of Oslo, as chief engineer at Norwegian Telecom, and as consultant on a variety of projects, including the first commercial electronic mail system in Norway.

His group designed and built Norway's first transistor-based computer, SAM, which you can see at Norsk Teknisk Museum in Oslo.

He was perhaps best known for his early work with the ARPANET and SATNET at NDRE. Yngvar Lundh and Pål Spilling were largely responsible for getting Norway connected to the Internet in the early 1980s.^[1,2,3,4]

I fondly remember Yngvar as a patient teacher, generous with his time and always willing to help with projects large and small. He played a major role in my university and career path, and I will very much miss his guidance and inspiration.

Yngvar had many hobbies, including gardening, bee keeping, wood working, ham radio (LA72C), and above all, sailing. After retirement, he moved from Skedsmokorset near Oslo to Tolvsrød near the coastal town of Tønsberg, allowing him easy access to his sailboat.

OLE J. JACOBSEN is the Editor and Publisher of *The Internet Protocol Journal*, a quarterly publication on all aspects of Internet technology. He has been active in the computer networking field since 1976, when he joined the Norwegian Defence Research Establishment, an early ARPANET site. Ole holds a B.Sc. in Electrical Engineering and Computing Science from the University of Newcastle upon Tyne, England. He serves on the board of the *Asia Pacific Network Operators Group* (APNOG), which hosts the annual *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT) conference, and has served on several ICANN and IETF nomination committees. In his spare time, Ole organizes pipe-organ concerts and demonstration events. E-mail: ole@protocoljournal.org

Book Review

Transforming Information Security

Transforming Information Security: Optimizing Five Concurrent Trends to Reduce Resource Drain, by Kathleen Moriarty, ISBN-13 978-1839099311, Emerald Publishing Limited, July 2020.

When I was asked to write a short review about Kathleen Moriarty's book, I took a copy with me on my summer holiday. I usually try to stay away from work-related literature during vacation, but in this case it was well worth it. With some 200 pages packed with facts and information, this book requires a bit of concentration and focus. But you get a lot in return for the effort.

With her extensive background and expertise in security, Kathleen analyses five trends in the current security debate: End-to-End Encryption, Strong Session Encryption, The Evolution of the Transport Protocol Stack, Data-Centric Security, and More User Control.

With these trends in mind, Kathleen comes to the conclusion that we need a fundamentally different approach to network and information security. She promotes a more manageable system with a minimised, secure operating system and layered or hosted (authorised) applications on top of it. Vendors need to take more responsibility managing vulnerability, and should enable automated updates that users can trust.

Security has become increasingly complex and requires specialised knowledge and expertise. There is already a huge shortage of security practitioners. Training more people and buying additional security tools and products is not going to scale. It is increasingly challenging to secure our networks and keep them manageable at the same time. Only wide-scale adoption of end-to-end encryption, increased capabilities of the end-points, and a change of network architecture and security practices will help in the mid and end terms.

But Kathleen doesn't leave it at these high-level statements. The book is full of practical tips and provides a wide range of *Internet Engineering Task Force* (IETF) standards, guidelines, and suggested security frameworks that IT and security staff can find useful—the list of references in itself is very useful and encourages further reading.

Kathleen walks us through various aspects of information security: from threat detection and prevention, to the use of security control frameworks, to the need for more automation and the importance of sharing information with peers in the network and security community.

She also provides an overview of many standards and protocols such as IPv6, *Quick UDP Internet Connection* (QUIC), *Manufacturer Usage Description* (MUD), routing overlay protocols, *DNS over Hypertext Transfer Protocol Secure* (DoH), and *DNS over TLS* (DoT) to name only a few, and explains their relevance in the overall security landscape.

Some sentences are packed with information, and it is worth it to read them twice.

The book provides a peek into the hopefully not-too-distant future where applying a more holistic view on security, automation, and sharing relevant information will benefit the networking and security community.

—Mirjam Kühne, mir@zu-hause.nl

Read Any Good Books Lately?

Then why not share your thoughts with the readers of IPJ? We accept reviews of new titles, as well as some of the “networking classics.” In some cases, we may be able to get a publisher to send you a book for review if you don’t have access to it. For more information, contact us at ipj@protocoljournal.org

Check your Subscription Details!

If you have a print subscription to this journal, you will find an expiration date printed on the back cover. For several years, we have “auto-renewed” your subscription, but now we ask you to log in to our subscription system and perform this simple task yourself. Make sure that *both* your postal and e-mail addresses are up-to-date since these are the only methods by which we can contact you. If you see the words “Invalid E-mail” on your copy this means that we have been unable to contact you through the e-mail address on file. If this is the case, please contact us at ipj@protocoljournal.org with your new information. The subscription portal is located here: <https://www.ipjsubscription.org/>

Fragments

Announcement Regarding IPv4 Address Block 43/8

As many people know, I have dedicated much of my career to the development of research networks and network technologies in Japan and Asia. This included the WIDE (*Widely Integrated Distributed Environment*) Project, founded in 1985 for computer networking Research and Development. In the early days of the WIDE Project, we were aware of the exciting advent of the Internet, and I was often in contact with Jon Postel and other Internet pioneers, about how it could be brought to Asia.

In the late 1980s, I recognized the Internet's importance in the world and in Asia. I requested a number of early IPv4 Class B assignments (/16s), directly from Jon Postel as NIC function delegation trial, as well as Class Cs and a Class A, for use by research networks in Japan. Since then, I have been administrating the Class A assignment, 43/8, to assist in the long-term development of the Internet in the Asia Pacific region.

In the early 1990s, I helped to establish the *Asia Pacific Network Information Centre* (APNIC) from the *Japan Network Information Center* (JPNIC), to provide continuing allocations of IPv4 address space for our region, Asia Pacific, at a time when the Internet was growing very quickly. APNIC launched in 1993 and has been very successful in managing IPv4 address space since then.

Since 1992, I continued to lead the WIDE project, which was then dedicated to the development and promotion of IPv6. Some of the 43/8 address space was used for this purpose, to assist Japanese networks with renumbering in their transition to IPv6. Some of this space, a /11 in total, was allocated by APNIC to participants in that project, and the rest retained by the WIDE project for other R&D activities.

The deployment of IPv6 has been slower than expected, but I'm very happy that finally, IPv6 is in full production around the Internet, and used by around 25% of Internet users globally. It's clear now that IPv6 will succeed and that the Internet will be greatly improved as the transition continues into the future.

IPv4 has a continuing role on the Internet, but a relatively short-term role, as IPv6 adoption increases. Therefore, IPv4 address space has a current value, but a value that will reduce and disappear over the next 10 years or so. While I have not been an active supporter of the commercialization of IP addresses, the fact is that a market for IPv4 addresses exists and the APNIC community has remained neutral by developing a proper policy framework for market transfers.

In considering the future of 43/8 I have again considered how it may be best used for its original purpose. After careful consideration, I have taken a decision to release this address block, for the purpose toward healthy development of today's Internet services and toward supporting Internet development in the AP region. This is possible by making it available on the IPv4 address market. This is an opportunity to produce a capital asset, with a significant impact on Internet development, if used well and carefully. It is an opportunity that exists today and might not be repeated at any point in the Internet's future.

As I mentioned, APNIC has now been established for 27 years, and it has performed a critical and successful role. APNIC has served very well as the *Regional Internet Registry* for our region, and it has had a great impact in the development of the Internet in our region. With the establishment of the *APNIC Foundation* in 2016, it's clear that APNIC is committed to the continuation and expansion of that good work.

Recognising APNIC's role and its successes, I have asked APNIC to receive a transfer of the unallocated portion of 43/8, on two conditions: that the block will be placed on the IPv4 address market for those who still need IPv4 addresses, and that the proceeds be used in support of Internet development in our region. I am grateful that the APNIC Executive Council has accepted this offer and is now proceeding accordingly, with the establishment of a charitable trust the *Asia Pacific Internet Development Trust*, (APIDT) to take responsibility for this asset and its disposal on the IPv4 address market.

I will remain closely involved, personally and through the WIDE Project, in the management of the Trust, and in its support of Internet development in our region, primarily through the APNIC Foundation. I am very happy to have taken this step and am looking forward to the results in the coming years and decades. I thank everyone involved in this process.

—Jun Murai, Founder, WIDE Project, March 25, 2020

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

We have just completed the annual *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT). The event was to have been held in Manila in the Philippines, but because of the global pandemic it was held as a “virtual” or online event instead. This change of venue is of course not unique to APRICOT. The year 2020 saw many events cancelled, postponed, or converted to online gatherings. In most cases, the Internet remained a reliable and resilient alternative as more and more organizations and individuals took advantage of various networked conferencing systems. Already several studies have documented how the Internet performed through the pandemic. For example, RIPE Labs published “The Lockdown Effect—Implications of the COVID-19 Pandemic on Internet Traffic,” which you can find through your favorite search engine.

Many of the core protocols of the Internet have been updated or otherwise enhanced over the years, particularly protocols that originally did not have security as part of their initial design. Development continues within *The Internet Engineering Task Force* (IETF) to improve all aspects of the Internet Protocol Suite, including novel uses of existing technologies. Our first article is a look at current developments in the *Domain Name System* (DNS).

The first IETF meeting was held in January 1986 with a mere 21 attendees. Thirty-five years later the typical IETF meeting attracts about 1,000 attendees from all over the world and lasts a full week, including the pre-IETF *Hackathon* and *Code Sprint* sessions. During the pandemic, IETF meetings too have been confined to online events, this month in “Virtual Prague.”

We don’t usually publish opinion pieces in this journal, but with 35 years of IETF development and more than 50 years since the origins of the Internet, this seems like a good time to pause and examine where we are with respect to the overall state of our digital economy. Geoff Huston asks, “What have we done?” in his provocative essay that we hope will inspire you to submit your own views in the form of a Letter to the Editor or perhaps an opinion column of your own.

DNS Trends

by Geoff Huston, APNIC

We used to think of computer networks as being constructed using two fundamental common infrastructure components: *names* and *addresses*. Every connected device had a stable protocol address to allow all other devices to initiate a communication transaction with it by addressing a data packet to this protocol address. And every device was also associated with a name, allowing human users and human-use applications to use a more convenient alias for these protocol addresses. By mapping names to protocol addresses, the realm of human use could navigate the services of the network by using symbolic names, while at the level of packets the data flow was directed by the network based on topology information of where these device addresses were located.

But that's 1980s thinking and 1980s network architectures.

Communications architectures have evolved, and today's Internet architecture has, very surprisingly, dispensed with that view of the role of addresses. These days, in no small part because of the exhaustion of the IPv4 address pool, but equally because of an architectural evolution that had to cope with the massive explosion of numbers of devices in networks, we've shifted to a client/server network model where clients initiate connections and servers respond. So now clients don't require a permanently assigned network-wide address. Instead, they can use an address only while it is communicating with a server and pass it back to a shared address pool otherwise. Equally, on the server side we've seen the aggregation of uniquely named service points into service delivery platforms, and the multiplexing function that directs clients into the appropriate service rendezvous point is performed at an application level rather than as an infrastructure function. We're now using the address infrastructure in very different ways than the way we had envisaged in the 1980s. Addresses in today's terms look more like ephemeral session tokens on the client side, and coarse rendezvous points on the server side. It is left to the application level to define the specific client-requested service.

But the architecture of the name space and its use has not been static either. The name infrastructure of the Internet is subject to the same evolutionary pressures, and it is these pressures I'd like to look at here. How is the *Domain Name System* (DNS) responding? This survey has three parts: trust, privacy, and all the other stuff.

Trust

Can you believe what the DNS tells you? The answer is that you probably can't!

Many parties have exploited this obvious failure in the trust model in many ways. The DNS is seen as an overt control channel.

For example, you can block access to a named service if that name does not resolve in the DNS. As a consequence, we've seen the rise of deliberate lies in the DNS where content and services that are categorised as harmful are removed from access by withholding the associated name resolution in the DNS. Numerous open resolvers have turned this filtering of the DNS into a positive attribute, and there are many so-called "clean feed" resolvers that do not resolve a collection of service names where the service is deemed to be harmful or criminal in some manner.^{[1] [2]}

This selective filtering of the DNS is a distinguishing feature in the realm of competitive open resolvers. We've also seen numerous national regimes placing the onus on ISPs to block certain services, and given that addresses are no longer uniquely associated with individual services, the implementation of these national regulations is invariably performed through DNS blocking.^[3]

We have also seen exercises to attempt to monetise the DNS, where "no such domain" (**NXDOMAIN**) DNS responses are rewritten to send you to a sponsoring search site through response rewriting.

DNS lies have also been used in the IPv6 transition environment where the DNS records—the protocol addresses—are synthesised to allow you to be steered through an IPv4-IPv6 transitional environment.

The motives of all these exercises may vary, but the result is the same, in so far as the DNS answer is a lie.

Then there are the hostile efforts to replace a genuine response with a lie in order to mislead you, in addition to the technique of response guessing to try to insert a fake response before the "normal" response. You can use this technique in DNS over the *User Datagram Protocol* (UDP) transport as the first UDP response whose query section matches the original query the asker used—whether or not it is the "genuine" response. We have also seen manipulated glue records and even attacks on fragmented packets.^[4] The insidious nature of these forms of attack is that they rely on the host system to run quite normally. It's the infrastructure of the name system itself that is being perverted here, and the applications are completely unaware of this manipulation.

The response to this need to detect any form of manipulation of the DNS response that has taken place, and, even better, to withhold the lie from the user, is to add a trust mechanism to the DNS. This trust mechanism takes the form of adding digital signatures to DNS responses. The idea is that a digital signature attached to a DNS response can allow the receiver of the response to be assured that the DNS information is current, that it is authentic, that it has not been manipulated or altered, and that it cannot be repudiated. *Domain Name System Security Extensions* (DNSSEC), the framework for adding digital signatures into the DNS, was some 10 years in the making.

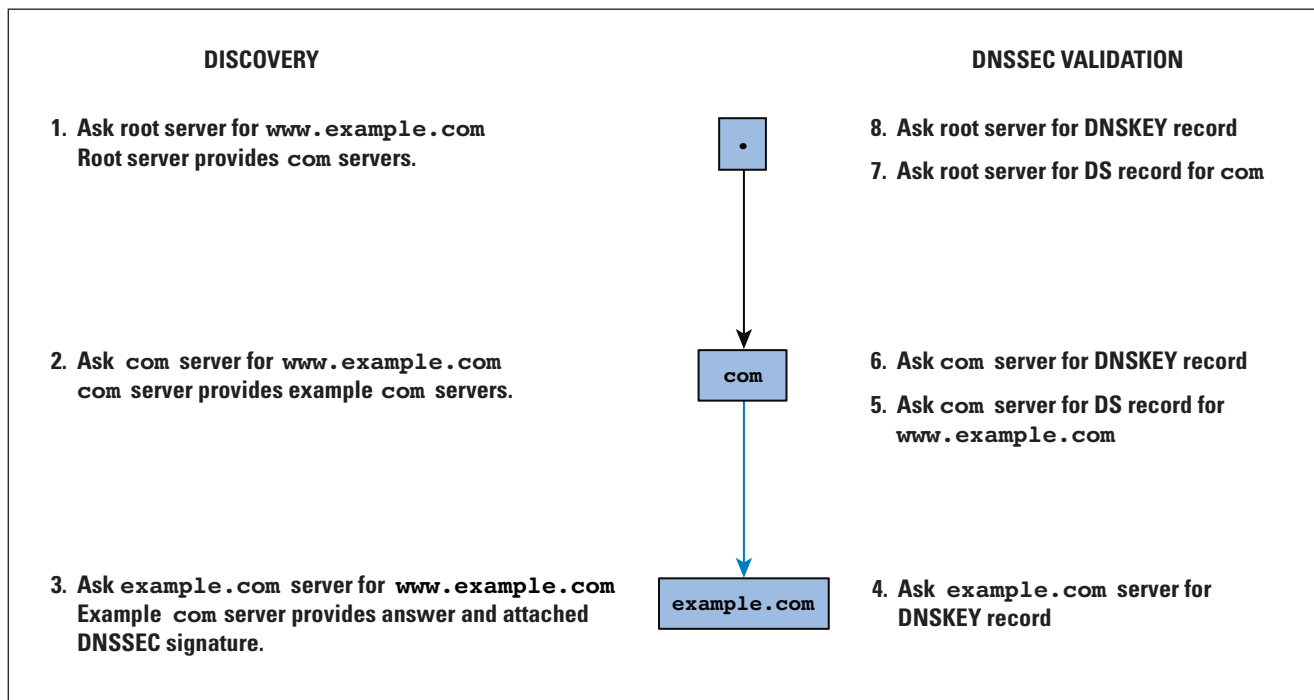

You can associate a key pair (or pairs) with a delegated zone in the DNS, and a set of five further DNS *Resource Records* (RRs) are defined in this framework to sign each entry and to aid in validation of the signature.^{[5][6][7]}

The commentary on DNSSEC deployment varies considerably. Some 25% of the world's users cannot reach a DNS-named service if they cannot validate the DNSSEC signature. That's triple the level from early 2014, so the adoption of validation is certainly gaining some momentum.^[8] At the same time, the number of DNSSEC-signed zones appears to be pitifully low. Of the hundreds of millions (perhaps billions these days) of delegated zones in the DNS, we see some 8M signed zones in one such survey.^[9] Perhaps a more relevant metric is the ranking of domain names by usage and the ratio of DNSSEC-signed zones in that set. The Alexa top 25 list is a good place to start. None of these is a DNSSEC-signed name.^[10] A scan of all **.com**, **.org**, and **.net** second-level domains found that between 0.75 and 1.0% of all domains in these three zones are signed.^[11] Zone signing is just not that common in today's DNS.^[12] It appears that turning on DNSSEC validation of DNS responses in a recursive resolver has very little downside, given that so few of the popular DNS names appear to be DNSSEC-signed in the first place!

Why is DNSSEC zone signing so uncommon? Are the content and service providers behind these DNS names unconcerned about potential misdirection of users? Of course not! They are extremely concerned because ultimately their potential revenue and reputation are at risk. Are they ignorant about DNSSEC? Again, not at all! Zone signing or not is a choice. These providers want to prevent users from being misdirected, but equally they want to reduce the dependence on intermediaries, and they want your service experience to be as efficient as possible. If DNSSEC was the only choice, then content and service providers would be using it. But it's not the only option. These days service provision uses *Transport Layer Security* (TLS). Almost every service URL out there is an HTTPS URL. Can you be misdirected with TLS? Not normally. Misdirection or deception requires leakage of the service provider's private key, or corruption of the Web *Public Key Infrastructure* (PKI) certificate system. TLS is also fast, because all the credentials needed to validate the certificate are provided in the TLS handshake.

Is DNSSEC validation as fast? Well, no. DNSSEC validation is a serial query sequence all the way back up the name delegation path (Figure 1). Is deployment of DNSSEC zone signing simple? No. There is local key management, the *Zone Signing Key* (ZSK)/*Key Signing Key* (KSK) key split, limited automation, and limited support for high-resilience hosting. And the fundamental criticism is that all this additional effort doesn't stop recursive resolvers from passing back lies in the DNS for DNSSEC-signed zones anyway, because most stub resolvers do not perform DNSSEC validation in any case.

Figure 1: DNSSEC Validation

The entire point is that lies in the DNS were just not possible with DNSSEC. But that assumes that all resolvers perform DNSSEC validation, and that's not the way we've deployed it so far. Many recursive resolvers perform DNSSEC validation. Very few stub resolvers perform DNSSEC validation. This scenario generally works in so far as the recursive resolver withholds the response if the DNSSEC validation fails. But what if the recursive resolver is the one that is telling the lie in the first place? The stub resolver is none the wiser, given that it's not validating, so the lie stands. If the ISP's recursive resolver is blocking some names, performing **NXDOMAIN** substitution, or redirecting actual names, then the stub resolver is just caught in the lie. With all that effort to sign the zone, and all that effort to validate the DNS response, there is absolutely no robust protection against being misdirected. TLS just seems to offer a solution that is faster, simpler, and more robust. No wonder few zone administrators use DNSSEC signing in the DNS service world. It's just a case of more pain, and no real gain.

Is DNSSEC good for anything else? As long as 75% of users sit behind nonvalidating DNS resolver systems—and virtually no users directly validate DNS responses in any case—we cannot place critical information in the DNS securely and expect everyone to be protected by DNSSEC. This means that the incentives for putting critical information into the DNS and protecting it with DNSSEC do not look very convincing. There is simply no natural market-based incentive for deployment of DNSSEC. This conclusion is distressing, because it would certainly be more useful for the network and its captive user population if its name system were trustworthy.

Many have said that the heart of numerous issues with the DNS lies in the choice of a transport protocol for the DNS. The use of UDP as the primary first-choice protocol and the fallback to TCP means that it's challenging to place large quantities of information in DNS answers while still operating within what we've become accustomed to in terms of parameters of speed and robustness.

Validation is a very inefficient process, and the inefficiency is increased by the DNS model where the onus is placed on the client, who is requesting the information, and not the server, who is the source of this information. End clients do not validate because every validation operation would entail further DNS queries in order to construct the validation chain, and the incremental time penalties would be unacceptable in terms of user expectation.

Frustratingly, we know how to make DNSSEC validation faster, and the approach is to pre-provision the validation answers. We can package up all the answers to the DNSSEC validation chain construction queries and include them as additional information to the original signed answer in a single chain extension in the response.^[13] However, it's unlikely that this inclusion is viable in a DNS-over-UDP framework. If we want to go down a TLS-like path and package up a validation chain into the DNSSEC-signed response, we will probably have to use DNS over TCP or *DNS over TLS* (DoT).^[14] The price of this trust solution is significant, and it creates a higher threshold for the benefits that trusted answers in the DNS can provide. If all this discussion is about protecting users from a Kaminsky-styled attack,^[15] then that's just not enough of a case. The benefit needs to be far more than helping justify the considerably higher costs in moving the DNS from UDP to a TCP-styled platform.

Privacy

Everybody looks at the DNS. Everybody. Because the Internet is funded by its users, then what users do on the Internet is of paramount interest to people who sell services to users. Because a lot of crime these days is cybercrime, the criminal and abusive behaviour on the Internet is of fundamental interest to those agencies whose role is to police such behaviours. Because the Internet is now largely about how individuals choose to live their lives and how and why they communicate with others, we've learned that what users do is of paramount interest to government.

How can you find out what users do? Easy. Look at the DNS. Every transaction on the Internet starts with a DNS query, and the DNS exposes every action. But it's worse than that. The DNS is needlessly and senselessly chatty. The DNS overexposes information. These queries and responses are collected, packaged, analysed, profiled, replayed, and traded at all points in the DNS.

How can we make the DNS not the go-to system to expose users and user behaviours to business and government alike? How can we improve its privacy?

There was little in the way of motivation to do anything about this question for years. After all, if the Internet actors are busy constructing a global economy based on surveillance capitalism, why should the parties conducting this surveillance make the task any harder than necessary? The watershed moment that changed the stance for many was the publication of material that Edward Snowden gathered. Government agencies had spent considerable sums in weaponizing the Internet and transforming it into a highly effective surveillance tool that operated at a scale of national populations. Their motivations were not overly concerned about your future purchases, but more about your personal profile. And of all the components of the Internet, the system that laid out all this information in a clear text prepackaged format was the DNS.

In response, we've been changing aspects of DNS behaviour to try to stop the most blatant forms of information leakage.

The first of this set of privacy-enhancing responses is called *Query Name Minimisation*.^[16] The change is to prevent the DNS name-resolution process from being an unconstrained extraneous information leak. This leakage largely relates to the interaction between recursive resolvers and the authoritative name servers. The task of the recursive resolver is to find the right name server to ask, and it starts at the root and asks the query. The response of the root-zone server will direct the queries to the name servers of the relevant delegated top-level domain name, and this process repeats as the resolver traverses down the delegation hierarchy until the resolver has an answer.

But in this process every name server in this sequence, from a root server down, is now aware of the full DNS name that is being resolved. Query Name Minimisation trims the name in these queries so that only the next label is exposed to each name server. Root servers will see only top-level domain name queries, while top-level domain name servers will see only second-level name queries, and so on (Figure 2).

There has been some further work to understand the most robust query type for this discovery process. The initial suggestion of **NS** queries has been supplanted by **A** queries in the light of experience with this approach. The issue of **CNAME** rewriting and the equally vexed question of Empty Non-Terminal domains and the variable behaviour of name servers in such situations have added some complications to this question. This technique of this approach is now widely used, although some implementations have taken some license with the specification and used their own re-interpretation of the technique. Some resolvers, apparently including Google's public resolver service, performs Query Name Minimisation to only the first three levels of the DNS name.

Figure 2: Query Name Minimisation

It appears as if the recursive resolver is deliberately withholding full query name information from the root servers and the top- and second-level domain name services, but is quite willing to disclose the full query name information to servers for zones that are deeper in the name hierarchy. Is this approach motivated by protecting user interests or by an effort to deny information to authoritative servers located at the upper levels of the name hierarchy?

Of course, if we were serious about user privacy, the *Client Subnet* extension would never have been specified.^[17] The knowledge of full query names that are emitted by a recursive resolver is to some extent mitigated by the inability to conclusively associate such queries with an end user. But if the query is also loaded with the IP address of the end client, or even the network subnet of the end client, then all pretence of privacy protection has been shredded. While Query Name Minimisation could be seen as a positive step in providing a greater level of concealing extraneous information in the DNS, the use of the Client Subnet value in queries is a gigantic leap backward!

A generic response to privacy considerations on the Internet has been channel encryption. *Telnet* was replaced by *ssh* because of the issues of running sessions over the Internet in the clear. Similarly, **HTTP** has been largely replaced by **HTTPS** for much the same reason. The DNS is increasingly an anachronism in still passing queries and responses in the clear. Not only does it permit eavesdropping, but it also enables efforts to manipulate the responses, all to the detriment of the user.

However, to repeat an earlier observation, the heart of many issues with the DNS lies in its choice of transport protocol. Encryption normally involves many steps, including the presentation and validation of credentials to confirm that clients are talking to the party they intended to talk to, and also to establish a session encryption key to allow encryption of the subsequent data exchange in a manner known to the two parties but unknown to all others. This type of encryption is challenging in UDP. The effort to implement TLS over UDP, namely *Datagram TLS* (DTLS)^[18], has the overhead of the exchange of credentials and session cipher establishment, so it's a long step away from a single packet exchange of query and response. DTLS also should avoid IP-level fragmentation, but it cannot avoid large payloads associated with this session establishment process. The result is that fragmentation is pushed up to the application layer and DTLS needs to handle payloads that extend across multiple DTLS datagrams. It appears that the additional overheads of DTLS roughly equate to the overheads of TLS over TCP, but with some added fragility relating to packet fragmentation that is not replicated in TCP. The result of this fragility of DTLS means that when we refer to DNS over TLS, we are in fact referring to *DNS over TLS over TCP* (DoT).^[14] It is this TCP-based implementation of TLS that has been implemented and deployed over the path between the stub resolver and the recursive resolver.

DoT adds encryption to the stub-to-resolver path; not only does encryption hide the query and response stream from eavesdroppers, but also DoT prevents alteration or manipulation of the response by third parties. The recursive resolver can still lie about the response, and unless the stub resolver is performing DNSSEC validation (and it's likely not) and the domain name is signed (which it most likely is not), then any DNS lie from the recursive resolver will be unnoticed, whether or not the transport channel from the recursive resolver to the stub resolver uses TLS. A lie is still a lie no matter how secure the packaging used to carry it is. DoT does not eliminate the potential for manipulation of DNS information, but limits the number of entities who are in a position to perform such manipulation and the place and method that the manipulation can be performed. It could be argued that with DoT all you really gain is being better informed as to who is lying to you!

How far should channel cloaking go? Should the identity of the other party be obscured? Should the fact that these transactions are DNS exchanges be obscured? DoT makes no effort to cloak its use. The use of TCP port 853 for DoT is a visible signal that there is an active DoT connection. The use of a novel port number is likely to cause many firewall configurations to trigger their drop filters. The IP address of the remote end is clearly visible, as is the TCP header. The TLS handshake may get around to using *Encrypted Client Hello* (ECH)^[19] and encrypt the server name at some point in the future, but in the case of DoT it probably is a minor artefact, given that name-based overloading of service IP addresses is not happening in DoT today and unlikely will in the future.

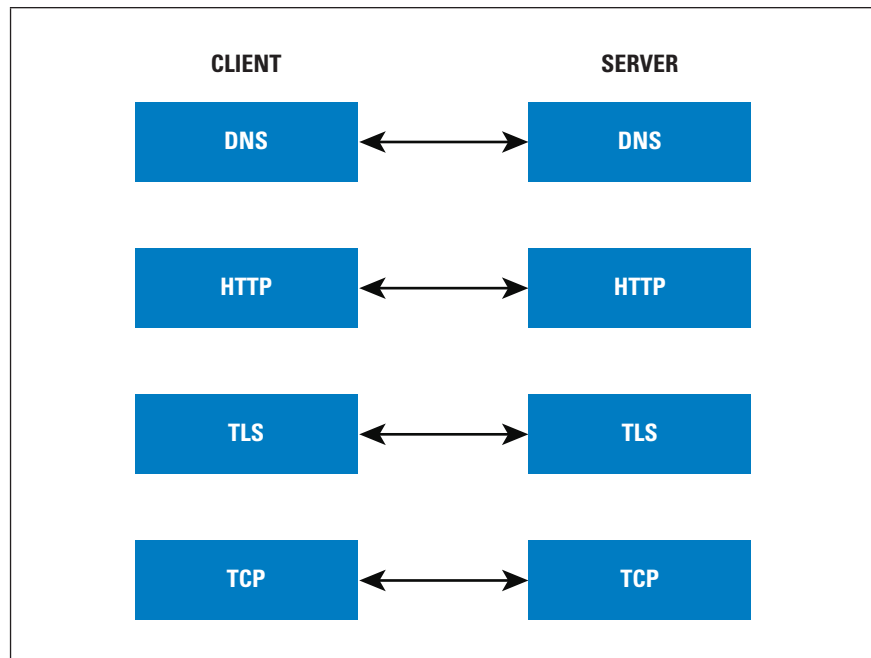

Is DoT going anywhere? It is unlikely in my view. Right now, it requires users to play with their DNS settings, and that is a massive barrier to widespread use. Some users may use it as a means to jump across one set of recursive resolver's DNS filters, such as those provided by their ISP, to hook up with another DNS resolver provider, but with the overt signalling that this is happening, an ISP can readily block this action if it wants to. In theory, the use of TCP permits larger DNS payloads, and we could possibly use *DNS Chaining*^[13] to make DNSSEC validation fast and efficient on end systems using DoT. But so many other preconditions, including server provisioning of DNS Chained responses and a reliable way for the DNS to manage large responses, mean that it is still a distant glimmer of a possibility and nothing more.

DoT is seen as a replacement for the existing DNS infrastructure service, where the DNS is a service located on the common platform and applications use the same DNS resolution calls to the platform as they always have. It's a platform approach to securing the DNS. Adoption is probably going to require some form of automated provisioning that typically involves the local access service provider.

Given that the major compromise threat actor here is the same access ISP, and given that the ISP operates the recursive resolver in any case, it's very challenging to understand the incremental benefit of DoT deployment to an ISP. Perhaps it may be that its benefit is as a barrier to other hosts in the local network. Local residential and enterprise environments are cluttered with IP stacks from many providers. A compromised stack is inside the external firewalls and is trusted merely by its physical location. DoT shifts the conversation of a DNS host into a protected channel where the protection is against other hosts on your local network!

DNS over HTTPS (DoH)^[20, 27] uses the same TCP and TLS foundations, but adds an HTTP context to the transactions. (Figure 3) A couple of changes here are interesting. The first is the switch to TCP port 443. It looks like any other HTTPS traffic and is not so readily identified in the network as being DNS traffic. Second, the DoH servers do not need to use dedicated IP addresses. Like the web itself, the HTTP protocol allows for named service points. And with TLS 1.3, with ECH you can conceal even the server name in an encrypted envelope. But there is a little more. HTTPS is an application-level protocol, and this approach allows an application to bypass the DNS services the platform provides. Therefore, no ISP-based platform-level configuration is necessarily relevant, and the application can not only conceal its DNS transactions from the local and remote networks, it can also hide these same transactions from the platform and other applications running on the same platform.

Figure 3: DNS over HTTPS (DoH)

If this development heads to DNS over HTTPS/3^[21], which uses *Quick UDP Internet Connection* (QUIC)^[22, 26], then numerous capabilities are unlocked. Not only is the transport control protocol cloaked behind an encryption envelope in QUIC, but you can make many DNS requests on a single transport channel simultaneously.

How far can we go with this effort to advance a privacy agenda in the DNS? Once we've deployed Query Name Minimisation, discarded Client Subnet, adopted DoH using HTTPS/3 as the application-to-recursive resolver protocol, and pushed DNSSEC validation to the application via attached chained DNSSEC responses, then you have realized much of the achievable trust and privacy agenda. At that point, much of the ability for a third-party onlooker to associate an end-entity identity with a DNS request is severely curtailed, and while a recursive resolver is still privy to these user transactions, the use of DNSSEC all the way to the edge makes response manipulation by any external party, even the recursive resolver itself, particularly challenging when the original DNS data is DNSSEC-signed.

The DNS privacy effort is moving on. The current question is: Should we encrypt the paths between a recursive resolver and authoritative servers? Assuming that Client Subnet has been abolished, there is little that such transactions directly reveal about the identity of the end user, and the larger the pool of clients that a recursive resolver serves, the larger the crowd each individual's queries can hide in. Irrespective of the questions of whether it is feasible (it is) and whether it is scalable (no clear answer, but it looks to have an appreciable incremental cost), the fundamental question of whether channel privacy makes any sense in a privacy context for the individual end user remains.

Other Topics

Other aspects of the technology evolution of the DNS are covered in the following sections.

Internationalized Domain Names (IDNs)

The DNS has traditionally used a 7-bit ASCII code for names. Upper and lower case are equivalent, and in addition to the Latin characters, DNS labels can use hyphens and number characters. In certain circumstances the underscore is also permitted. The expansion of the DNS into a larger character repertoire^[23] has not been a stellar success. The design decision was to preserve the capabilities of the DNS system and use encoding to map the larger character set into this restricted alphabet.

The choice of *Unicode*^[28] as the underlying character repertoire for this expanded character set was not a very good choice. Unicode involves a contract between an application and a printer. It does not matter that Unicode has multiple ways to print the same glyph on a printer. The printer does not care. But the DNS cares. The DNS has no concept of “what it means,” and alternate Unicode strings that are presented in an identical way on a screen actually map to distinct DNS names. So, the effort in the use of Unicode in the DNS has been one of trying to push the Unicode glyph set back into the box and try to specify canonical subsets of Unicode that minimise display similarity. This request is tough, and made even harder by the increasing variance in display glyphs used to display the same Unicode code point. This challenge is most evident in emoji characters.

Why is it a problem? Because the Internet still works on a rather crude model of “what you see is what you get.” If alternate ways of coding the same visual outcome are possible, then they are distinct labels in the DNS and can be associated with distinct service points. The possibilities to dupe unsuspecting users is of course a natural and inevitable outcome of this process.

DNS Abuse

These days “DNS Abuse” is a current topic, particularly in the *Internet Corporation for Assigned Names and Numbers* (ICANN) world. The phrase describes an effort to engender a level of self-regulation in the DNS supply industry, where behaviours are governed largely by contractual provisions between the registrant and the registrar, and between the registrar and a common registry. It allows various forms of abusive behaviours, including criminal activities, that use the DNS to be sanctioned by contractual enforcement including takedown of the DNS names. It’s a lot like the self-regulatory measures that are common in the finance industry, but without the reporting framework, without any common legal framework for enforcement, and without any penalties for breaches.

My suspicion is that it will turn out to be no more effective than the similar measures to undertake self-regulation in the finance sector, and probably even more ineffectual than the rather unimpressive results that the banking sector has posted. It's unlikely to be successful in reducing the levels of abusive and criminal behaviour that use the DNS and the Internet.

DNS Fragmentation

DNS fragmentation is also a perennial topic in the evolution of the name space. The pressures for a single, consistent name space are embedded in the concept of a single network. Communications systems rely on assumptions of referential integrity, and referential integrity typically implies that the same DNS name refers to the same resource.^[24]

We've seen this concept tested many times, from alternate root systems of a couple of decades ago to private name spaces today in the enterprise environment. A good case in point about referential fragmentation is the use of search terms as a replacement for the DNS. The objective of a search engine is to try to customise the responses to best match the known preferences of the querier, and when *I* attempt to pass a pointer to you about a digital resource, the search term that I use that will expose this resource may not be exposed when *you* enter the same search term in your context. This possible difference is not only an attribute of search engines, but a feature.

However, DoH enables other forms of DNS fragmentation. It enables you to lift a name space out of common network infrastructure and place it into the context of an attribute of an application. The application can direct DoH queries to server infrastructures of its own choosing and provide responses that pertain to the application as distinct from a lookup in a common distributed database. The ability in HTTPS to push objects to the application client also allows you to use so-called *Resolverless-DNS*^[25], where an application can improve the performance of name resolution functions by performing them in advance of the time they are needed.

Name Flattening

DNS *name flattening* has been a constant pressure in the DNS. Nobody wants to have their critical service names **buried.deep.down.in.the.dns.under.a.bunch.of.other.names**. Not only do such names take longer to resolve, they increase the set of dependencies in the same way because presumably a greater number of service providers all the way down in the name hierarchy exist. DNS users want shorter names. The shorter the better. The result is that the name space is under constant erosive pressure to flatten down. The ultimate place to land is in the top level of the DNS, in the root zone, and as the price premium for top-level domain comes down, the pressure to inflate this zone with significantly larger numbers of entries is an inevitable consequence.

The Future of Names

But perhaps the forces of evolutionary pressure are more fundamental and parallel the evolutionary forces of the Internet itself.

The silicon industry is indeed prodigious, and there are many more processors in this world than people. While we have constructed the DNS name space using an analogue of natural language terms as a means of facilitation of human use, this use pattern is not necessarily the dominant use pattern of the DNS any longer. One view of the DNS today is a universal signalling and tunnelling protocol, and the use of the DNS as a command-and-control channel for malware bot armies testifies to the efficacy of such use of the DNS!

It's likely that as the number of such devices increases, the use of the DNS as an orchestration mechanism increases in importance and the human use of the DNS becomes increasingly marginalised. Human-use DNS may well become an esoteric luxury business. The high-touch activity of DNS name management is unsustainable in a shift from human to largely automated use, and the business models and institutions that populate this space will need to adjust to a names business that provides names not as a branding attribute using natural language tokens, but as an undistinguished commodity activity. In the same way that we have transformed IP addresses from end-point identifiers to ephemeral session tokens, we may well see the DNS as a code base for command and control of highly distributed automated systems, and that is very different from the distributed database lookup that we originally constructed for the human-use model of the DNS.

When we think of a DNS query as a set of instructions to a DNS server, and the DNS server as a distributed processing environment, the DNS changes from a distributed database to a distributed computation and signalling environment. The composition of labels in such a DNS is no longer roughly derived from dictionaries of known words from human languages, but instead is encoded instructions where the labels are in effect a coded program for a name resolver to execute. It is certainly a different future for the DNS as we know it, but its probable commoditisation in the future is in line with the plight of carriage, switching, and content in the Internet!

From this perspective, the evolution of the DNS parallels the larger evolution of the Internet itself, where the infrastructure is not about a human-usable framework any longer, but instead is focussed on providing a highly automated environment where the elements are themselves programs and automata.

That does not mean that the human-use DNS will disappear. But the DNS as we know it today may end up as a small set of high-end luxury boutique activities that make a feature of the luxury of custom procedures to manage persistent names.

In the meantime, the rest of the DNS heads deeper into a commodity utility world of large sets of algorithmically generated transient names that are managed entirely automatically and tailored for one-off use by other processes. It may be that the overwhelming use of tomorrow's DNS has nothing much to do with human names any longer and will be concentrated on serving a largely automated framework that uses the DNS to support a general command-and-control signalling framework. Ephemeral names are as good as, if not better than, persistent names. Registration and attribution processes are largely irrelevant.

The DNS may still be valuable, but individual names will be completely worthless!

- [30] Geoff Huston, “DNS Oblivion,” APNIC Labs, December 15, 2020.
<https://labs.apnic.net/?p=1392>

GEOFF HUSTON, B.Sc., M.Sc. A.M., is the Chief Scientist at APNIC, the Regional Internet Registry serving the Asia Pacific region. He has been closely involved with the development of the Internet for many years, particularly within Australia, where he was responsible for building the Internet within the Australian academic and research sector in the early 1990s. He is author of numerous Internet-related books, and was a member of the Internet Architecture Board from 1999 until 2005. He served on the Board of Trustees of the Internet Society from 1992 until 2001. At various times Geoff has worked as an Internet researcher, an ISP systems architect, and a network operator. E-mail: gih@apnic.net

Opinion: What Have We Done?

by Geoff Huston

One of the roles of an opinion piece is to challenge your assumptions and present alternative perspectives, and that is certainly what I plan to do here. You may not agree with my views. I'm not even sure that I agree with them all of the time, because some of these opinions are pretty bleak. But if this article provokes you to make your own assessment of the Internet in a broader context of the evolving relationship between society and this technology, then that is perhaps as much as I could ever hope to achieve here. I should also say that I'm writing this opinion piece as an individual and nothing more. I am not pretending to speak on behalf of my employer in any way. These are *my* words and thoughts.

I was asked to speak at an *Internet Governance Forum* during the COVID-cursed year of 2020. I was briefed that “the most useful thing would be to hear your thoughts on what are the big issues at the moment. Where you see things heading. It would mean that you’d be speaking on your areas of interest from your perspective, not necessarily trying to channel some sort of universal Internet zeitgeist.”

I have found this brief a challenging one. In some decades of working in this space I’ve heard many boom-and-bust talks. In addition, I have seen techno-exuberance reach dizzying heights—and then expositions of sobering realities bring it all back to Earth. But behind this phenomenon I have not seen many perspectives that challenge the very fundamentals of the Internet. We appear to assume that the technology is either beneficial, or at worst neutral, and it’s the humans in the loop that overreact. Perhaps, even more dangerously, we assume that the technology is competently implemented. This assumption is perhaps the most dangerous one!

My personal view is that we are heading to a Bad Place. A *very* Bad Place.

A Revolution

Compared to our somewhat naive expectations about the role of computers and networking in the 1980’s, we have come a long way down a path that now seems to have taken a turn into some dark—and possibly malign—spaces. How else could we have ended up in accusations of rigged elections, “fake” news, and truly bizarre paranoid notions of some form of “deep state” that seems to sit within the collective social psyche these days. But it’s not all just a parade of some ridiculous memes that appear to be rooted in human credulity, because we also have to acknowledge the wholesale destruction of livelihoods and the creation of a new technology economy that is based largely on surveillance capitalism. The digital automation of our society has a highly disruptive aspect, and I think we can confidently assert that we are in the middle of a social revolution as fundamental as the industrial revolution. However, in this case we seem to have backed into this one with our eyes closed.

How could we have missed all the signals? Why are we still thinking that the old social contracts are still valid when they are clearly broken? What went wrong? Well, I'm sure exploring that subject would make a great thesis, but we have two problems. Firstly, I have only a few minutes of your time with this article, and secondly, I really don't know why it all went so wrong anyway! So, without truly knowing how it happened, we find ourselves trapped in another massive revolution.

What advice can I offer? Well, if we are talking about social revolutions, then I should say, "Don't trust that Robespierre guy. He's going to kill us all!" Or perhaps, "Napoleon is a genocidal maniac! He hasn't come back from Elbe to make it all better!" But such dire warnings are ineffective because no one listens.

What should I say here?

Perhaps I should simply apologise for my small part in this mess we find ourselves in.

Because it has all turned out so horrendously bad, I think we should have been more aware of the risks, even if at the time they may have sounded totally far-fetched. We said of the Internet: "This is so good everyone should be able to play." And we said: "The Internet is for everyone." But we never really thought about what we really meant when we proclaimed the universality of the Internet. "Everyone should be able to do this?" has turned into "What have we done to ourselves?"

Code

I am probably not a brilliant programmer. In fact, I should admit that I'm a shocking programmer—and I know I'm not the only one. In fact, I'm probably pretty average as a coder. And if that's the average in our profession, then all I can say is that we are all shockingly bad programmers.

We are building these massive edifices of mind-boggling complexity and then replicating all this rather shoddy software in billions of devices. We were told to "move fast and break things," and we did exactly that. We learned to use the end user as the test case. But the consequences are ugly. Your average car has at least 300 processors and huge amounts of code. It mostly works, but just remember that the network that contains the drive control systems also probably contains the entertainment system. *And all this complexity is probably provided by the lowest bidder!* It's cheaper that way. And much riskier. Modern machinery is now at a level of complexity that visibly defies human understanding or control. God alone knows exactly what is in the software-controlled systems on a Boeing 737 Max 8. Boeing apparently does not. Or even the firmware in your fancy digital front doorbell. Bitter experience has taught us that we can turn a few hundred million baby web cams into a massively destructive attack force within seconds.

The *Key Performance Indicators* in our industry are best described by the currently oh-so-fashionable Agile process: “Let’s write even crappier code even faster, and let’s break more of it!”

Nobody knows how these systems work anymore. Nobody truly understands the dependencies anymore, if they ever did, and the continual stream of software upgrades should give you ample evidence that we are only just bailing out the bilge as fast as we can to stop the entire ship from sinking!

We spend hundreds of millions of dollars on staffing shiny cyber defence bodies to try to show what a great job we are doing to defend ourselves when, in fact, the problem is not the folks who are driving the hostile trucks through the wide-open doors. The real problem is that it’s the people just like me who produced the insanely poor code in the first place who left all these gaping holes behind them. Because none of us really is up to the task. And I don’t know about everybody else, but I am still on the keyboard. Still writing code. Collectively we have done an amazing job. The Internet is now busted! And it’s not clear that we can fix the problem. We can’t make it better. Sorry.

Security

It is evident that we have no desire to build truly secure systems. In the rush to digitise our world of services we are taking extraordinary risks. The term “web security” is the punchline to some demented sick joke because the online world is held together by a level of naive trust that makes all other forms of human credulity look restrained and cautious! Even when we thought about what better security might look like, the response was that we have neither the time nor the money to do a better job. We believe that the consumer is so impatient that milliseconds matter far more than security. We continue to cut corners and build fast, faulty code. Maybe we should have said “no” and walked away from the keyboard. But we didn’t. Sorry.

We thought we were helping people communicate, because after all, communication is what drives the human experience. We knew that if you change how we communicate you change the nature of human society. We knew that. But we didn’t consider that message seriously. None of us envisioned the perversion of that nobly motivated ambition into the incessant deluge of waste products from the social media factory. We only appreciated the role of content mediators when we eliminated them from the planet. This situation is not pretty. We choose to listen only to what we agree with. The Internet has become a vanity-reinforcing gigantic distorted selfie. Sorry.

No Rules

We built this new world so quickly that we outpaced everything else. This new technology has no controls, no regulation, no competition. In the rush to be the first to unleash the ruthless forms of surveillance capitalism on an unsuspecting populace, we have bypassed all the conventional forms of care and restraint. Just seven digital giants dominate our world.

Their unstinting efforts to lobby politicians has turned the political process into a fatally corrupted empty shell. We moved too quickly and no one else kept up.

We wrote our own rules, and Rule Number One was: “Just do it.” From Uber to Google the word was “disruption.” But the wholesale destruction of the old-world business environment wasn’t the worst thing we did. Destruction of retail shopping wasn’t the worst thing we did. Far worse is that we privatised the public communications space. We turned our culture and our public discourse into private property. We privatised our intellectual achievements. Who owns antibiotics? Who owns my genetic code? Who owns my personal profile? We turned everything into a transaction. We destroyed our libraries and replaced them with search engines. We replaced journalism with tweets. Our world is no longer a collection of public spaces, but a collection of private enclosures. In some small way, I helped build that reality. Sorry.

No Way Back

Can I provide some helpful suggestions, offer some motivation, or provide some palliative comfort by asserting that our voices matter, and we can change our world for the better? No. I think that we already betrayed you 30 years ago. The glittering prizes that this new technology promised us turned out to be tawdry, corrupted, and debased. We thought technology would be a compelling force for good. We were wrong. I am truly sorry.

The task before us right now is not to make it better. That is way too ambitious. We just can’t make it better. There is no way to back out now. Having unleashed these digital monstrosities, we cannot just tie them up again and put everything back into a box. That we cannot do. The best we can do is to somehow accept the terrible situation and the betrayal of trust that got us here and try to deal with it without making it even worse.

Sorry.

—*Geoff Huston*, gih@apnic.net

Upcoming Articles in IPJ

“Automatic Disaggregation in the Routing in Fat Trees (RIFT) Protocol,” by Bruno Rijsman. RIFT is a new routing protocol being defined in the IETF. This article focuses on one particular feature of RIFT, namely automatic aggregation and disaggregation.

“Network Functions Virtualization (NFV),” by William Stallings. NFV provides a powerful, vendor-independent approach to implementing complex networks with dynamic demands. NFV builds on well-established technologies, including virtual machines, containers, and virtual networks. With the demand from 5G and cloud service providers, as well as enterprises with large internal networks, NFV is becoming an increasingly widespread technology.

Postel Service Award Presented to Onno W. Purbo

The Internet Society, a global nonprofit organization that promotes the development and use of an open, globally connected, and secure Internet, recently presented the prestigious *Jonathan B. Postel Service Award* to Onno W. Purbo for his sustained and substantial technical contributions, leadership, and service to the global Internet community.

Named in honor of the technical community legend Jonathan Postel, this award recognizes extraordinary people like Mr. Purbo who have committed themselves to the technological development, growth, and strength of the Internet. Known as “Indonesia’s Internet

Liberator,” Mr. Purbo is a prolific and well-published Internet advocate who has played a key role in democratizing Internet access, making it more affordable especially in Indonesia’s rural areas.

“Mr. Purbo’s contribution to the digital sector is invaluable and this award marks what he has achieved and inspired others to achieve. His initiative of meaningful Internet access and Community Networks have instilled the growth of not only affordable but accessible Internet in various areas across Indonesia. I am confident this award will embolden others to innovate and follow his steps and overcome the challenges in their communities especially in improving digitalization,” said Johnny Plate, Minister of Communication and Information Technology for Indonesia.

Of his many achievements, Mr. Purbo is best known for pioneering the Internet in Indonesia through sophisticated use of wireless and *Voice over Internet Protocol* technologies. He led the first Internet connection at the Institute of Technology in Bandung and used it to build the first Indonesian educational network. He also championed the deregulation of WiFi frequencies and introduced cyber cafes, neighborhood networks, and community cellular networks to Indonesia. Mr. Purbo organized the first community telephony network over Internet and led the re-introduction of ICT into the Indonesian high school curriculum.

Currently, he is involved in the largest Indonesian FREE e-Learning service, which has brought more than 700 courses to nearly 40,000 participants and trained more than 8,000 teachers on e-learning operations.

“It is an honor to receive the highest and priceless acknowledgment given to Indonesia from the Internet communities,” said Mr. Purbo.

“With modified simple off-the-shelf gadgets and equipment, one may fulfill the right to access information and knowledge, which is the necessary foundation for any nation to move forward. The Internet Society has acknowledged the approach is one of the right routes towards the Internet for all. The job is indeed not finished. The Postel Service Award sheds light on the way to go for all of us and inspires extraordinary enthusiasm for moving towards a knowledge-based society.”

Mr. Purbo was selected by a distinguished international committee comprised of former Postel Award winners which includes Internet visionaries and luminaries. Now in its 21st year, the Postel Award was established in 1999 by the Internet Society to honor individuals and organizations that, through their work, embody the spirit of Jonathan Postel, whose technical influence can be seen at the very heart of many of the protocols which make the Internet work. Andrew Sullivan, President and CEO of the Internet Society, presented the award, which includes a US\$20,000 honorarium and a crystal engraved globe, during a virtual ceremony as part of the 109th *Internet Engineering Task Force* (IETF) meeting which took place November 16–20, 2020.

History of Networking Recordings

Russ White writes: “In 2017, I realized a lot of the people I’ve worked with over the years were retiring. When these people leave the networking community, they take a wealth of knowledge about the intent, challenges, and inventions of the early Internet. I decided to capture as much of this history in oral format as possible—hence the history of networking recordings were started. I thought, at first, this would be a small, short-lived series, but I have been amazed by the reaction of the community, and the number of technologies and organizations involved in the design and operation of computer networks.

If you know of someone who should be here, please contact me, as I would like to collect as much oral history in this area as I can for this and future generations. These recordings are released under Creative Commons License (CC BY-NC-ND 4.0). This means recordings can be distributed for any noncommercial purposes by anyone, so long as they are released in full (with no modifications).”

The recordings can be found here:
<https://rule11.tech/history-of-networking/>

NSA Recommends How Enterprises Can Securely Adopt Encrypted DNS

The *National Security Agency* (NSA) recently released a cybersecurity document, “Adopting Encrypted DNS in Enterprise Environments,”^[1] explaining the benefits and risks of adopting the encrypted *Domain Name System* (DNS) protocol, *DNS over HTTPs* (DoH), in enterprise environments. The document provides solutions for secure implementation based on enterprise network needs.

DNS translates domain names in URLs into IP addresses, making the Internet easier to navigate. However, it has become a popular attack vector for malicious cyber actors. DNS shares its requests and responses in plaintext, which can be easily viewed by unauthorized third parties. Encrypted DNS is increasingly being used to prevent eavesdropping and manipulation of DNS traffic. As encrypted DNS becomes more popular, enterprise network owners and administrators should fully understand how to properly adopt it on their own systems. Even if not formally adopted by the enterprise, newer browsers and other software may try to use encrypted DNS anyway and bypass the enterprise’s traditional DNS-based defenses.

DoH encrypts DNS requests, preventing eavesdropping and manipulation of DNS traffic. While good for ensuring privacy in home networks, DoH can present risks to enterprise networks if it isn’t appropriately implemented. The recommendations detailed will assist enterprise network owners and administrators in balancing DNS privacy and governance for their networks. It outlines the importance of configuring enterprise networks appropriately to add benefits to, and not hinder, their DNS security controls. These enterprise DNS controls can prevent numerous threat techniques used by cyber threat actors for initial access, command and control, and exfiltration.

NSA recommends that an enterprise network’s DNS traffic, encrypted or not, be sent only to the designated enterprise DNS resolver. This ensures proper use of essential enterprise security controls, facilitates access to local network resources, and protects internal network information. All other DNS resolvers should be disabled and blocked.

NSA seeks to regularly release unique, actionable, and timely cybersecurity guidance to secure the Department of Defense, National Security Systems, and the Defense Industrial Base. For more information or other cybersecurity products, visit:

<https://www.NSA.gov/cybersecurity-guidance>.

WebRTC Becomes a Standard

The *World Wide Web Consortium* (W3C) and the *Internet Engineering Task Force* (IETF) recently announced that *Web Real-Time Communications* (WebRTC), which powers myriad services, is now an official standard, bringing audio and video communications anywhere on the Web.

WebRTC, comprised of a *JavaScript* API for Web Real-Time Communications and a suite of communications protocols, allows any connected device, on any network, to be a potential communication endpoint, on the Web. WebRTC already serves as a cornerstone of online communication and collaboration services. The WebRTC framework provides the building blocks from which web and app developers can seamlessly add video chat to a range of applications, including tele-education and tele-health, entertainment and gaming, professional and workforce collaboration.

With the foundations standardized and deployed as a royalty-free feature in Web browsers and other devices and platforms, setting up a secure audio-video communication system with WebRTC has become a built-in capability, eliminating the need to install plugins or download separate applications.

WebRTC is massively deployed as a communications platform and powers video conferences and collaboration systems across all major browsers, both on desktop and mobile. Billions of users can interact now that WebRTC makes live video chat easier than ever on the Web. In commercial products and open source projects, WebRTC has vastly expanded the ability to deploy real-time interaction solutions to customers and users.

The year 2020 has shown both how critical WebRTC already is in a world where travel and physical contacts need to be limited, as well as the many improvements that can be brought to the technology to address new usages that have emerged. Organizations are leveraging WebRTC to conduct training, interviews, strategic planning or as a substitute for in-person meetings. Schools and universities have shifted to virtual learning platforms. Families and friends make daily use of products that are built with WebRTC or parts of it.

With the use of WebRTC expanding beyond the initial core design to power video conferences and collaboration systems in web browsers and other ecosystems, more features and more optimizations are now needed. The IETF *WebTransport* work is aiming to build out additional web support for a variety of transport properties. The *WebRTC Ingest Signaling over HTTPS* work is focusing on the development of a protocol to support one-way WebRTC-based audiovisual sessions between broadcasting tools and real-time media broadcast networks. Similar work to expand the use cases of WebRTC is ongoing in the W3C. For more information visit:

<https://www.w3.org/TR/webrtc/>

<https://www.ietf.org/blog/webrtc-milestone/>

Nominations Open for Prestigious Internet Hall of Fame

The Internet Society recently announced that nominations are now open for the next *Internet Hall of Fame* class of inductees. The nomination period will close April 23, 2021 and inductees will be announced at an awards ceremony to be held later this year. The Internet Hall of Fame, now in its tenth year, recognizes a select group of visionaries, leaders and luminaries who have made significant contributions to the development and advancement of the open, global Internet.

Through the work of these individuals, including Vint Cerf, Robert Kahn, Leonard Kleinrock, Tim Berners-Lee, and Elizabeth Feinler, among many others, the Internet Hall of Fame reflects the history of the Internet's development and evolution.

"At no point in time has the importance of the Internet and its chief characteristic—to connect—been felt so broadly, and so acutely," said Andrew Sullivan, President and CEO of the Internet Society.

"The critical role the Internet has played throughout the pandemic reinforces now, more than ever, the significance of the people who originally conceived, built, guided and promoted this global network. It is our privilege to highlight their work and contributions."

Individuals worldwide who have played an extraordinary role in the conceptualization, building, and development of the Internet globally will be considered for induction. In addition to those who have been more visible, the Internet Hall of Fame also seeks nominees who have made crucial, behind-the-scenes contributions. Criteria for evaluation include:

Impact: The contribution has made an extraordinary impact on the development or growth of the Internet, and was and may still be directly relevant to the Internet's ongoing advancement and evolution.

Influence: The contribution, relative to the Internet, has significantly influenced: 1) the work of others in the field; 2) society at large; or 3) another more defined but critical audience or region.

Innovation: The contribution has broken new ground with original thinking/creativity that has established new paradigms, eliminated significant obstacles, or accelerated Internet advancements.

Reach: The contribution has significantly impacted the Internet's reach among society at large, within key audiences or specific geographies, with global impact.

Founded in 2012, the Internet Hall of Fame is an ongoing awards program established by the Internet Society to recognize a distinguished and select group of leaders and luminaries who have made significant contributions to the development and advancement of the global open Internet. More information on the program can be found at <http://www.internethalloffame.org/>.

Domain Abuse Activity Reporting

ICANN's *Domain Abuse Activity Reporting* (DAAR) project is a system for studying and reporting on domain name registration and security threat (domain abuse) behavior across *top-level domain* (TLD) registries. The overarching purpose of DAAR is to develop a robust, reliable, reproducible, and replicable methodology for analyzing security threat activity that can then be later used by the ICANN community to facilitate informed policy decisions.

The system collects TLD zone data and complements these data sets with a large set of high-confidence reputation (security threat) data feeds. The aggregated and anonymized data collected by the DAAR system can serve as a platform for studying or reporting daily or historical registration or abuse activity by each registry. The data is currently being pushed to registries using the ICANN *Service Level Agreement Monitoring* (SLAM) system.

The data collected out of the DAAR system is being used to generate the DAAR monthly reports. The reports are point-in-time analysis of all TLDs for which data was available. The report provides aggregated statistics and time-series analysis about security threats of interest to DAAR namely phishing, malware, spam, and botnet command-and-control. For more information visit:

<https://www.icann.org/octo-ssr/daar>

Read Any Good Books Lately?

Then why not share your thoughts with the readers of IPJ? We accept reviews of new titles, as well as some of the “networking classics.” In some cases, we may be able to get a publisher to send you a book for review if you don’t have access to it. For more information, contact us at ipj@protocoljournal.org

Check your Subscription Details!

If you have a print subscription to this journal, you will find an expiration date printed on the back cover. For several years, we have “auto-renewed” your subscription, but now we ask you to log in to our subscription system and perform this simple task yourself. Make sure that *both* your postal and e-mail addresses are up-to-date since these are the only methods by which we can contact you. If you see the words “Invalid E-mail” on your copy this means that we have been unable to contact you through the e-mail address on file. If this is the case, please contact us at ipj@protocoljournal.org with your new information. The subscription portal is located here: <https://www.ipjsubscription.org/>

Thank You!

Publication of IPJ is made possible by organizations and individuals around the world dedicated to the design, growth, evolution, and operation of the global Internet and private networks built on the Internet Protocol. The following individuals have provided support to IPJ. You can join them by visiting <http://tinyurl.com/IPJ-donate>

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

Thank You!	32
Call for Papers	34
Supporters and Sponsors	35

Since the launch of *The Internet Protocol Journal* in 1998, we have covered several aspects of the core technologies used in the global Internet and in enterprise networks. Routing protocols such as the *Border Gateway Protocol* (BGP) continue to play a critical role in the operation of these networks, but other routing protocols are being developed by the *Internet Engineering Task Force* (IETF) for use in data center environments. One such protocol is the *Routing in Fat Trees Protocol* (RIFT).

Route *aggregation* is used to summarize a set of specific routing-table entries into a single, less-specific route, in order to reduce the size of routing tables. Disaggregation is the opposite of aggregation whereby an aggregate route is divided into several more-specific routes. In our first article, Bruno Rijsman explains how automatic disaggregation is accomplished in RIFT.

Security has also been a recurring theme in this journal. Most of the protocols used in today's Internet were originally designed without comprehensive security in mind, but the IETF has produced security enhancements for many of the core protocols. Securing the routing system itself has proven challenging because it requires widespread deployment in order to be effective. Starting with our next issue, Geoff Huston presents a two-part article entitled "A Survey on Securing Inter-Domain Routing." Make sure your subscription details are up to date!

The IETF is, of course, not the only organization that produces standards for computer networks. Our second article, by William Stallings, is an overview of *Network Functions Virtualization*, an emerging set of standards being developed by the *European Telecommunications Standards Institute* (ETSI).

The generous support of individuals and organizations makes publication of this journal possible. We are pleased to welcome our latest sponsor, *The APNIC Foundation*. More information about the foundation is available on page 30 of this issue.

Automatic Disaggregation in the Routing in Fat Trees Protocol

by Bruno Rijsman

Routing in Fat Trees (RIFT) is a new routing protocol being defined in the *Internet Engineering Task Force* (IETF).^[1] RIFT is optimized for large networks that have a highly structured topology such as fat tree, *Clos*, or similar topologies. It is typically used as a scalable and fast-converging *Interior Gateway Protocol* (IGP) for the underlay in data centers, but it has other use cases as well.^[2]

RIFT brings several innovations to the table without requiring any changes to existing networking hardware (“silicon”), including:

- *Zero Touch Provisioning* (ZTP) virtually eliminates the need for configuration and auto-detects miscabling.
- RIFT is *anisotropic*: it is a link-state protocol north-bound and a distance-vector protocol south-bound, combining the advantages of link-state with the advantages of distance-vector/path-vector.
- RIFT is inherently loop-free, allowing it to distribute traffic across all available paths (not just the shortest path).
- A built-in flooding-reduction mechanism greatly reduces flooding traffic in densely connected topologies such as fat trees.
- With the automatic aggregation feature, in the absence of failures, each node needs only a single multi-path default route pointing north. This feature reduces the size of the routing tables at or close to the leaf nodes, and hence the cost of top-of-rack switches.
- With the automatic disaggregation feature, if a failure occurs the north-bound default route is automatically disaggregated into more specific routes, but only to the extent needed to route around the failure.
- RIFT supports large data-center networks without the need for splitting the network into multiple areas.
- RIFT offers very fast convergence—even in very large networks.
- Because of the simplicity of RIFT functionality on leaf switches, you can easily run it on servers; this feature is also known as *Routing on The Host* (RoTH). It enables support for multi-homed servers with automatic recovery from link and node failures.
- Model-based (Thrift) specification of the routing protocol messages accelerates development, enhances interoperability, and most importantly, improves security by removing most message-parsing vulnerabilities.

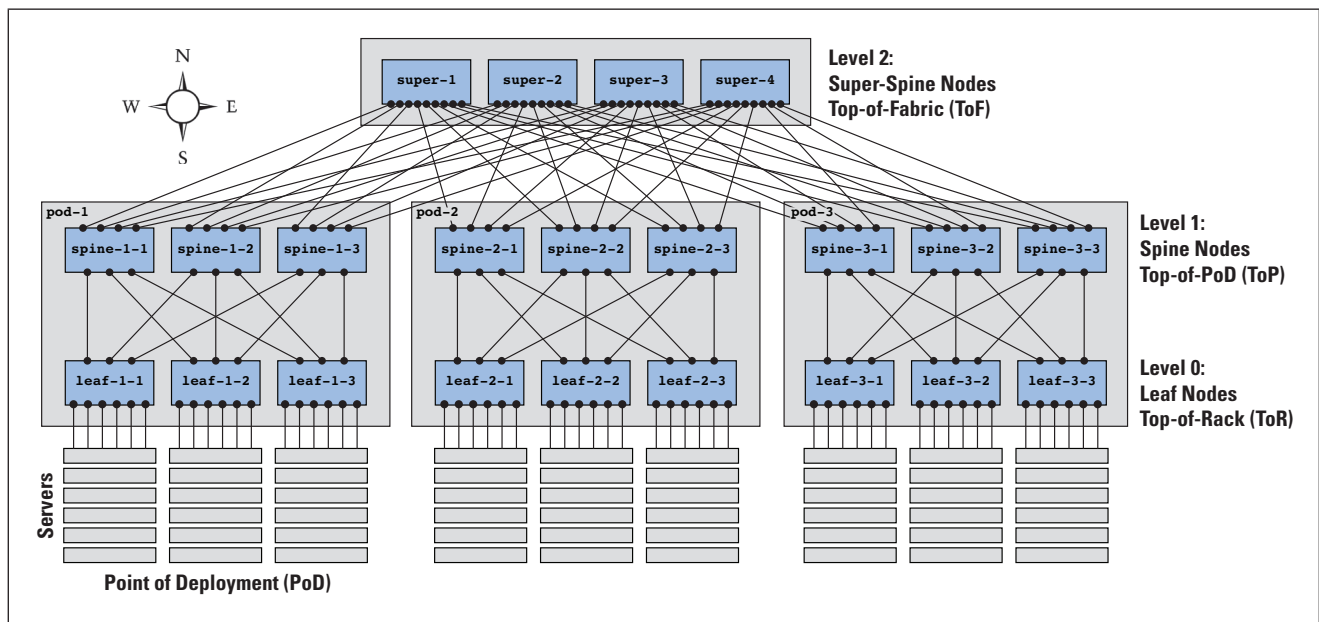

RIFT offers an open-source implementation^[3] and at least one commercial implementation.^[4]

In this article, we focus on one feature of RIFT: automatic aggregation and disaggregation, which is one of the most novel and most interesting innovations in the RIFT protocol. For a more general overview of RIFT, see the presentation at APNIC^[5] or the recently released (and free) *Day One book on RIFT*.^[6] For a discussion of link-state routing in data centers (including RIFT), see the article “Recent Developments in Link State on Data-Center Fabrics,” also published in this journal.^[7]

Introduction to RIFT

You can use RIFT in topologies where it makes sense to speak of north and south directions, which allows you to divide the nodes into levels, including fat-tree data center topologies such as the one shown in Figure 1.

Figure 1: Fat-Tree Data Center Topology

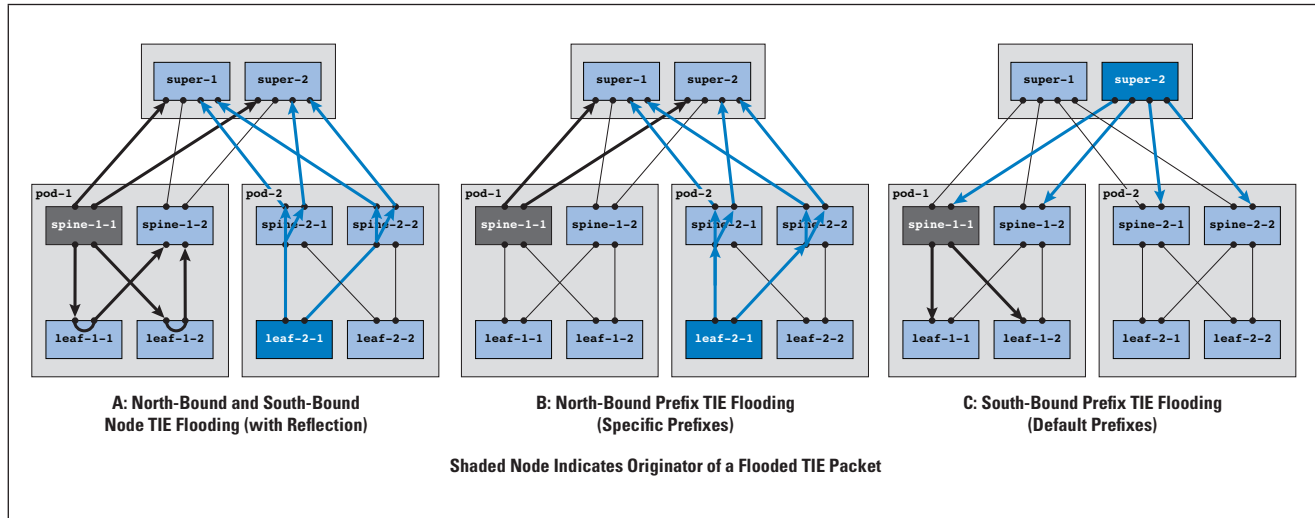

In many respects, RIFT is a link-state protocol similar to *Intermediate System-to-Intermediate System* (IS-IS):

- RIFT routers exchange hello packets, called *Link Information Element* (LIE) packets, to establish adjacencies with neighbor routers.
- RIFT routers originate link-state packets, called *Topology Information Element* (TIE) packets, to describe the state, adjacencies, originated prefixes, disaggregated prefixes, and other information about the router.
- RIFT reliably floods the link-state packets across the network. It uses *Topology Information Description Element* (TIDE) packets to summarize the contents of the link-state database and *Topology Information Request Element* (TIRE) packets to acknowledge and request TIE packets. Together, TIDEs and TIREs are used to make the flooding reliable.

- RIFT stores link-state packets in its *Link State Database* (LSDB).
- RIFT runs the *Shortest Path First* (SPF) algorithm on the topology stored in the link-state database to compute the shortest path to each destination.

RIFT is unique in that it has different rules for flooding TIE packets in both the north-bound south-bound directions, as shown in Figure 2:

Figure 2: TIE Flooding Rules

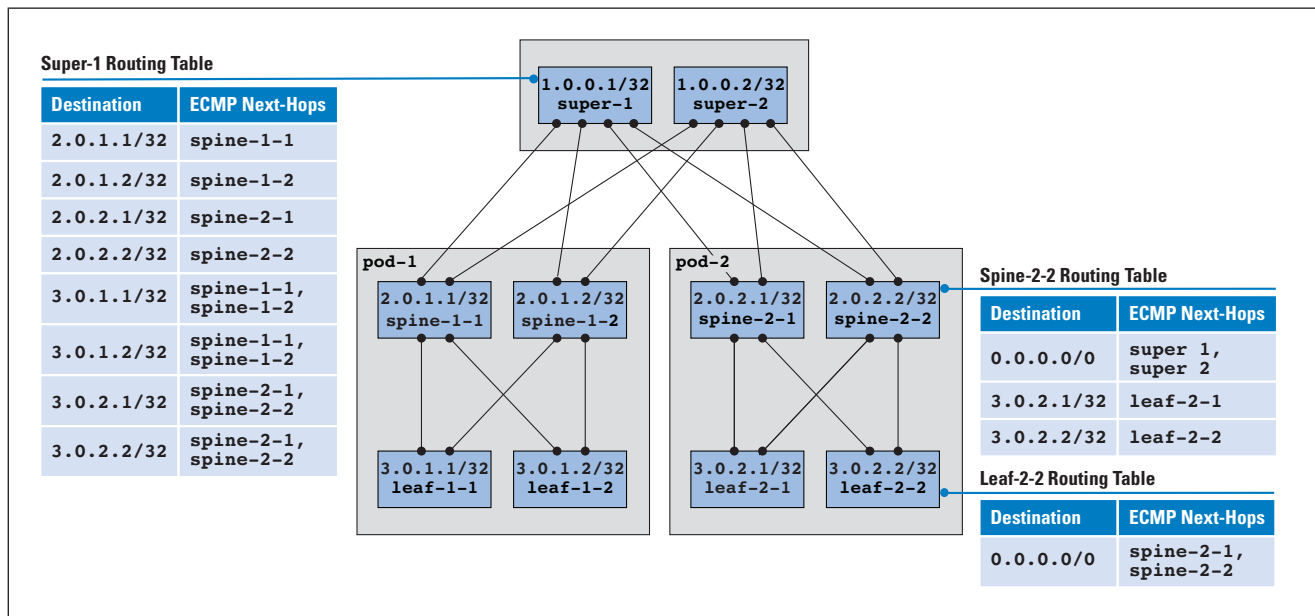

- Each node advertises its adjacencies in node TIEs that are flooded in both the north-bound and south-bound directions. Furthermore, the level just below the originator of the node TIE “reflects” the node TIEs back-up. This reflection allows nodes to discover the adjacencies of other nodes at the same level (refer to diagram A in Figure 2).
- Each node advertises its local prefixes in prefix TIEs, which are flooded only in the north-bound direction. (Shown in diagram B in Figure 2).
- Each node advertises a fabric default route (typically `0.0.0.0/0` and `::/0`) in prefix TIEs that are flooded exactly one hop (but no further) in the south-bound direction (see diagram C in Figure 2). The top-of-fabric nodes always originate a default, and the lower nodes originate a default only if they have received at least one default from a parent. This model makes the south-bound flooding similar to distance-vector routing and it is the reason that RIFT is colloquially described as link-state towards the spine and distance-vector towards the leaves.
- RIFT also allows for east-west “short-cut” links and has flooding rules for those links (not shown in the figure).

- RIFT also includes a flooding-reduction mechanism that avoids multiple copies of the same TIE being sent to the same node (that mechanism is not shown here). For example, in diagrams A and B in Figure 2 node super-1 receives two identical copies of the TIE from leaf-2-1.

After the TIEs are flooded across the network in the manner described previously, the RIFT nodes run the SPF algorithm to compute the routing tables. Actually, RIFT does at least two SPF runs: one for the north-bound and one for the south-bound direction.

Figure 3 shows an example of typical RIFT routing tables (in the absence of failures):

Figure 3: Typical RIFT Routing Tables in the Absence of Failures

We can see the following routes:

- *Specific routes for all south-bound traffic:* These routes are typically host /32 (for IPv4) or /128 (for IPv6) routes.
- *Fabric default routes for all north-bound traffic:* These routes are typically 0.0.0.0/0 or ::/0 routes.

Both the north-bound default routes and the south-bound, specific routes, are multi-path routes, distributing the traffic across all available paths. The next-hops can be weighted according to the bandwidth available on each path.

RIFT Automatic Aggregation and Disaggregation

The *aggregation*^[8] concept has existed in routing protocols since the beginning. Aggregation allows you to summarize a set of specific routes by a single, less-specific route, called the *aggregate route*. The most common use case for aggregation is to reduce the size of the routing table by summarizing unneeded details.

The concept of *disaggregation*^[9] has also been used for a long time. Disaggregation is the opposite of aggregation: it takes a single less-specific route (the aggregate route) and divides it into several more-specific routes. The most common use case for disaggregation is traffic engineering.

In existing protocols such as the *Border Gateway Protocol* (BGP), *Open Shortest Path First* (OSPF), and IS-IS, aggregation and disaggregation typically are manually configured for optimization purposes. In RIFT, on the other hand, aggregation and disaggregation are automatic and always enabled. RIFT automatically aggregates routes (typically to the default route) wherever possible. And RIFT automatically disaggregates routes wherever needed, for example, because of link or node failures.

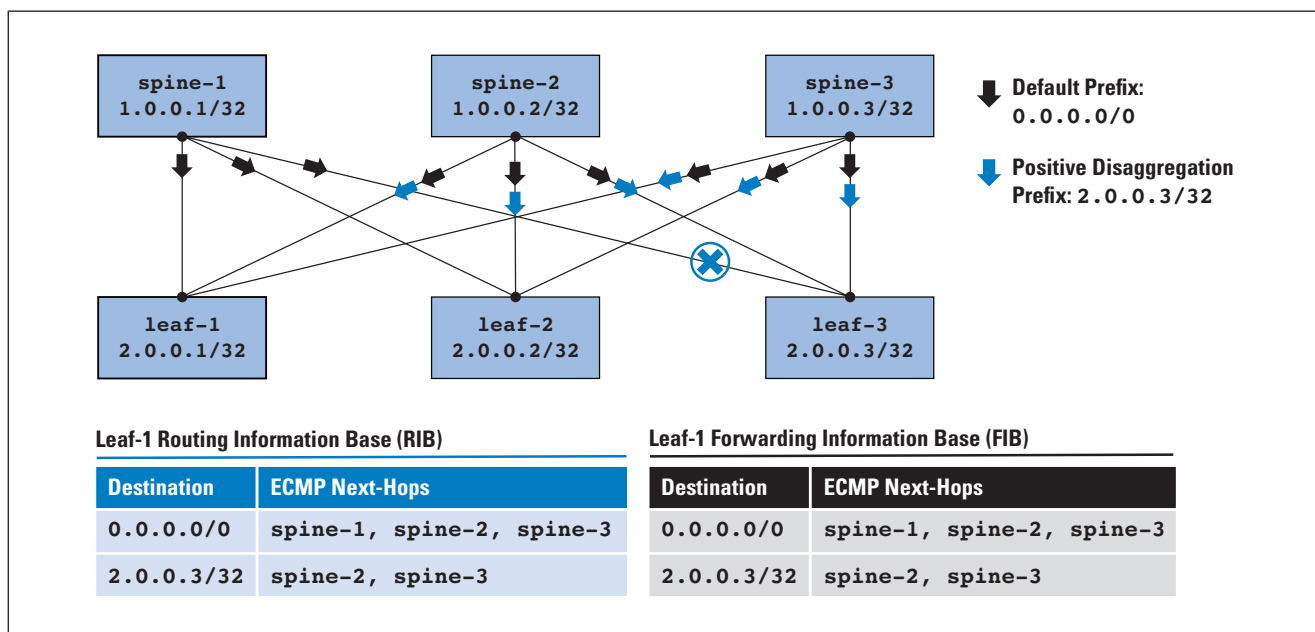

Disaggregation actually has two modes in RIFT:

- *Positive Disaggregation* works by advertising a more specific route to “attract” traffic to a repair path away from a failed path. Advertising more-specific prefixes is exactly how disaggregation works in existing protocols.
- *Negative Disaggregation* works by advertising a so-called *negative prefix* to “repel” traffic away from a failed path towards a repair path. This new mechanism does not have an equivalent in existing widely deployed protocols. Negative disaggregation is needed only in certain large topologies, namely multi-plane topologies.

RIFT Positive Disaggregation

Earlier we saw that RIFT normally uses default routes for north-bound traffic, which reduces the size of the forwarding tables, but it may cause traffic to be black-holed when a link failure occurs (refer to Figure 4):

Figure 4: Positive Disaggregation in a Two-Level Fabric

Consider a link failure between spine-1 and leaf-3, as shown in Figure 4. When leaf-1 wants to send traffic to leaf-3 and follows its north-bound *Equal-Cost Multi-path Routing* (ECMP) default route, it might select spine-1 as the next hop, which black-holes the traffic.

To avoid such black-holing of traffic, spine-2 and spine-3 each automatically triggers positive disaggregation. Following is the sequence of events from the perspective of spine-2, but the same sequence of events happens at spine-3:

1. Spine-2 has a south-bound route **2.0.0.3/32**, whose next-hop is leaf-3.
2. Spine-2 knows the adjacencies of spine-1 because the leaves reflected the spine-1 node TIE of spine-1 to spine-2. Hence, spine-2 knows that spine-1 does not have an adjacency with leaf-3 and that spine-1 cannot reach **2.0.0.3/32**.
3. Spine-2 automatically initiates positive disaggregation by flooding a positive disaggregation prefix TIE containing prefix **2.0.0.3/32** in the south-bound direction (the blue arrows in Figure 4).
4. Leaf-1 and leaf-2 install the more-specific route prefix **2.0.0.3/32** in their forwarding table. In the end, this route ends up being a two-way ECMP route across spine-2 and spine-3 (but not spine-1). Note that it takes a finite amount of time for the route to reach its full ECMP next-hop set, which may cause transitory in-cast issues (these issues can be addressed with implementation-specific mechanisms).
5. Leaf-1 and leaf-2 still rely on the default route for all other destinations. This route is a three-way ECMP route across all three spines.

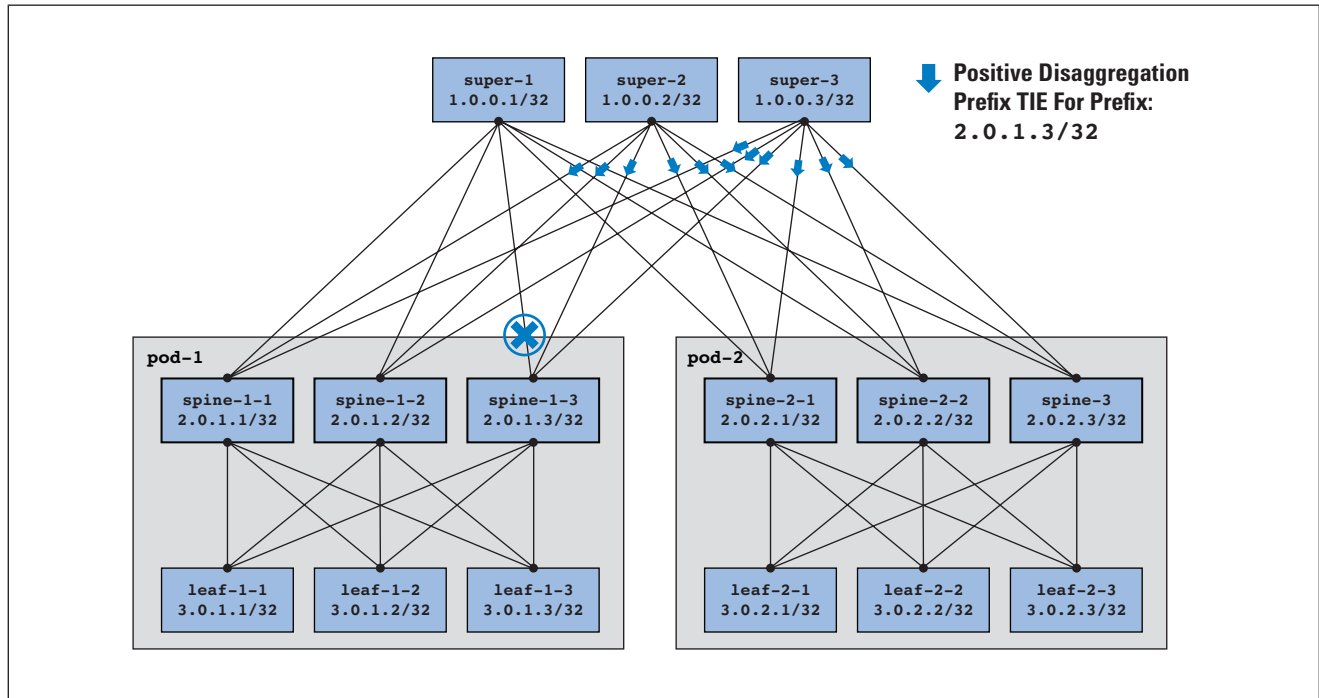

In summary, spine-2 and spine-3 detected that a link was broken in the topology, and they automatically initiated positive disaggregation to “attract” the traffic away from the failed path (spine-1) towards a repair path (themselves).

We now consider positive disaggregation in a more-complex scenario, namely a three-level fabric. In Figure 5, the link from super-1 to spine-1-3 has failed.

Super-2 and super-3 will automatically initiate positive disaggregation for prefix **2.0.1.3/32** because:

1. Super-2 and super-3 have a south-bound route for prefix **2.0.1.3/32** with only one next-hop, namely spine-1-3.
2. Super-2 and super-3 know that super-1 does not have an adjacency with spine-1-3.
3. Super-2 and super-3 conclude that super-1 can no longer reach **2.0.1.3/32**. Hence, they initiate positive disaggregation for that prefix.

Figure 5: Positive Disaggregation Repairs a Single Failure in a Three-level Fabric

However, at this point super-2 and super-3 will not yet initiate positive disaggregation for prefixes 3.0.1.1/32, 3.0.1.2/32, and 3.0.1.3/32 because:

1. Super-2 and super-3 have routes for prefixes 3.0.1.1/32, 3.0.1.2/32, and 3.0.1.3/32, each with three ECMP next-hops, namely spine-1-1, spine-1-2, and spine-1-3.
2. Super-2 and super-3 know that super-1 does not have an adjacency with spine-1-3, but it does still have an adjacency with spine-1-1 and spine-1-2.
3. Super-2 and super-3 conclude that although super-1 can still reach 3.0.1.1/32, 3.0.1.2/32, and 3.0.1.3/32: not through spine-1-3 but still through spine-1-1 and spine-1-2. Hence, they do not initiate positive disaggregation for those prefixes.

We leave it as an exercise for the reader to verify that super-2 and super-3 will initiate disaggregation for 3.0.1.1/32, 3.0.1.2/32, and 3.0.1.3/32 when all links from super-1 to pod-1 are broken.

Multi-Plane Topologies

In the fat-tree topologies that we have considered thus far, every spine is connected to every super-spine. When the network becomes large, you reach a point where the super-spines don't have enough ports to connect to every spine. Such networks often use a multi-plane topology such as the one shown in Figure 6 on the following page.

Figure 6: A Multi-Plane Topology (with East-West Inter-Plane Links)

For now, ignore the loops that connect the super-spines together; they are explained later. In a multi-plane topology, the spines and super-spines are partitioned into planes. In Figure 6, we have a blue plane, a black plane, and a dark grey plane. The super-spines in a plane are connected only to the spines in that same plane.

In such a multi-plane topology, the RIFT positive disaggregation mechanism does not always work because node TIEs are reflected only between super-spines in the same plane. The dark grey super-spines, for example, do not know the adjacencies of the blue or black super-spines. Hence, a super-spine in one plane cannot detect that a super-spine in a different plane has lost connectivity to some set of prefixes.

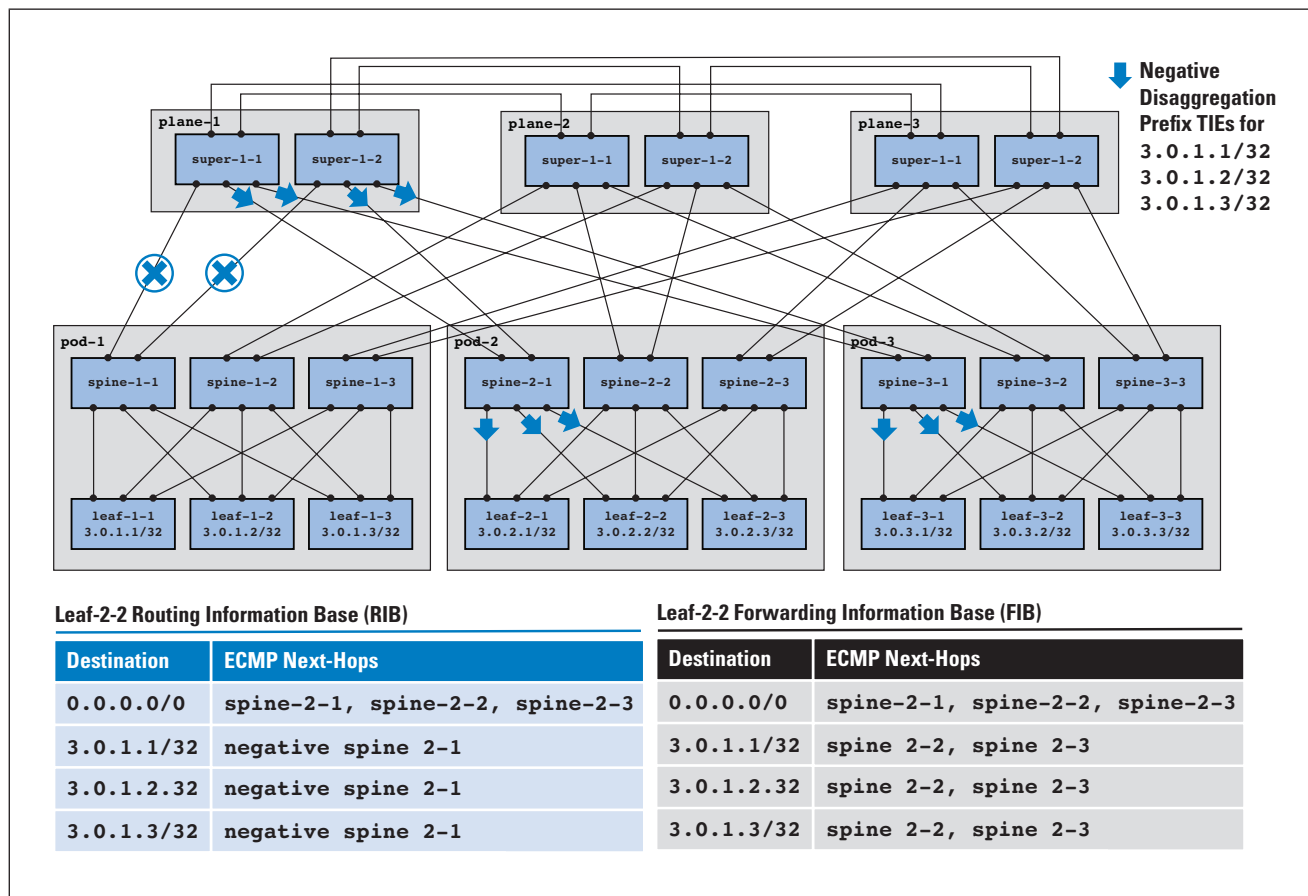

Negative Disaggregation

RIFT uses a different disaggregation mechanism, called *negative disaggregation*, to recover from failures in multi-plane topologies.

To make negative disaggregation work, the super-spines in different planes need to be interconnected using east-west inter-plane links as shown in Figures 6 and 7. These east-west inter-plane links are used only for control-plane traffic, and they do not carry user traffic (so they can be low-bandwidth links).

To understand negative disaggregation, consider the following multi-plane topology:

Figure 7: Negative Disaggregation

Triggering Negative Disaggregation

The super-spines run the south-bound *Shortest Path First* (SPF) algorithm twice:

1. The *normal SPF run* excludes the east-west inter-plane links. The resulting routes are installed in the *Routing Information Base* (RIB) and the *Forwarding Information Base* (FIB).
2. The *special SPF run* includes the east-west inter-plane links. The resulting routes are not installed in the RIB or FIB. If the special SPF run finds any extra reachable prefixes that were not reachable in the normal SPF run, then those extra prefixes are declared to be “fallen leaves,” and they trigger negative disaggregation.

In Figure 7, from the perspective of super-1-1 and super-1-2, the prefixes in pod-1 are fallen leaves because they can be reached only through other planes (that is, using east-west inter-plane links). The special SPF run will find the prefixes in pod-1, but the normal SPF run will not find the prefixes in pod-1.

After a super-spine detects fallen-leaf prefixes, it advertises those prefixes in a negative disaggregation prefix TIE, which is flooded south in the topology.

The super-spine is telling the rest of the network “don’t send any traffic destined to the fallen-leaf prefix to me because I cannot reach it.”

In a sense, negative disaggregation is the opposite of positive disaggregation. In positive disaggregation, the repair path advertises a positive disaggregation route to *attract* the traffic away from the broken path. In negative disaggregation, the broken path advertises a negative disaggregation prefix to *repel* traffic away towards the repair path. The mechanism for choosing the repair path is described in the sections that explain negative next-hop-to-positive next-hop translation.

Propagation of Negative Disaggregation

Unlike positive disaggregation (which is never propagated), negative disaggregation can be recursively propagated southwards. RIFT uses special rules for south-bound flooding of negative disaggregation prefix TIEs: a node propagates a negative disaggregation prefix *only* if it was received from *all* of the parent nodes, meaning that this node does not have any path left to the fallen leaf.

In Figure 7, spine-2-1 has received a negative disaggregation prefix TIE for the prefixes in pod-1 from both of its parent nodes, namely super-1-1 and super-1-2. Hence, spine-2-1 propagates the negative disaggregation prefix TIE further south-bound. The same happens at spine-3-1.

Negative Disaggregation in the RIB

When a node receives a negative disaggregation prefix TIE, it is stored in the LSDB and it takes part in the SPF calculation, just like a normal prefix TIE. However, the resulting route is installed in the RIB using a negative next-hop instead of a positive next-hop.

In Figure 7, leaf-2-2 has a north-bound default route `0.0.0.0/0` with three ECMP next-hops: spine-2-1, spine-2-2, and spine-2-3. These next-hops are normal (that is, positive) next-hops; the traffic will be distributed across all three spines in the pod.

Leaf-2-2 also has north-bound more-specific routes `3.0.1.x/32` (the prefixes in pod-1) with a negative next-hop spine-2-1. A negative next-hop in the RIB is a control-plane construct, meaning “don’t send the traffic to this next-hop.” The intent of this negative next-hop is to avoid sending traffic for `3.0.1.x/32` into plane-1 because plane-1 is disconnected from pod-1.

Note that a negative next-hop is something different from a discard next-hop. A discard next-hop causes traffic to be dropped. A negative next-hop causes traffic to be sent somewhere else using a less-specific route. We will now explain how it works.

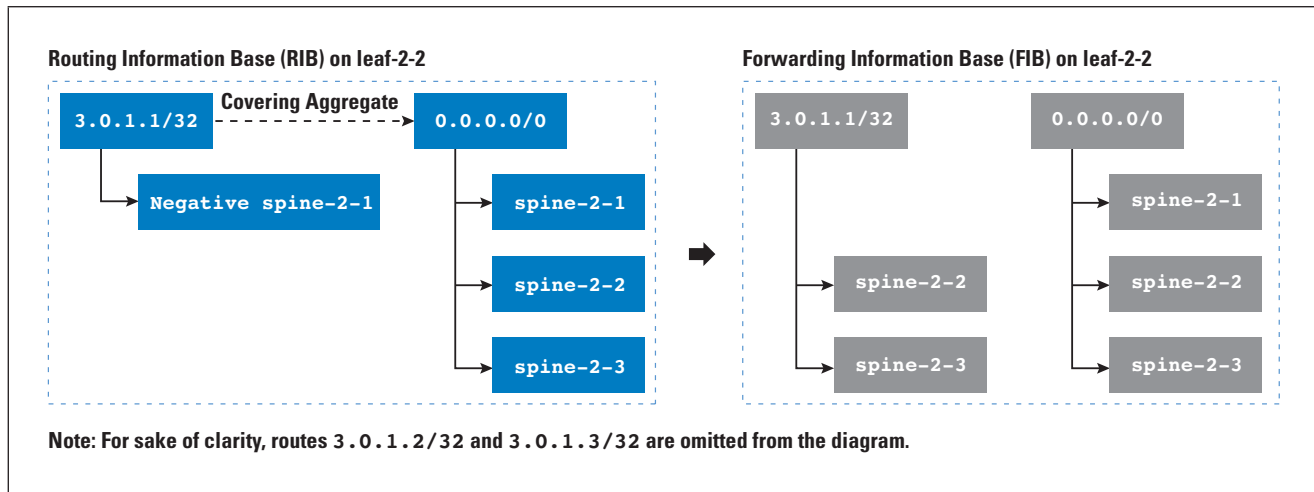

Negative Disaggregation in the FIB

Negative next-hops do not exist in current-generation forwarding hardware; they are a RIFT abstraction that exists only in the control plane and not in the forwarding plane.

When a RIFT route is installed from the RIB into the FIB, the RIB negative next-hop (where not to send the traffic) is translated into positive next-hops (where to send the traffic to instead).

Figure 8 illustrates how this translation works:

Figure 8: Translating Negative Next-Hops in the RIB into Positive Next-Hops in the FIB

What is happening in this simple example is the following:

- We have a route to `3.0.1.1/32`, which has a negative next-hop.
- We find the most specific aggregate route that covers this route, which is the default route, `0.0.0.0/0` in this case.
- We add up the next-hops of routes `3.0.1.1/32` and `0.0.0.0/0`, keeping in mind that a negative and positive next-hop cancel each other out.

We started with a route for `3.0.1.1/32` with negative next-hop `spine-2-1`. We translated the negative next-hop `spine-2-1` into the complementary positive ECMP next-hops `spine-2-2` and `spine-2-3`. These translated next-hops are stored in the FIB.

Further Reading

For more-detailed information about RIFT disaggregation, see Pascal Thubert's slides on negative disaggregation presented at the IETF [10], the RIFT-Python open-source documentation,^[11,12] or my blog post on the topic,^[13] which goes into more detail.

Conclusion

In this article, we have introduced the RIFT protocol and described how RIFT uses automatic aggregation (north-bound default routes) to reduce the size of the routing table.

We have explained how RIFT uses automatic disaggregation to reroute traffic around failed links and nodes. We have further described the two types of disaggregation in RIFT, namely *Positive Disaggregation* and *Negative Disaggregation*.

Positive Disaggregation *attracts* traffic to the repair path by advertising more-specific routes, except that RIFT advertises these routes automatically instead of as a result of manual configuration. Negative disaggregation *repels* traffic away from the broken path. This approach is novel in that it relies on the new concept of a “negative next-hop.” These negative next-hops are translated into normal positive next-hops in the data-plane hardware.

Acknowledgements

I would like to thank Tony Przygienda (the father of RIFT), Pascal Thubert (the father of negative disaggregation), and Melchior Aelmans (one of my co-authors on the RIFT book) for our frequent and deep conversations on the RIFT protocol, and for their review of this article. I would like to thank Mariano Scazzariello and Tommaso Caiazzì (both PhD students at Roma University in Italy) for implementing negative disaggregation in RIFT-Python and their extensive testing of RIFT at scale.^[16]

Network Functions Virtualization

by William Stallings

Network Functions Virtualization (NFV) originated from discussions among major network operators and carriers about how to improve network operations in the high-volume multimedia era. These discussions resulted in the publication of the original 2012 NFV White Paper by an NFV Industry Specification Group within the *European Telecommunications Standards Institute* (ETSI).^[1] In the white paper, the group listed as the overall objective of NFV the leveraging of standard IT virtualization technology to consolidate many network equipment types onto industry-standard high-volume servers, switches, and storage, which could be located in data centers, network nodes, and at the end-user premises.

The white paper highlights that the source of the need for this new approach is that networks include a large and growing variety of proprietary hardware appliances, leading to the following negative consequences:

- New network services may require additional different types of hardware appliances and finding the space and power to accommodate these boxes is becoming increasingly difficult.
- New hardware means additional capital expenditures.
- After new types of hardware appliances are acquired, operators are faced with the rarity of skills necessary to design, integrate, and operate increasingly complex hardware-based appliances.
- Hardware-based appliances rapidly reach end of life, requiring much of the procure-design-integrate-deploy cycle to be repeated with little or no revenue benefit.
- As technology and services innovation accelerates to meet the demands of an increasingly network-centric IT environment, the need for an increasing variety of hardware platforms inhibits the introduction of new revenue-earning network services.

The NFV approach moves away from the dependence on a variety of hardware platforms to the use of a small number of standardized platform types, with virtualization techniques used to provide the needed network functions. In the white paper, the group expresses the belief that the NFV approach is applicable to any data-plane packet-processing and control-plane function in fixed and mobile network infrastructures.

NFV deployment has become increasingly widespread, being used by telecommunications providers, cloud service providers, and large enterprises, such as in the banking and financial services industry.^[2] Perhaps the main driver for NFV is 5G wireless networks.^[3] NFV is an integral part of 5G and is indeed required by 5G standards.^[4]

Concepts

NFV builds on standard *Virtual Machine* (VM) technologies, extending their use into the networking domain. This departure from traditional approaches to the design, deployment, and management of networking services is significant. NFV decouples network functions, such as *Network Address Translation* (NAT), firewalling, intrusion detection, *Domain Name System* (DNS), and caching, from proprietary hardware appliances so they can run as software on VMs.

Virtual-machine technology enables migration of dedicated application and database servers to *Commercial Off-The-Shelf* (COTS) x86 servers. You can apply the same technology to network-based devices, including:

- *Network Function Devices*: Such as switches, routers, network access points, and deep packet inspectors
- *Network-related Compute Devices*: Such as firewalls, intrusion detection systems, and network management systems
- *Network-attached Storage*: File and database servers attached to the network

In traditional networks, all network elements are enclosed boxes, and hardware cannot be shared. Each device requires additional hardware for increased capacity, but this hardware is idle when the system is running below capacity. With NFV, however, network elements are independent applications that are flexibly deployed on a unified platform comprising standard servers, storage devices, and switches. In this way, software and hardware are decoupled, and capacity for each application is increased or decreased by adding or reducing virtual resources.

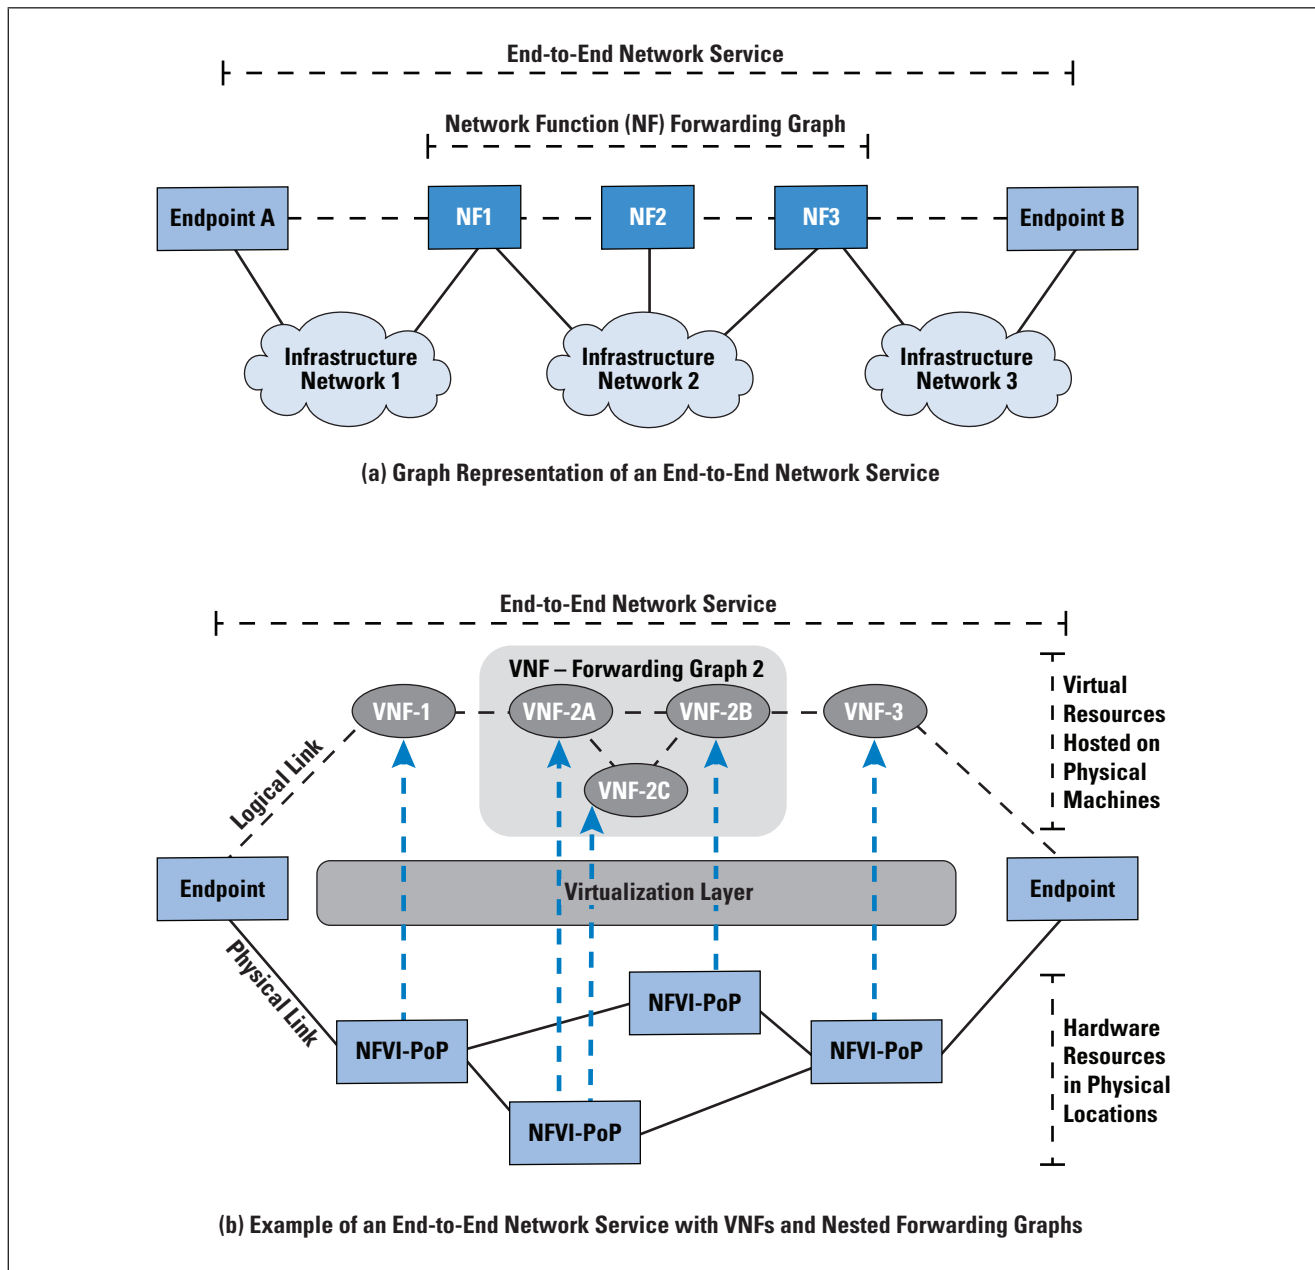

Consider a simple example from the *NFV Architectural Framework* document. Figure 1a shows a physical realization of a network service. At a top level, the network service consists of *endpoints* connected by a forwarding graph of network functional blocks, called *Network Functions* (NFs). Examples of NFs are firewalls, load balancers, and wireless network access points. In the Architectural Framework, NFs are viewed as distinct physical nodes. The endpoints are outside the scope of the NFV specifications and include all customer-owned devices. So, in the figure, endpoint A could be a smartphone and endpoint B a *Content Delivery Network* (CDN) server.

Figure 1a highlights the network functions that are relevant to the service provider and customer. The interconnections among the NFs and endpoints are depicted by dashed lines, representing logical links. These logical links are supported by physical paths through infrastructure networks (wired or wireless).

Figure 1b shows a virtualized network service configuration that could be implemented on the physical configuration of Figure 1a. *Virtual Network Function* (VNF) 1 provides network access for endpoint A, and VNF 2 provides network access for B.

The figure also depicts the case of a nested VNF forwarding graph (VNF-FG-2) constructed from other VNFs (that is, VNF-2A, VNF-2B, and VNF-2C). All of these VNFs run as virtual machines on physical machines, called *Points of Presence* (PoPs). This configuration illustrates several important points. First, VNF-FG-2 consists of three VNFs even though ultimately all of the traffic transiting VNF-FG-2 is between VNF-1 and VNF-3. The reason for this situation is that three separate and distinct network functions are being performed. For example, it may be that some traffic flows need to be subjected to a traffic policing or shaping function, which could be performed by VNF-2C. So, some flows would be routed through VNF-2C while others would bypass this network function.

Figure 1: A Simple NFV Configuration Example

A second observation is that two of the VMs in VNF-FG-2 are hosted on the same physical machine. Because the two VMs perform different functions, they need to be distinct at the virtual resource level but can be supported by the same physical machine. But this setup is not required, and a network management function may at some point decide to migrate one of the VMs to another physical machine, for reasons of performance. This movement is transparent at the virtual resource level.

Principles

As Figure 1 suggests, the VNFs are the building blocks used to create end-to-end network services. Three key NFV principles are involved in creating practical network services:

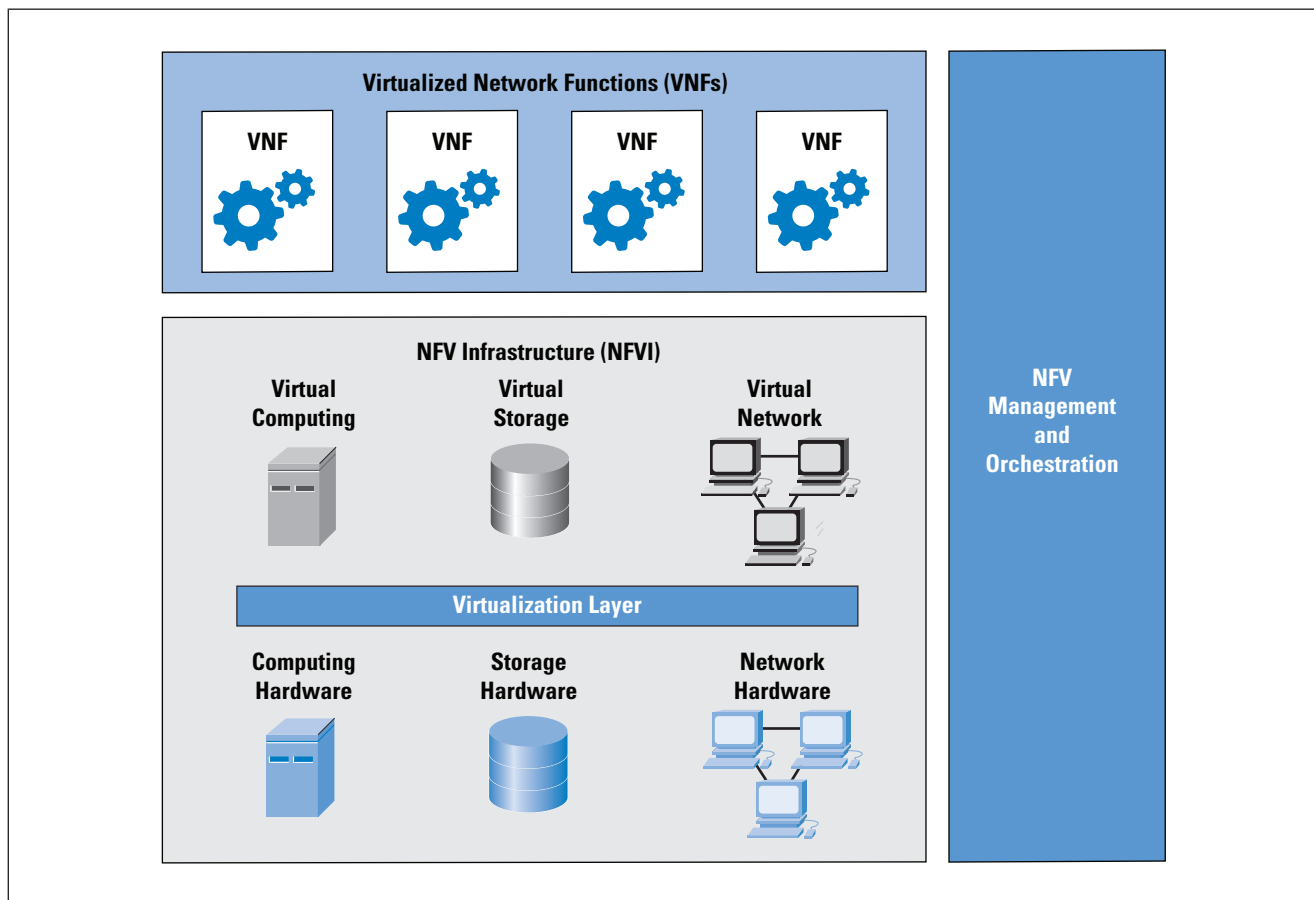

- *Service Chaining*: VNFs are modular and each VNF provides limited functionality on its own. For a given traffic flow within a given application, the service provider steers the flow through multiple VNFs to achieve the desired network functions. This practice is referred to as *service chaining*.
- *Management and Orchestration* (MANO): This feature involves deploying and managing the lifecycle of VNF instances. Examples of functions are VNF instance creation, VNF service chaining, monitoring, relocation, shutdown, and billing. MANO also manages the NFV infrastructure elements.
- *Distributed Architecture*: A VNF may be made up of one or more *VNF Components* (VNFC), each of which implements a subset of the VNF functions. Each VNFC may be deployed in one or multiple instances. These instances may be deployed on separate, distributed hosts in order to provide scalability and redundancy.

Figure 2 shows a high-level view of the NFV framework defined by ISG NFV. This framework supports the implementation of network functions as software-only VNFs. Figure 2 provides an overview of the NFV architecture, which is examined in more detail subsequently.

The NFV framework consists of three domains of operation:

- *Virtualized Network Functions*: These functions are a collection of VNFs, implemented in software, that run over the NFVI.
- *NFV Infrastructure* (NFVI): The NFVI performs a virtualization function on the three main categories of devices in the network service environment: computer devices, storage devices, and network devices.
- *MANO*: This function encompasses the orchestration and lifecycle management of physical and/or software resources that support the infrastructure virtualization and lifecycle management of VNFs. NFV management and orchestration focuses on all virtualization-specific management tasks necessary in the NFV framework.

Figure 2: High-Level NFV Framework

The ISG NFV Architectural Framework document specifies that in the deployment, operation, management, and orchestration of VNFs two types of relations between VNFs are supported:

- *VNF Forwarding Graph (VNF-FG):* Covers the case where network connectivity between VNFs is specified, such as a chain of VNFs on the path to a web server tier (for example, firewall, network address translator, or load balancer).
- *VNF Set:* Covers the case where the connectivity between VNFs is not specified, such as a Web server pool.

NFV Reference Architecture

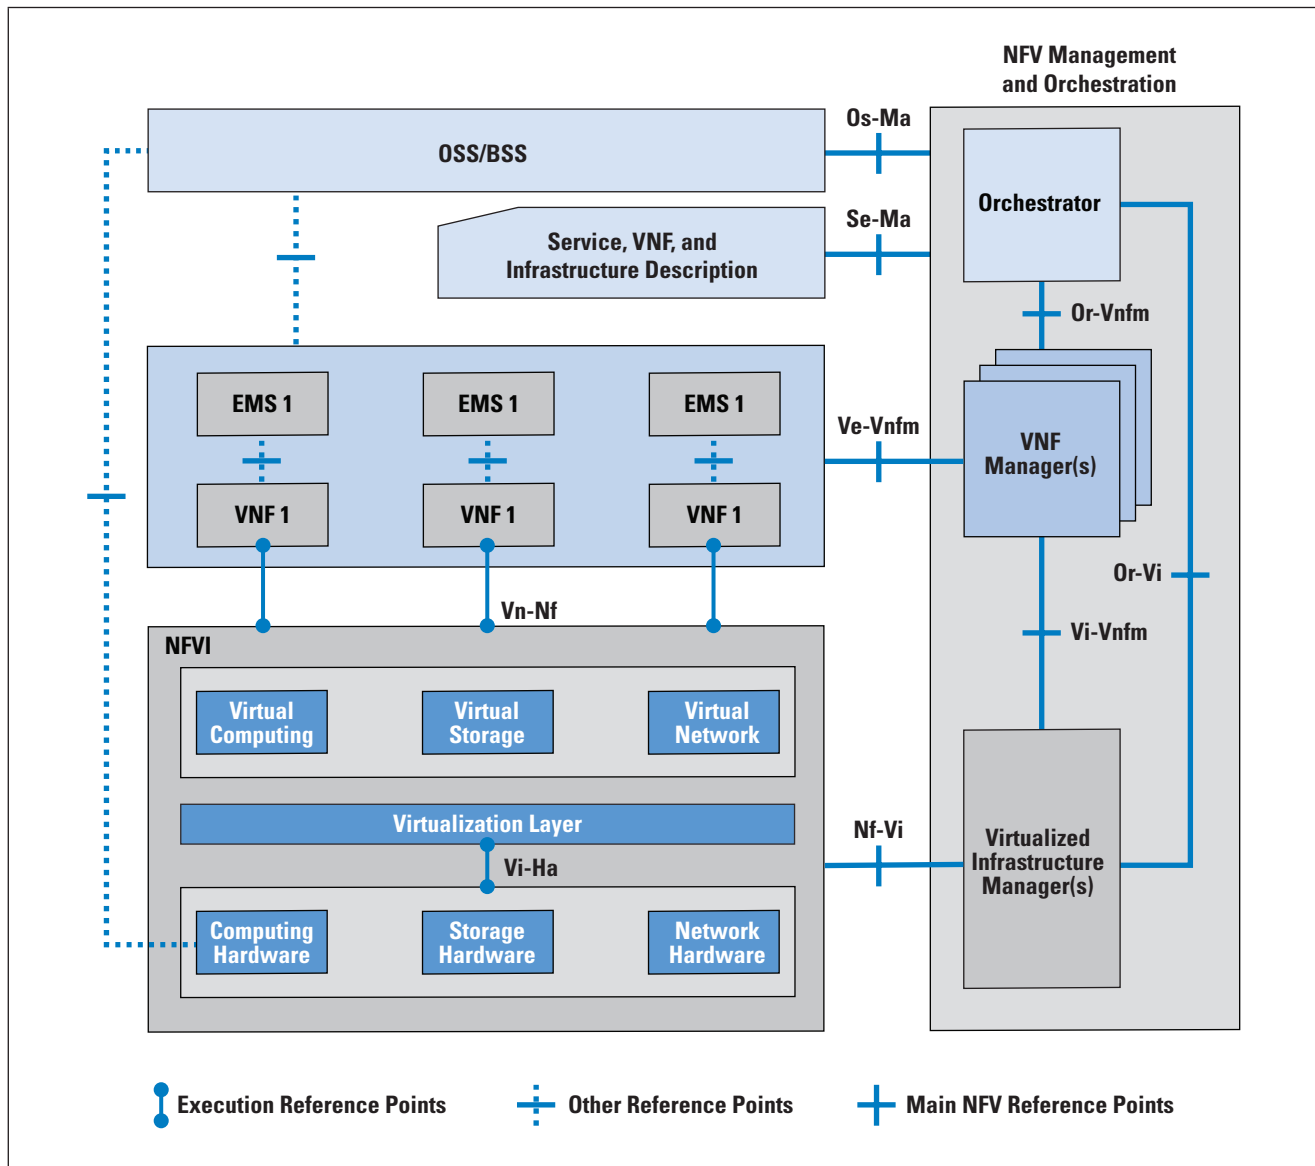

Figure 3 shows a more detailed look at the ISG NFV reference architectural framework.

The architecture consists of four major blocks:

- *NFV Infrastructure (NFVI):* This block comprises the hardware and software resources that create the environment in which VNFs are deployed. NFVI virtualizes physical computing, storage, and networking and places them into resource pools.

- *VNF/EMS*: This collection of VNFs is implemented in software to run on virtual computing, storage, and networking resources, together with a collection of element management systems that manage the VNFs.
- *NFV Management and Orchestration (NFV-MANO)*: This framework manages and orchestrates all resources in the NFV environment, including computing, networking, storage, and VM resources
- *Operational and Business Support Systems (OSS/BSS)*: The NFV service provider implements this system.

Figure 3: NFV Reference Architectural Framework

It also is useful to view the architecture as consisting of three layers. The NFVI together with the virtualized infrastructure manager provides and manages the virtual resource environment and its underlying physical resources.

The VNF layer provides the software implementation of network functions, together with element management systems and one or more VNF managers. Finally, there is a management, orchestration, and control layer consisting of OSS/BSS and the NFV orchestrator.

NFV Management and Orchestration

The NFV management and orchestration facility includes the following functional blocks:

- *NFV Orchestrator*: Responsible for installing and configuring new *Network Services* (NS) and VNF packages; NS lifecycle management; global resource management; and validation and authorization of NFVI resource requests.
- *VNF Manager*: Oversees lifecycle management of VNF instances.
- *Virtualized Infrastructure Manager*: Controls and manages the interaction of a VNF with computing, storage, and network resources under its authority, as well as their virtualization.

NFV Infrastructure

The heart of the NFV architecture is a collection of resources and functions known as the *NFV Infrastructure* (NFVI). The NFVI encompasses three domains (Figure 4):

Figure 4: NFV Domains

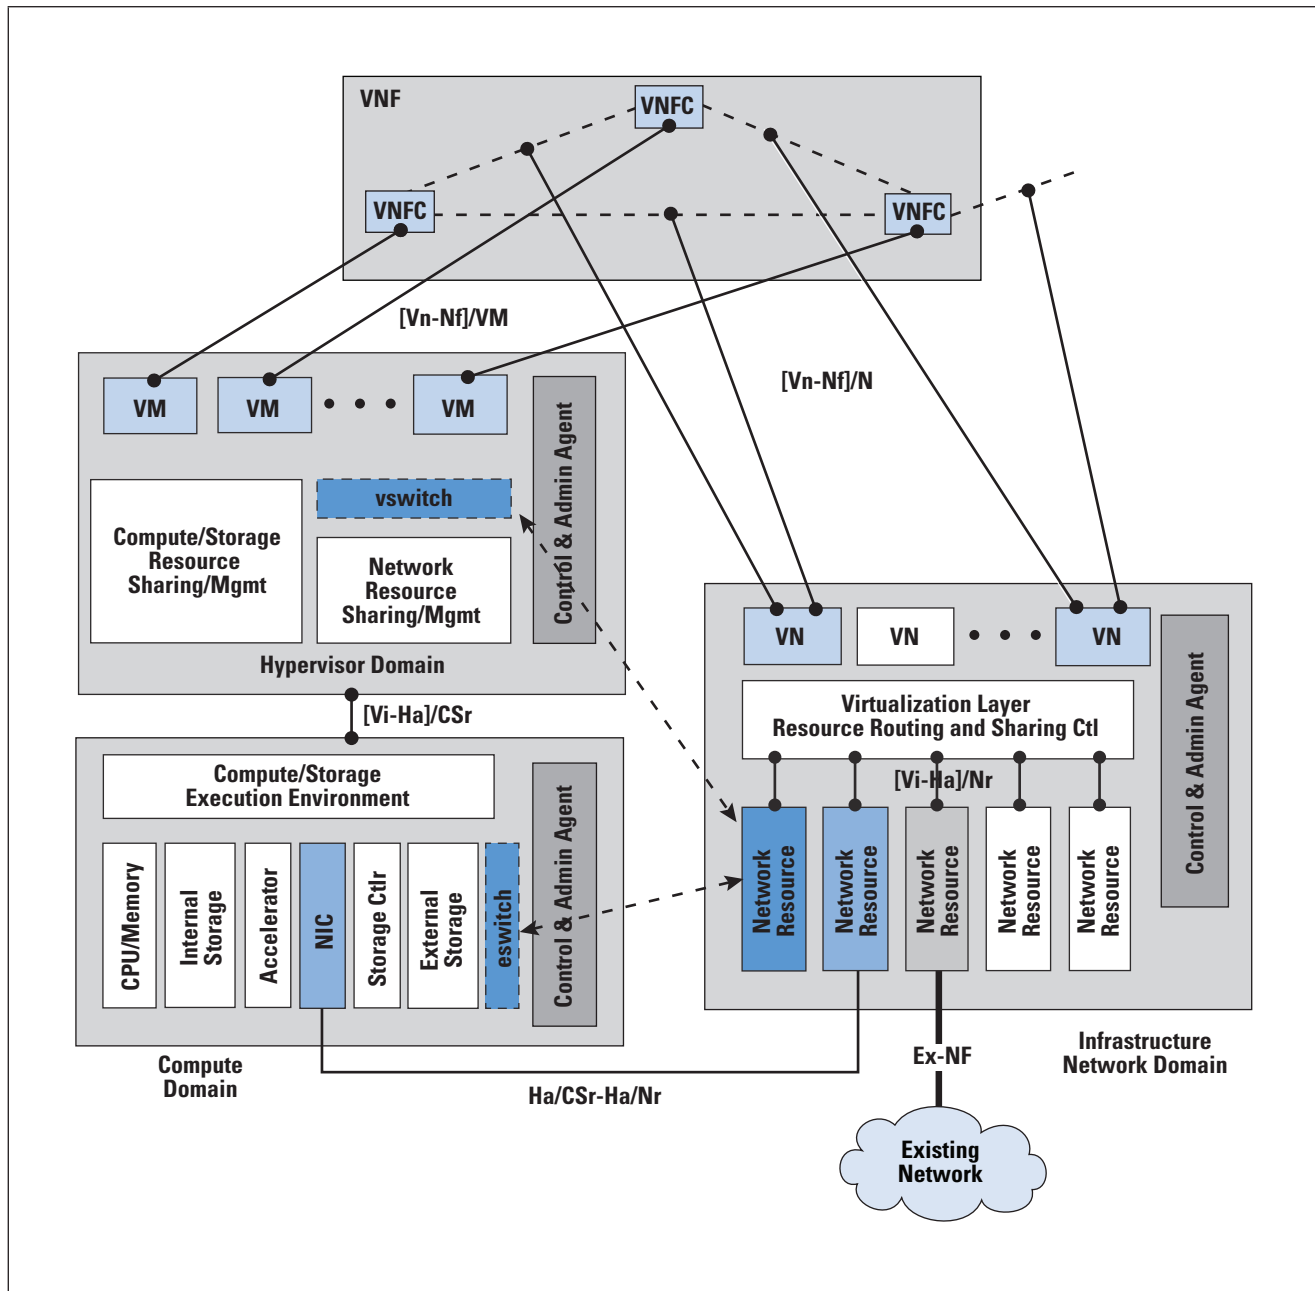

- *Compute Domain*: Provides COTS high-volume servers and storage
- *Hypervisor Domain*: Mediates the resources of the compute domain to the VMs of the software appliances, providing an abstraction of the hardware
- *Infrastructure Network Domain*: Comprises all the generic high-volume switches interconnected into a network that you can configure to supply infrastructure network services.

Logical Structure of NFVI Domains

The ISG NFV standards documents lay out the logical structure of the NFVI domains and their interconnections. The specifics of the actual implementation of the elements of this architecture will evolve in both open-source and proprietary implementation efforts. The NFVI domain logical structure provides a framework for such development and identifies the interfaces between the main components, as shown in Figure 5.

Figure 5: Logical Structure of NFVI Domains

Compute Domain

The principal elements in a typical compute domain may include the following:

- *CPU/Memory*: A COTS processor, with main memory, that executes the VNFC code
- *Internal Storage*: Non-volatile storage housed in the same physical structure as the processor, such as flash memory
- *Accelerator*: Accelerator functions for security, networking, and packet processing
- *External Storage with Storage Controller*: Access to secondary memory devices
- *Network Interface Card (NIC)*: An adapter circuit board installed in a computer to provide a physical connection to a network; it provides the physical interconnection with the infrastructure network domain
- *Control & Admin Agent*: Connects to the *Virtualized Infrastructure Manager (VIM)*; see Figure 2
- *eswitch*: Server-embedded switch; the eswitch function, described in the following paragraph, is implemented in the compute domain, but functionally it forms an integral part of the infrastructure network domain
- *Compute/Storage Execution Environment*: The execution environment that the server or storage device presents to the hypervisor software

To understand the functions of the eswitch, first note that broadly speaking, VNFs deal with two different kinds of workloads: control plane and data plane. Control-plane workloads are concerned with signaling and control-plane protocols such as the *Border Gateway Protocol (BGP)*. Typically, these workloads are more processor- than I/O-intensive, and they do not place a significant burden on the I/O system. Data-plane workloads are concerned with the routing, switching, relaying, or processing of network traffic payloads. Such workloads can require high I/O throughput.

In a virtualized environment such as NFV, all VNF network traffic would go through a virtual switch in the hypervisor domain, which invokes a layer of software between virtualized VNF software and host networking hardware. This situation can create a significant performance penalty. The purpose of the eswitch is to bypass the virtualization software and provide the VNF with a *Direct Memory Access (DMA)* path to the NIC. The eswitch approach accelerates packet processing without any processor overhead.

Hypervisor Domain

The hypervisor domain is a software environment that abstracts hardware and implements services, such as starting a VM, terminating a VM, acting on policies, scaling, live migration, and high availability. The principal elements in the hypervisor domain follow:

- *Compute/storage Resource Sharing/Management*: This service manages these resources and provides virtualized resource access for VMs.
- *Network Resource Sharing/Management*: This service manages these resources and provides virtualized resource access for VMs.
- *Virtual Machine Management and Application Programming Interface (API)*: This service provides the execution environment of a single VNFC instance.
- *Control & Admin Agent*: This agent connects to the *Virtualized Infrastructure Manager (VIM)*; see Figure 3.
- *vswitch*: The vswitch function, described in the following paragraph, is implemented in the hypervisor domain. However, functionally it forms an integral part of the infrastructure network domain.

The vswitch is an Ethernet switch implemented by the hypervisor that interconnects virtual NICs of VMs with each other and with the NIC of the compute node. If two VNFs are on the same physical server, they are connected through the same vswitch. If two VNFs are on different servers, the connection passes through the first vswitch to the NIC and then to an external switch. This switch forwards the connection to the NIC of the desired server. Finally, this NIC forwards it to its internal vswitch and then to the destination VNF.

Infrastructure Network Domain

The *Infrastructure Network Domain (IND)* performs numerous roles. It provides:

- The communication channel between the VNFCs of a distributed VNF
- The communications channel between different VNFs
- The communication channel between VNFs and their orchestration and management
- The communication channel between components of the NFVI and their orchestration and management
- The means of remote deployment of VNFCs
- The means of interconnection with the existing carrier network

An important distinction is to be made between the virtualization function provided by the hypervisor domain and that provided by the infrastructure network domain. Virtualization in the hypervisor domain uses VM technology to create an execution environment for individual VNFCs.

Virtualization in IND creates virtual networks for interconnection of VNFCs with each other and with network nodes outside the NFV ecosystem. These latter types of nodes are called *Physical Network Functions* (PNFs).

Virtualized Network Functions

A VNF is a virtualized implementation of a traditional network function. Table 1 contains examples of functions that could be virtualized.

Table 1: Potential Network Functions to Be Virtualized

Network Element	Function
Switching elements	Broadband network gateways, carrier-grade Network Address Translation (NAT), and routers
Mobile network nodes	Home Location Register/Home Subscriber Server, gateway, GPRS support node, radio network controller, and various node B functions
Customer premises equipment	Home routers and set-top boxes
Tunneling gateway elements	<i>IP Security</i> (IPSec)/SSL virtual private network gateways
Traffic analysis	<i>Deep packet inspection</i> (DPI) and <i>quality of experience</i> (QoE) measurement
Assurance	Service assurance, <i>service-level agreement</i> (SLA) monitoring, and testing and diagnostics
Signaling	Session border controllers and IP Multimedia Subsystem components
Control plane/access functions	<i>Authentication, Authorization, and Accounting</i> (AAA) servers, policy control and charging platforms, and <i>Dynamic Host Configuration Protocol</i> (DHCP) servers
Application optimization	Content-delivery networks, cache servers, load balancers, and accelerators
Security	Firewalls, virus scanners, intrusion detection systems, and spam protection
Support for General Topologies (not just DC fabrics)	No

As discussed earlier, a VNF comprises one or more *VNF Components* (VNFCs). The VNFCs of a single VNF are connected internal to the VNF. This internal structure is not visible to other VNFs or to the VNF user. An important property of VNFs is elasticity, which means being able to perform one or more of the following:

- *Scale up*: Expand capability by adding resources to a single physical machine or virtual machine.
- *Scale down*: Reduce capability by removing resources from a single physical machine or virtual machine.
- *Scale out*: Expand capability by adding additional physical or virtual machines.
- *Scale in*: Reduce capability by removing physical or virtual machines.

Every VNF has an associated elasticity parameter of no elasticity, scale up/down only, scale out/in only, or both scale up/down and scale out/in.

A VNF is scaled by scaling one or more of its constituent VNFCs. Scale out/in is implemented by adding/removing VNFC instance(s) that belong to the VNF being scaled. Scale up/down is implemented by adding/removing resources from existing VNFC instance(s) that belong to the VNF being scaled.

Summary

NFV provides a powerful, vendor-independent approach to implementing complex networks with dynamic demands. NFV builds on well-established technologies, including virtual machines, containers, and virtual networks. With the demand from 5G and cloud service providers, as well as enterprises with large internal networks, NFV is becoming an increasingly widespread technology.

Further Reading

Greater technical detail is available in many survey papers on NFV.^[5, 6, 7, 8] ETSI maintains an NFV web site that includes the ETSI NFV specifications, white papers, tutorials, and a variety of other documents and links (<https://www.etsi.org/technologies/nfv/>). A detailed discussion of the role of NFV in 5G is in [9].

Our Privacy Policy

The *General Data Protection Regulation* (GDPR) is a regulation for data protection and privacy for all individual citizens of the *European Union* (EU) and the *European Economic Area* (EEA). Its implementation in May 2018 led many organizations worldwide to post or update privacy statements regarding how they handle information collected in the course of business. Such statements tend to be long and include carefully crafted legal language. We realize that we may need to provide similar language on our website and in the printed edition, but until such a statement has been developed here is an explanation of how we use any information you have supplied relating to your subscription:

- The mailing list for *The Internet Protocol Journal* (IPJ) is entirely “opt in.” We never have and never will use mailing lists from other organizations for any purpose.
- You may unsubscribe at any time using our online subscription system or by contacting us via e-mail. We will honor any request to remove your name and contact information from our database.
- We will use your contact information only to communicate with you about your subscription; for example, to inform you that a new issue is available, that your subscription needs to be renewed, or that your printed copy has been returned to us as undeliverable by the postal authorities.
- We will never use your contact information for any other purpose or provide the subscription list to any third party other than for the purpose of distributing IPJ by post or by electronic means.
- If you make a donation in support of the journal, your name will be listed on our website and in print unless you tell us otherwise.

Workshop: Measuring Network Quality for End-Users

The *Internet Architecture Board* (IAB) is organizing a virtual workshop, September 14–16, 2021. The Internet in 2021 is quite different from what it was 10 years ago. Today, it is a crucial part of everyone’s daily life. People use the Internet for their social life, for their daily jobs, for routine shopping, and for keeping up with major events. An increasing number of people can access a Gigabit connection, which would be hard to imagine a decade ago. And, thanks to improvements in security, people trust the Internet for both planning their finances and for everyday payments.

At the same time, some aspects of end-user experience have not improved as much. Many users have typical connection latency that remains at decade-old levels. Despite significant reliability improvements in data center environments, end users often see interruptions in service. Transport refinements, such as QUIC, Multipath TCP, and TCP Fast Open are still not fully supported in some networks. Likewise, various advances in the security and privacy of user data are not widely supported, such as encrypted DNS to the local resolver. We believe that one of the major factors behind this lack of progress is the popular perception that throughput is often the sole measure of the quality of Internet connectivity. With such narrow focus, people don’t consider questions such as:

- What is the latency under typical working conditions?
- How reliable is the connectivity across longer time periods?
- Does the network allow the use of a broad range of protocols?
- What services can be run by clients of the network?
- What kind of IPv4, NAT or IPv6 connectivity is offered, and are there firewalls?
- What security mechanisms are available for local services, such as DNS?
- To what degree are the privacy, confidentiality, integrity and authenticity of user communications guarded?

Improving these aspects of network quality will likely depend on measurement and exposing metrics to all involved parties, including to end users in a meaningful way. Such measurements and exposure of the right metrics will allow service providers and network operators to focus on the aspects that impacts the users’ experience most and at the same time empowers users to choose the Internet service that will give them the best experience. The IAB is holding this workshop to convene interested researchers, network operators, and Internet technologists to share their experiences and to collaborate on the steps needed to define properties and metrics with the goal of improving Internet access for all users. The workshop will discuss the following questions:

- What are the fundamental properties of a network that contribute to good user experience?
- What metrics quantify these properties, and how to collect such metrics in a practical way?
- What are the best practices for interpreting those metrics, and incorporating those in a decision-making process?
- What are the best ways to communicate these properties to service providers and network operators?
- How can these metrics be displayed to users in a meaningful way?

We realize that the answers to these questions will vary depending on the different experiences of the participants. For example, a commercial video-streaming platform may prioritize higher throughput and to rely on latency-hiding techniques, while a massive multiplayer online game may prioritize lower jitter, and invest into techniques for graceful degradation of the user experience in case of reduced network capacity. At the same time, researchers from the academia may be looking at properties and metrics that haven't been adopted by the industry at all. Likewise, participants may endorse different methodologies for interpreting the metrics and for making decisions. We are actively looking for identifying such methodologies and for capturing the respective best practices.

While this workshop isn't focusing on the solution space, we are welcoming submissions that dive into particular technologies, to the extent of helping to set the context for the discussion. Comparing the merits of specific solutions, however, is outside of the workshop's scope. Interested participants are invited to submit position papers on the workshop questions. Paper size is not limited, but brevity is encouraged. Interested participants who have published relevant academic papers may submit these as a position paper, optionally with a short abstract. The workshop itself will be a virtual meeting over several sessions, with focused discussion based on the position paper topics received. The logistics for the workshop is as follows:

- Submissions Due: August 2, 2021, midnight AOE (Anywhere On Earth)
- Invitations Issued by: August 16, 2021
- Workshop Dates: September 14–16, 2021 (1400–1800 UTC each day)
- Send Submissions to: **`network-quality-workshop-pc@iab.org`**

The Program Committee members are Jari Arkko, Olivier Bonaventure, Vint Cerf, Stuart Cheshire, Sam Crawford, Nick Feamster, Jim Gettys, Toke Høiland-Jørgensen, Geoff Huston, Cullen Jennings, Mirja Kuehlewind, Jason Livingood, Matt Mathias, Randall Meyer, Kathleen Nichols, Christoph Paasch, Tommy Pauly, Greg White, and Keith Winstein. The workshop co-chairs are Wes Hardaker, Eugeny Khorov, and Omer Shapira.

Position papers from academia, industry, the open source community and others that focus on measurements, experiences, observations and advice for the future are welcome. Papers that reflect experience based on deployed services are especially welcome. The organizers understand that specific actions taken by operators are unlikely to be discussed in detail, so papers discussing general categories of actions and issues without naming specific technologies, products, or other players in the ecosystem are expected. Papers should not focus on specific protocol solutions. The workshop will be by invitation only. Those wishing to attend should submit a position paper to the address above; it may take the form of an Internet-Draft.

All inputs submitted and considered relevant will be published on the workshop website. The organizers will decide whom to invite based on the submissions received. Sessions will be organized according to content, and not every accepted submission or invited attendee will have an opportunity to present as the intent is to foster discussion and not simply to have a sequence of presentations. Position papers from those not planning to attend the virtual sessions themselves are also encouraged. A workshop report will be published afterwards.

For more information, see:

The APNIC Foundation

The *Asia Pacific Network Information Centre* (APNIC) and the *APNIC Foundation* share a common vision of “a global, open, stable, and secure Internet that serves the entire Asia Pacific community.” Under its charter, the Foundation seeks to “advance education, on a non-profit making basis, in technical, operational and policy matters relating to Internet infrastructure, through undertaking or funding activities in Hong Kong and elsewhere in the Asia and the Pacific region.”

Incorporated in September 2016 and operational in early 2017, the Foundation was first discussed by the APNIC *Executive Council* (EC) in 2014, when it set out to explore a mechanism to support and expand the APNIC Development Program. The EC wanted to do this by raising funds, independent from APNIC membership contributions, to support regional Internet development efforts in the future

Projects and activities funded by the Foundation are designed and managed by APNIC, in collaboration with funding partners interested in Internet development. These activities are implemented by APNIC and our partners, which include a growing group of community trainers and technical advisors, and other like-minded organizations.

The Foundation is guided by an independent Board of Directors—selected by the APNIC EC—that includes recognized and respected experts from the Asia Pacific Internet community.

The Foundation's staff are based in the APNIC office in Brisbane, Australia. The Foundation welcomes support from, and collaboration with, other foundations, agencies and organizations working to develop the Internet in the Asia Pacific.

With more than 13,000 direct and indirect Members in almost every economy of the Asia Pacific, APNIC has spent over 20 years supporting the Internet to serve the region's 3 billion citizens. Many of its 80-plus staff travel regularly in the region to support Members, provide training and technical assistance, or share expertise and information. APNIC also partners with many organizations through MoUs, sponsorships and informally to support the continuing development of the Internet. APNIC's success in partnering and seeking financial support for its activities is founded on five important assets:

- A strong technical focus and regional recognition as a source of best practice and expertise.
- Neutrality and independence from any particular vendors, services, or technologies.
- A non-profit organization with financial strength and transparency.
- Robust regional networks and relationships.
- Long track record of successful management and implementation.

The APNIC Foundation builds on and supports these strengths and APNIC's strong history of success in training and community development.

APNIC development partners have included the Australian *Department of Foreign Affairs and Trade* (DFAT); Canada's *International Development Research Centre* (IDRC); the *Swedish International Development Cooperation Agency* (Sida); the *Japan International Cooperation Agency* (JICA); the World Bank; the United Nations' *International Telecommunications Union* (ITU), the *Internet Corporation for Assigned Names and Numbers* (ICANN), the DotAsia Organization, and the Internet Society. For more information, visit: <https://apnic.foundation/>

EU Launches COVID Certificate

In June 2021, the *European Union* (EU) announced the *Digital Green Certificate*, also known as "Corona Pass" or *Digital COVID Certificate* (DCC), to certify that a European resident has been vaccinated, has recently received a COVID test, or has recovered from the COVID-19 virus. The certificate is used to facilitate travel within EU, and in some cases to allow entrance to some large indoor events. The certificate itself is a QR code, and the majority of its components rely on standards developed by the *Internet Engineering Task Force* (IETF). Éric Vynce explains the details in a blog post here:

<http://evyncke.blogspot.com/2021/06/open-source-standards-at-rescue-to.html>

Thank You!

Publication of IPJ is made possible by organizations and individuals around the world dedicated to the design, growth, evolution, and operation of the global Internet and private networks built on the Internet Protocol. Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

According to Wikipedia, *Autonomic Computing* refers to the self-managing characteristics of distributed computing resources, adapting to unpredictable changes while hiding intrinsic complexity to operators and users. The concept has been expanded to computer networks by the *Autonomic Networking Integrated Model and Approach* (ANIMA) working group of the *Internet Engineering Task Force* (IETF). They recently published six *Request For Comments* (RFCs) about autonomic networking. Our first article provides an overview of the ANIMA model and describes these specifications and several usage scenarios in detail.

During the last two weeks of September 2021, several *Voice over IP* (VoIP) providers became the target of a *Distributed Denial of Service* (DDoS) attack. The victims included the provider that I use for my office telephone service, as well as its upstream provider. According to some reports, the attack left several critical institutions without telephone service, including some 911 emergency call centers. As I write this, my service appears to have been restored, but only after a large-scale re-engineering of the network that my provider uses. DDoS mitigation is not an easy task, especially for services that are real-time in nature such as telephone calls. Although I don't expect to learn all of the details of this incident, I do hope that we can cover the topic in more general terms in future articles. If you know any experts on DDoS mitigation, please ask them to get in touch! In the meantime, check out the article entitled "May I ask who's calling, please? A recent rise in VoIP DDoS attacks," which you can find on *The Cloudflare Blog*.

Security has been a recurring theme in this journal. Most of the protocols used in today's Internet were originally designed without comprehensive security in mind, but the IETF has produced security enhancements for many of the core protocols. Securing the routing system itself has proven challenging because it requires wide-spread deployment in order to be effective. In this issue, Geoff Huston presents Part One of a two-part article entitled "A Survey on Securing Inter-Domain Routing."

In May 2021, six *Request For Comments* (RFCs) about autonomic networking were published [5–10] as a result of the work of the *Autonomic Networking Integrated Model and Approach* (ANIMA) working group of the *Internet Engineering Task Force* (IETF). These RFCs complete the initial charter of that working group, which was started in late 2014 (see [11] for a summary of its inception); however, the first documents to be discussed in the IETF and *Internet Research Task Force* (IRTF) were posted in 2012^[13]. This foundation now allows the industry to build IETF-standardized network solutions for an *Autonomic Networking Infrastructure* (ANI) into every network device.

This article starts with an overview of the reasoning behind autonomic networking and a description of an early usage scenario. It then gives an overview of the newly published specifications and how they will interwork with existing network management, before concluding with several specific use cases.

One way to summarize autonomic networking is “plug and play” for professional networks. It can mean plug and play “for the ISP” or “for the enterprise” or “for industrial networks.” This step is a significant one forward from the well-known idea of plug and play for home networks, which the IETF addresses in the HOMENET working group.

IBM coined the term “autonomic computing” in 2001. The autonomic nervous system acts largely unconsciously and regulates bodily functions such as heart rate. IBM defined autonomic computing as “self-managing distributed computing resources, adapting to unpredictable changes while hiding intrinsic complexity from operators and users.” This definition led naturally to the idea of autonomic networking, which became a topic of discussion and work in the IRTF *Network Management Research Group*. The result was RFCs [1,2], which describe the outline of an envisioned autonomic networking infrastructure and ultimately resulted in the creation of the ANIMA working group. Since then, various aspects of the problem space were addressed in research, and in proprietary implementations by some vendors. But as always, the need is for interoperability, so proprietary methods have to give way to industry standards. This interoperability task is the job of the ANIMA working group.

The goal is self-management of networks, including self-configuration, self-optimization, self-healing, and self-protection (sometimes collectively called *self-X*). Autonomic networking puts operational intelligence into algorithms at the node level, to minimize dependency on human administrators and central management. Autonomic nodes will discover information about the surrounding network and negotiate parameter settings with their neighbors and other nodes. Later, nodes may also have learning and cognitive capability, that is, the ability to self-adapt their decision-making process based on information and knowledge sensed from their environment.

Science fiction? Not really. Distributed routing protocols as introduced with the ARPANET in the 1970s and later in the Internet are at their core autonomic: self-configuring, self-optimizing, and self-healing. Examples include *Open Shortest Path First* (OSPF) and *Intermediate System-to-Intermediate System* (IS-IS). But over the decades, even those protocols have evolved to become provisioning monsters requiring the human configuration of obscure parameters and policies. A whole industry and research discipline for network *Operations, Administration, and Management* (OAM) evolved to define architectures consisting of ever-more-complex layers between the human intent for the service-level objectives of the network (and by implication its protocols) and all the detailed parameters that need to be provisioned consistently and dynamically into each network device whenever there is any change. (As evidence, consider that the IETF alone has published more than 120 *Yet Another Next Generation* (YANG) modules and sub-modules, each of which contains many individual parameters.)

In today's networks, routing and traffic-engineering parameters are almost exclusively implemented through a centralized set of *Software-Defined Networking* (SDN) controller and orchestrator tools configured by human operators. Although a great improvement on older methods, these solutions are still difficult and expensive to build, maintain, validate, predict, secure, and above all to make reliable and resilient. These problems are rarely seen from the outside, except when network services are under oversight of regulatory entities that publish reports of those problems, such as [12].

SDN architectures are also highly proprietary—very often from a single vendor—and they typically require significant customization through programming for any multi-vendor network deployment. They therefore require network owners to not only hire network operators, but also have them become SDN developers. And sometimes, expensive experts have to travel unexpectedly at any hour of the day to fix or update systems. These issues largely arise because of the lack of the automation inside switches and routers that autonomic networking aims to enable.

Nevertheless, these SDN methods are the best option for existing large networks. They are marketed with terms that evolved in the last few years, such as *Zero-Touch Networks*, *Intent-Based Networking*, or *Self-Driving Networks*. In the metaphor of a network being a car, today's networks are like children's pedal cars guided from behind by an attentive parent, whereas ANIMA wants them to be like a self-driving car.

The long-term vision for autonomic networking is broader than the newly published standards. The autonomic networking infrastructure defined in the recent ANIMA RFCs is intended to provide foundational building blocks. These building blocks are meant to fit seamlessly with existing network and SDN/OAM designs and to improve their metrics such as simplicity, reliability, and security. Likewise, the ANI allows designers to more easily embed automation into network devices whenever there is a need. It is worth noting that today, unlike in the past, it is economic to provide enough computing power in network elements to support autonomy.

What Can the Autonomic Networking Infrastructure Do for You?

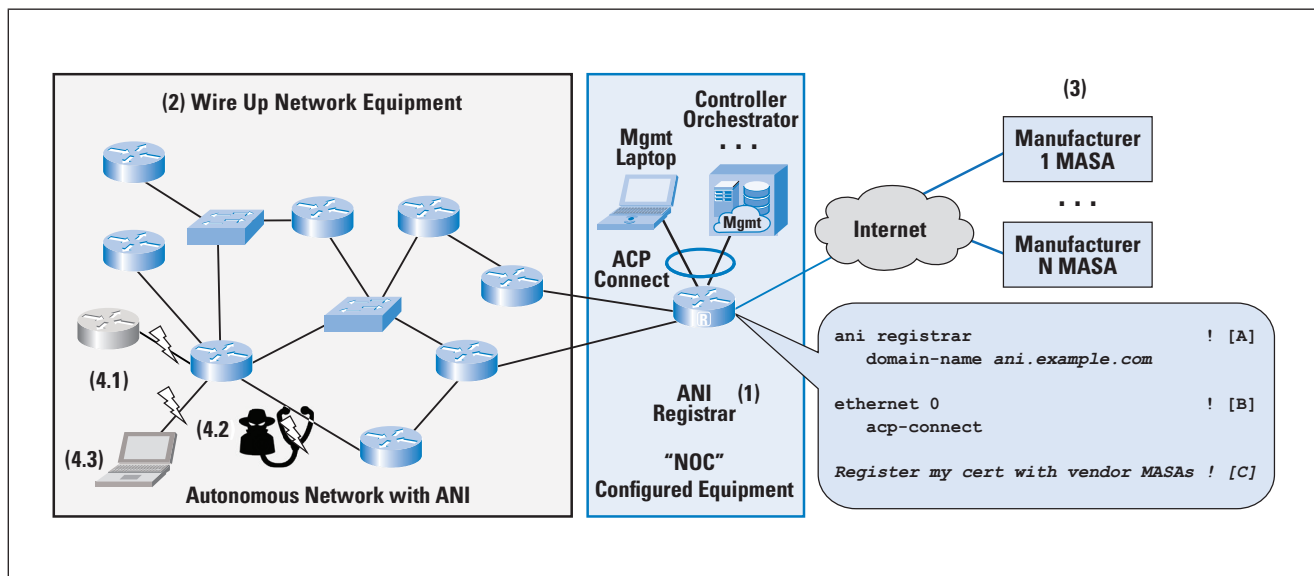

Instead of jumping directly into an explanation of how the ANI works, we first give a simple example of what the operator experience of a simple autonomic network could be.

In Figure 1, an operator wants to deploy a new network of devices such as routers and switches, namely those in the box labeled (2). These devices may be scattered across different physical locations, such as different offices or buildings. The actual reception of the new, factory-fresh equipment, unpacking, and physical attachment to pre-existing links may be performed in different locations by personnel who need to know only how to connect power and network cables accurately.

In contrast, without autonomic solutions, this process is very complex, insecure, and error-prone, and the description of all the challenges experienced would be much longer than this article. The challenges may be as simple as connecting a new device into a wrong Ethernet port, whereas any port would work for autonomic bootstrap. An operator must often ask the local installer to repeatedly power-cycle a device to activate a new or fixed configuration, a process that will be automatic in the ANI. In the worst case, the operator must ask the local installer to perform complex actions such as connecting a laptop to the device and configuring obscure and badly documented features. This situation can result in bizarre telephone interactions such as the operator asking the installer "Please take a photo of that screen and message it to me."

To avoid this situation, many device installations nowadays are done by staging. The device is first shipped to a central location where expert operators pre-configure and secure it on a trusted network, and then it is shipped again to the final deployment location.

Figure 1: An Example Autonomic Network

This process is more secure and more predictable, but it is a lot more expensive and slower. Eliminating the need for staging is hence one of the main advantages of the autonomic bootstrap process.

With the ANI, the operator only sets up a seed router—called the *ANI registrar*—for example in a *Network Operations Center* (NOC). The rest is fully automatic and secure, with local installation of new equipment by less-expert personnel (“plug in power cable, plug data cable into any free Ethernet port”). The NOC setup consists of only three simple steps:

- A. Set up the router labeled (1) as the registrar and assign a name to the ANI.
- B. Configure some local port(s) to provide link-layer access to the ANI, to connect management equipment such as a laptop for manual access or an SDN controller.
- C. Register the certificate of the registrar with the *Manufacturer Authorized Signing Authority* (MASA) services of the vendors whose routers and switches are being used in the new network. (We will soon describe what that registration does.)

Before this seed setup is in place, you may physically interconnect new routers or switches (2), but they will not do anything. When they have connectivity to a configured registrar, they will automatically form an ANI as follows:

Each new ANI device (at that stage called a *pledge*) automatically obtains a connection with the ANI registrar and attempts to enroll, receiving an ANI certificate so that it can participate. But the registrar first needs to prove to the ANI device that it is its “owner.” To do that, the registrar communicates (for example over the Internet) with the MASA of the vendor of that device.

That MASA has the information that this pledge is actually owned by this registrar's network and returns a security voucher that the registrar can present to the pledge, such that the pledge may now trust the registrar and therefore accepts an ANI certificate from the registrar. This process runs completely automatically without any further hand holding or configuration. This part of the ANI is known as *Bootstrapping Remote Secure Key Infrastructure* (BRSKI)^[10] (pronounced "Brewski").

After a new device is enrolled with an ANI certificate, it begins to establish a secure *Autonomic Control Plane* (ACP) connection with all its neighbors, authenticated and authorized mutually by ANI certificates of the device. This step too happens without further hand-holding or configuration. ACP connectivity is always established or re-established between any neighboring ANI routers or switches, regardless of any change in topology. It cannot be affected by faulty operator or SDN configuration of these devices. The goal of the ACP is quite simple: *If there is a physical path to a router or switch, the ACP will automatically provide encrypted and authenticated IPv6 connectivity to it that an operator cannot remove or misconfigure.* This function is exactly the type needed to avoid operational breakdowns such as [12].

Assume all devices were physically connected to each other as shown in Figure 1 and the ANI registrar is connected last (after it was configured). As a result, within minutes, all the devices will have run through BRSKI and set up the ACP. As a result, the network operator now has secure IP connectivity over the ACP from the management laptop and SDN controller to all ANI devices and can configure them manually or through SDN automation using this connectivity. Each ANI device has a permanent and private IP address within the ANI that does not change, even if the device is physically moved in the network.

How is this procedure different from 30-year-old Ethernet technology? Surely you can simply buy a set of inexpensive Ethernet switches, interconnect them, attach a configuration system at one point, and have achieved the same thing?

Indeed, the simplicity of operating Ethernet networks was an inspiration for the ANI, but beyond that, the ANI is fundamentally different. The ANI is above all secure, whereas the default behavior of traditional switches is not. An ANI device can join the ANI only if the operator actually owns it, as cryptographically certified by its manufacturer's MASA, for example via sales records, meaning that a stolen device cannot be enrolled for the ANI in another network. It also means that a device not belonging to this network operator (4.1) cannot be enrolled in this ANI network to launch an attack. To be clear, the operator has not relinquished any control or authority to the manufacturer by this process; only the operator decides which devices may attach to the network and what they may or may not do. The manufacturer's only role is to certify that each device is genuine.

All ACP traffic is encrypted hop-by-hop; therefore, an attacker cannot snoop or spoof any management traffic that uses the ACP, including any legacy unencrypted management protocol (4.2).

Lastly, ANI devices, even after having formed the ACP, are still unconfigured, ideally meaning that they should behave like current unconfigured routers: there is nothing running that could provide undesirable network connectivity to any hosts that attach, like some insecure or malicious laptop (4.3). Such an attached device would get no connectivity whatsoever. As a result, there is never a window of opportunity for attackers to impair unprotected equipment. Instead, the NOC has all the time it needs to remotely provision the devices. In later stages, such provisioning will occur autonomically, as we shall see.

Compared to many other zero-touch solutions, the ANI does not focus only on so-called *day-0/day-1* behavior up until the network is operational. Instead its services last through the whole life cycle. The ANI provides automated certificate renewal for all ANI devices to maintain and refresh its security model. The ACP protects any network OAM traffic that uses it. By its use of hop-by-hop encryption it also continuously protects the whole network and attached OAM equipment from traffic injection or spoofing attacks.

The use of the MASA service is one of the crucial benefits of the ANI process to enable reliable and secure device deployment without prior staging. Without a MASA, if an unconfigured device is connected to an unintended or hostile network, systems that use its default credentials can easily “kidnap” it. Furthermore, an attacker could then intercept the enrollment process in order to gain access to the whole network. For a network connection to become hostile, it is often sufficient for some virus-impaired device (such as a PC) to be on the same LAN or for the attacker to have impaired other network services such as the *Domain Name System* (DNS). Using a MASA to restrict access to cryptographically authorized devices closes off this avenue of attack.

Nevertheless, the MASA concept has raised concerns over the extent of control or observation by the manufacturer. In fact, the MASA can do neither. It can only generate cryptographic vouchers to inform the device and the person who owns it, thereby precluding configuration by anyone else. Manufacturers can operationalize this service in many ways, according to their customers’ requirements. The workflow described previously, where the owner communicates with the MASA during the enrollment of the device into its owner’s network, is just the simplest option for many owners because it offloads the difficult steps onto the manufacturer.

When a distinguished but elderly scientist states that something is possible, he is almost certainly right. When he states that something is impossible, he is very probably wrong.^[14]

Technical Outline of the ANIMA Model

As always in network management, literally thousands or millions of details cannot be standardized, or even described centrally. What we can do is define a model, a platform, and a toolkit, just as the *Simple Network Management Protocol* (SNMP) and the *Network Configuration Protocol* (NETCONF) have done in the past.

The main terminology we will use is the following. More details about these terms is available in RFC 7575^[1] and RFC 8993^[8]:

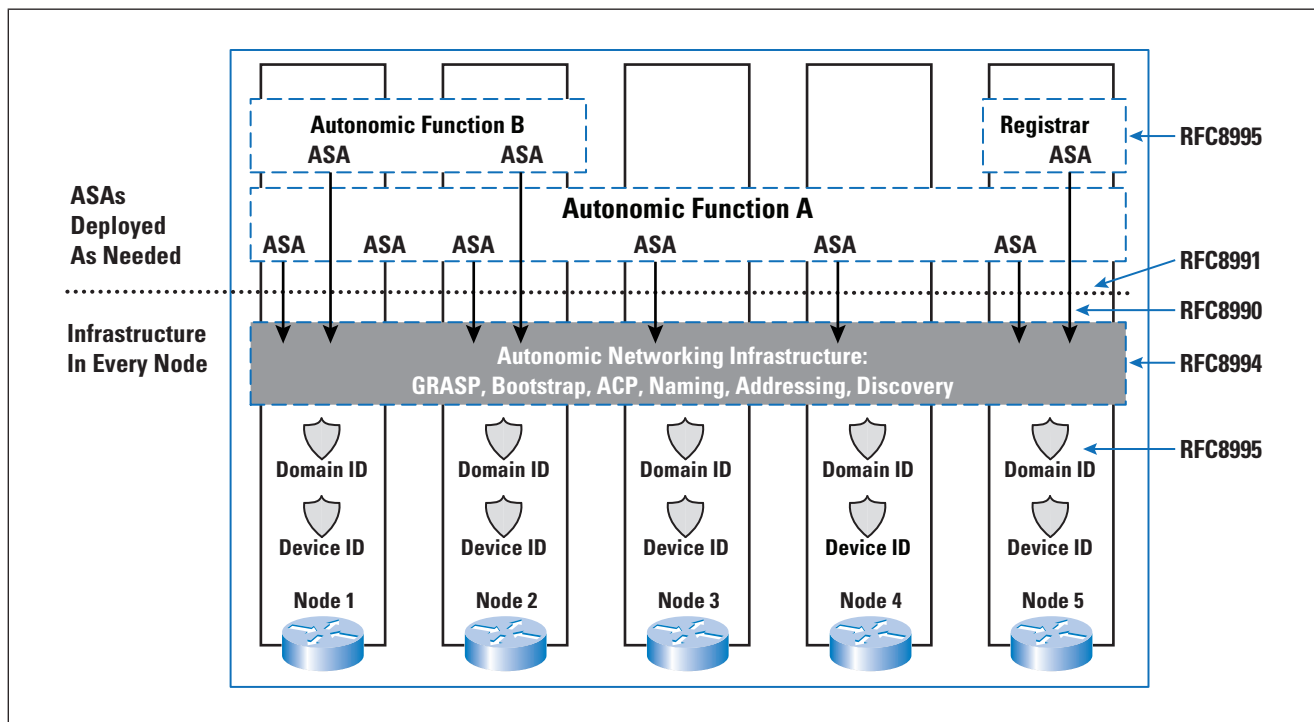

- *Autonomic Function*: A specific self-managing feature or function
- *Autonomic Service Agent* (ASA): An agent that implements an autonomic function, in part (for a distributed function) or whole
- *Autonomic Node*: A node that embodies autonomic functions
- *Autonomic Control Plane* (ACP): A self-configuring, fully secure, virtual network used for all autonomic messaging

The main items in the model follow:

- Bootstrapping and trust infrastructure^[10]. This item covers how nodes are authenticated and securely admitted to an autonomic network, and how they establish mutual trust.
- *Secure Autonomic Control Plane* (ACP)^[9]. This part is an automatically constructed and encrypted virtual network that contains only authenticated nodes that rightfully belong to a particular autonomic domain.
- Discovery for autonomic nodes: This item is a mechanism by which nodes attached to the ACP can discover each other. In practice, discovery occurs at a finer grain than nodes, because it really operates at the level of the capabilities and objectives of a node.
- Negotiation and synchronization for autonomic nodes: After nodes have discovered each other, they can synchronize data between themselves, or actively negotiate parameters and resources.
- Autonomic functions operate by negotiating and synchronizing data with their peers in other nodes, and by directly configuring manageable devices in their own scope.
- Discovery, synchronization, and negotiation proceed by use of the *GeneRic Autonomic Signaling Protocol* (GRASP)^[5].
- *Autonomic Service Agents* (ASAs) are composed of one or more autonomic functions, typically using GRASP via an *Application Programming Interface* (API)^[6].
- Centrally defined policy or configuration rules may be obtained by an ASA via GRASP synchronization, or if appropriate by conventional methods such as an interface to NETCONF or *Domain Name System Service Discovery* (DNS-SD).

Figure 2 shows an outline of the model as a whole, described in detail in RFC 8993^[8].

Figure 2: Layered Model of Network with Autonomic Functions

The only way of discovering the limits of the possible is to venture a little way past them into the impossible.^[14]

Some Details of Self-configuring Security

ANIMA does not attempt a monolithic bootstrap of a network from a predefined configuration. Instead, it proceeds step-by-step, and security comes first. The first stage of creating a secure autonomic control plane is bootstrapping a suitable key infrastructure that covers all the nodes that will constitute the ACP. This process is done, as previously described, by BRSKI.^[10] The process uses manufacturer-installed X.509 certificates (in IEEE 802.1AR IDevID format), in combination with a MASA. The network administrator decides which devices are authorized to join the network (for example, by serial number), but relies on the manufacturer to validate the certificate of each device whenever the device attempts to join the network via a local “join proxy.” These proxies all use a single “domain registrar” node that mediates the authorizing service. The join proxies themselves join the network by the same process; a GRASP mechanism is used for joining nodes (known as *pledges*) to find proxies, and for proxies to find each other and the registrar. Only the registrar needs to be configured in advance.

The ACP forms itself among pledges as soon as the pledges have completed their BRSKI enrollment. It is best described as a *Virtual Routing and Forwarding* (VRF) instance. It is based on a virtual router at each node, consisting of a separate IPv6 forwarding table to which the virtual interfaces of the ACP are attached, and an associated IPv6 routing table separate from the data plane.

Packet transmission is visible only as IPv6 link-local packets, encapsulating the autonomically created overlay network. This choice was made to ensure that there is no dependency on any pre-existing data plane (either IPv4 or IPv6), because autonomic functions must be able to operate *even if the normal data plane and normal routing are broken*. Even then, the ACP provides a secure channel to reach each node for (re-)configuration, without requiring a physically isolated console port. To start the ACP, all that is required is for each node to create its own IPv6 link-local address on each physical interface, as any modern network device does by default. The VRF consists of point-to-point IPv6 links and is secured using *Internet Protocol Security* (IPsec) with *Internet Key Exchange Protocol Version 2* (IKEv2) or *Datagram Transport Layer Security* (DTLS). From the viewpoint of autonomic service agents, the ACP uses an automatically generated IPv6 Unique Local Address prefix, and it uses *Routing Protocol for Low-Power and Lossy Networks* (RPL) internally. Like BRSKI, the ACP bootstraps itself, starting with a GRASP-based discovery process.

The security that the ANI itself requires is a simple but effective based “group-walled-garden” model for *Private Key Infrastructure* (PKI). It provides strong protection against intruders because of its certificate-based model with automated renewals. It also provides for simple ejection of impaired nodes through certificate revocation, certificate status verification, or short-lived certificates. Further levels of security are easily added when necessary. For example, the ANI itself already uses the common certificate-derived role-based security that distinguishes registrars from other nodes, so that no arbitrary impaired node can overtake the domain by acting as a fake registrar. You can expand such role-based security to other crucial roles in autonomic functions.

Of course, it would be naive to assume that, even with this key infrastructure and encrypted network, no malicious device, code, or user will ever penetrate the autonomic system. A malicious ASA could, for example, attempt a *Denial of Service* (DoS) attack within the ACP. The ANI platform provides services such as authentication, confidentiality, credential management, connectivity, and discovery to ASAs. An interesting analogy is *Transport Layer Security* (TLS), which provides authentication and confidentiality to web services. However, TLS cannot prevent the web services themselves from being untrustworthy, for example by breaking expectations of confidentiality by selling user data. In the same way, ASAs need to be intrinsically trustworthy on their own, regardless of whether they use the ANI. All legitimate ASAs should be designed to take appropriate precautions, and a watchdog ASA could be implemented to detect suspicious activity.

After the secure control plane has configured itself, the next stage is to bootstrap connectivity for network management. When this connectivity is achieved, conventional mechanisms (such as an SDN controller) can already reliably and securely reach remote nodes and configure them safely without risk of cutting themselves off.

In addition, fully autonomic management mechanisms (that is, ASAs) can start up. To understand how this process works, we first need to add more details about the GRASP protocol.

GRASP

The *GeneRic Autonomic Signaling Protocol* (GRASP)^[5] is used for signaling between ASAs, including special-purpose mini-ASAs that support BRSKI (discovery of join proxies and the domain registrar) and ACP creation (discovery of ACP neighbors). Readers will notice that these operations must take place *before* ACP security is in place, so they use a highly restricted subset of GRASP that is limited to specific link-local operations.

After that, GRASP runs over the ACP to guarantee security, so there are no restrictions on allowed operations and any two ASAs in the local domain may trust and communicate with each other. GRASP provides discovery, flooding, synchronization, and negotiation mechanisms for the objectives that ASAs support.

Rather than being a traditional type-length-value protocol, GRASP messages use *Concise Binary Object Representation* (CBOR), which provides an extensible data model derived from *JavaScript Object Notation* (JSON), but with a simple and efficient binary encoding. The flexibility of CBOR enables GRASP to accommodate a very wide range of data types, with protocol elements often mapping directly into various high-level language representations.

The word “objective” has a special meaning in GRASP. It is a data structure whose main contents are a *name* and a *value*. An objective occurs in three contexts: *discovery*, *negotiation*, and *synchronization*. A single ASA may support multiple independent objectives.

The *name* of an objective is simply a unique string describing its purpose.

The *value* consists of a single configurable parameter or a set of parameters of some kind. The parameter(s) apply to a specific service, function, or action. They may in principle be anything that can be set to a specific logical, numerical, or string value, or a more complex data structure. Basically, an objective is defined in the way that best suits its application; that is the great advantage of CBOR encoding. If desired, for example, the *value* of an objective could be expressed in the JSON data model. When an objective is shared between ASAs by flooding, synchronization, or negotiation, each ASA will maintain its own copy of the objective and its latest value.

GRASP messages allow for *discovery* of an ASA that handles a given objective name; *flooding* a given objective to all ACP nodes (the simplest form of synchronization); *synchronization* of the value of a given objective between two peer ASAs; and *negotiation* of the value of a given objective with a peer ASA.

An API for GRASP has been defined^[6] and implemented as part of a *Python* 3 prototype, making it very easy to implement demonstration ASAs in *Python*. A partial GRASP implementation has also been made as part of an ACP implementation in the *Rust* language.

Talking to the NOC

As noted previously, a key requirement for the success of ANIMA is smooth integration with existing network management tools and in particular with NOCs. To this end, an integration mechanism has been documented.^[4] The simplest approach is for trusted edge devices in the ACP to “leak” the (otherwise encrypted) ACP natively to certain network management hosts, presumed to be well secured. These edge devices would act as default routers to those management hosts and provide them with IPv6 connectivity into the ACP. A more complex approach would allow the management hosts simultaneous connectivity into the ACP and the traditional data plane.

A related issue is that if the NOC uses *DNS Service Discovery* (DNS-SD) to announce management services to managed nodes, these announcements will not be automatically available in the ACP, which for security reasons will not have routed access to the data plane where the DNS is available. This situation again can be solved by a trusted edge device that obtains service information from DNS-SD and redistributes it within the ACP, possibly by the GRASP flooding mechanism. For example, the information for a service named *syslog* could be flooded in a GRASP objective named *SRV.syslog*. Here, the flexibility of CBOR encoding is of great value because a JSON-like structure of service data is common.

Extending that point, since GRASP easily conveys JSON (or practically any other format), it is possible to integrate ASAs communicating via GRASP into almost any part of an existing network management system. For example, an ASA acting as a NETCONF client could retrieve YANG documents from a NOC database via GRASP and the ACP.

Autonomic Function Example 1: Address Management

A use case that has been fully defined is a GRASP-based mechanism for managing and assigning IP address prefixes.^[7] Firstly, we define two GRASP objectives for IPv4 or IPv6 prefix management at the edge of large-scale *Internet Service Provider* (ISP) networks. The first objective can be represented thus (in a simplified form):

```
["PrefixManager", [IP_version, prefix_length, prefix]]
```

and the second as:

```
["PrefixManager.Params", parameter_info]
```

The first objective will be used in GRASP negotiations between two “prefix manager” ASAs in nodes that need to delegate address space to subsidiary routers (using standard IPv6 prefix delegation), when one node is short of spare prefixes and the other one has an adequate pool of unused prefixes. If negotiation succeeds, prefixes will be transferred from the pool of one ASA pool to the other ASA pool. If negotiation fails, the ASA that is short of prefixes will use GRASP discovery to find another ASA that can help it. Each participating ASA will require persistent storage to manage its own address pool and to survive power outages or other failures such as network partitions. This feature will completely obviate any need for human management of an ISP’s distributed pool of prefixes, beyond initially configuring the maximum pool in one place.

The second objective may be flooded to all “prefix manager” ASAs to convey relevant policy, which can be enforced during prefix delegation by individual agents. For example, if the flooded parameter information is as follows:

```
[
  [{"role", "A"}, {"prefix_length", 34}],
  [{"role", "B"}, {"prefix_length", 44}],
  [{"role", "C"}, {"prefix_length", 56}]
]
```

...it would mean that devices of type A are allowed to receive IPv6 prefixes of length 34 bits, and so on.

You could use this mechanism in a variety of ways. One use case is where the three roles previously discussed correspond to three functions in an IP Radio Access Network: Radio Network Controller Site Gateways, Aggregation Site Gateways, and Cell Site Gateways. These devices will determine their own roles, and then select the prefix length they are allowed to request and offer to each other accordingly. Only central actions are to define the policy to be flooded out and to assign the operator’s total address space to a single device that will progressively delegate it to gateways that request prefixes.

This example illustrates that GRASP’s use of CBOR and its easy representation of JSON-like formats gives it great expressiveness and flexibility. While much work remains to be done on individual autonomic functions, the ANI and GRASP provide a solid and flexible foundation for further development.

Autonomic Function Example 2: Automating IP Multicast

One common interesting challenge for writing distributed autonomic service agents is solving problems that require decisions about the network topology—in a distributed fashion.

A simple example is automating deployment of a service such as IP Multicast, which needs to determine a small set of designated rendezvous routers, where a key requirement is their location balanced between the center and the edges of a network.

Using the ANI and GRASP, it is practical to build such distributed algorithms, for example using common criteria, such as calculation of one's own average path length as an indicator of centrality, and then running a distributed election algorithm that accounts for this and other criteria such as node performance and speed of attachment links to elect a few top contenders for the role, which then auto-configure the service and their precedence in it.

Autonomic Function Example 3: Automatic Protocol Security

We will end by considering an important early operational role for distributed autonomic behavior. That could start soon with very pragmatic incremental in-network automation, perhaps developed by operators as simple scripts in a scripting language such as *Python* or *Tcl* that can run locally on routers.

Consider an existing network where basic services are already running, for example, IPv4 and/or IPv6 addressing and routing. A software upgrade to the routers that adds support for the ANI could be installed, without affecting any of the pre-existing configuration and services. One of the most desirable services is protocol security, for example in routing protocols such as OSPF, IS-IS, and many others.

Most protocols have their own security mechanism and/or keying material requirements. However, security is often not configured because there is no automated key management, including key roll-over and revocation. Without good automation of key management, either networks fail to enable protocol security, or operators set up a single, network-wide password that is never changed. With the ANI, automation of such functions becomes much simpler, by using GRASP, running securely inside the ACP.

With this information in mind, you could easily write a *Python* or *Tcl* script using the GRASP API to auto-configure routing protocol security:

- *Discover* ANI neighbors on links that use the same routing protocol.
- *Generate* a random key.
- *Negotiate* the key with a neighbor.
- *Configure* a routing protocol key locally on the router.
- Periodically wake up, renegotiate, and configure a new key.
- Take suitable action if a neighbor disappears or re-appears.

Some protocols may not even have security included in the protocol itself, for example *Protocol Independent Multicast* (PIM). Instead, you need to secure packets via *IPsec Security Associations* (SAs). For those protocols, the previous script would then auto-configure the IPsec SA instead of an in-protocol key parameter. Such scripts are, of course, autonomic service agents by another name.

In summary, GRASP with ANI can solve the recurring core problems of in-network automation between routers:

Q: How do I communicate with a peer (link-local or across other routers) without having any configured IP connectivity?

A: ACP provides this connectivity automatically with no human intervention.

Q: How do I discover what peers with what type of services are available (especially when not link-local)?

A: GRASP discovers the peers.

Q: Should I trust these peers?

A: Your trust comes from the ANI certificate used for the ACP. No nodes that have not been registered for the domain and authenticated by their manufacturer can join.

Q: How can I avoid re-inventing a new protocol to coordinate with peers?

A: Use GRASP.

Securing existing protocols is only one example where you can use ANIMA immediately. Many or all the benefits apply equally to any other in-network function with similar issues: establishing and adjusting *Quality of Service* (QoS) and other policies; auto-configuring decentralized protocol instances; monitoring, fault isolation, and troubleshooting; and even auto-configuring the most basic user network configuration, such as IP prefix distribution as in the previous example. When completely new services are required, ASAs should be developed in languages best suited for such a task. This immediate applicability to real-world problems provides a significant deployment incentive.

Summary and Conclusion

The ANI is a foundation for network automation and it serves two purposes:

- For existing network OAM designs it provides core functions to more easily build and deploy networks with secure, resilient network management. ANI provides automated public key deployment and renewal and zero-touch auto-configured in-band network management connectivity that is protected from being brought down by operator or network management tool errors.
- For ongoing further automation of network OAM (with or without an ultimate goal of fully autonomic networking), the ANI provides fundamental functions to build distributed, in-network automation agents (ASA) without having to re-implement their core dependencies each time: security, mutual trust, connectivity, and network-wide and peer-to-peer common signaling (via GRASP).

As a system, ANI may look overwhelming at first with its large set of constituent components (buzzword bingo), but it is fundamentally a very pragmatic approach, with the goal of making network complexity self-managing.

- *The basis of ANI is a set of long-term, well-known, and widely-used protocol components:* IPv6, X.509, IPsec, DTLS, RPL, CBOR, etc.
- The core innovations of ANI are built on top of this foundation: BRSKI, Voucher, MASA on top of X.509, ACP on top of IPsec, DTLS and RPL, and GRASP on top of CBOR.
- *ANI is highly modular:* All components are defined to be fully reusable individually or in concert. Adopt and deploy only the subset you need.

Any sufficiently advanced technology is indistinguishable from magic.^[15]

A Survey on Securing Inter-Domain Routing

Part 1 – BGP: Design, Threats, and Security Requirements

by Geoff Huston, APNIC

The Border Gateway Protocol (BGP) is the inter-domain routing protocol on the Internet, and after some 30 years of operation, BGP is now one of its more venerable core protocols. One of the major ongoing concerns related to BGP is its lack of effective security measures, and as a result the routing infrastructure of the Internet continues to be vulnerable to various forms of attack.

In Part 1 of this study, we will look at the design of BGP, the threat model, and the requirements from a security framework for BGP. In Part 2 we will look at the various proposals to add security to the routing environment and also evaluate the current state of the effort in the *Internet Engineering Task Force* (IETF) to provide a standard specification of the elements of a secure BGP framework.

Introduction

The Internet is a decentralised collection of interconnected component networks (autonomous systems). These networks are composed of *end hosts* (who originate and/or receive IP packets, and are identified by IP addresses) and active forwarding elements (routers) whose role is to direct IP packets as they pass through the network. The routing system is responsible for propagating the relative location of IP addresses to each routing element, so that routers can make consistent and optimal routing decisions in order to pass a packet from its source to its destination. Routing protocols are used to perform this information propagation.

The routing system of the Internet is divided into a two-level hierarchy. One level is *intra-domain* routing, which the set of autonomous routing systems operating within each component network use. The other level is a single *inter-domain* routing system that maintains the inter-network connectivity information that straddles these component networks. A single inter-domain routing protocol, BGP^[1] has provided inter-domain routing services for the disparate component networks on the Internet since the late 1980s.^[2] Given the central role of routing in the operation of the Internet, BGP is one of the critical protocols that provide essential coherence to the Internet.

The underlying distributed distance vector computations of BGP rely heavily on informal trust models associated with information propagation to produce reliable and correct results. You could liken them to a hearsay network—information is flooded across a network as a series of point-to-point exchanges, with the information being incrementally modified each time it is exchanged between BGP speakers. The design of BGP was undertaken in the relatively homogeneous and mutually trusting environment of the early Internet.

Consequently, its approach to information exchange was not designed primarily for robustness in the face of various forms of negotiated trust or overt hostility on the part of some routing actors.

Hostile actors are a fact of life in today's Internet. It's quite reasonable to characterise today's Internet environment as one where trust must be explicitly negotiated rather than assumed by default. This environment is no longer consistent with the inter-domain trust framework that BGP originally assumed. The BGP mutual trust model involves no explicit presentation of credentials, no propagation of instruments of authority, nor any reliable means of verifying the authenticity of the information being propagated through the routing system. Hostile actors can attack the network by exploiting this trust model in inter-domain routing to their own ends.

An attacker can easily transform routing information in ways that are extremely difficult for any third party to detect. For example, false routing information may be injected, valid routing information removed, or information altered to cause traffic redirection.^[3,4,5] You can use this approach to prevent the correct operation of applications, to conduct fraudulent activities, and to disrupt the operation of part (or even all) of the network in various ways. The consequences range from relatively inconsequential (minor degradation of application performance due to sub-optimal forwarding paths) through to catastrophic (major disruption to connectivity and comprehensive loss of any form of cohesive Internet). To resist this subversion of integrity of routing information, each BGP speaker must have:

- Sufficient information at hand to verify the authenticity and completeness of the information being provided to it via the inter-domain routing system, and
- The ability to generate authoritative information such that other BGP speakers may verify the authenticity of information that this speaker is passing into the inter-domain routing system.

A key question is whether we can add further information into the inter-domain routing environment such that attempts to pervert, remove, or withhold routing information may be readily and reliably detected. Any proposed scheme must also be evaluated for its impact on the scaling properties of BGP.

To ground any such evaluation of BGP, it's useful to briefly review the design of the BGP protocol.

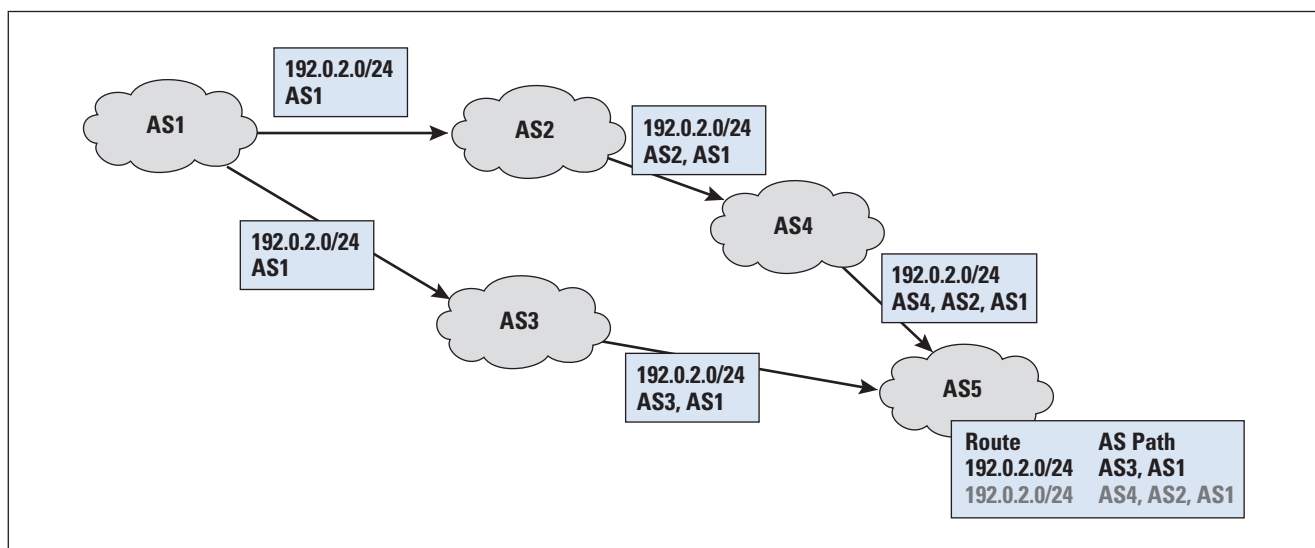

The Design of BGP

BGP underwent numerous refinements over its early operational life. The protocol was originally described in RFC 1105 in June 1989,^[6] allowing the inter-domain architecture of the Internet to move on from a constrained architecture of *core* and attached *stub* domains into a framework of peer routing domains without any central core.

A refinement to this protocol, BGP-2, was described in RFC 1163 in June 1990,^[7] and a further refinement, BGP-3, was described in RFC 1267 in October 1991.^[8] The current version, BGP-4, was first deployed within the Internet in 1993. The RFC describing this protocol, RFC 1771,^[9] was published in March 1995, and was subsequently refined with the publication of RFC 4271 in January 2006.^[1] The core protocol has been stable for some years now, although further refinement has been undertaken through the use of negotiated capabilities undertaken at BGP session startup.

BGP is an instance of what we commonly refer to today as a *Bellman-Ford Distance Vector* routing algorithm.^[10,11] This algorithm allows a collection of connected devices (BGP speakers) to each learn the relative topology of the connecting network. Its basic approach is very simple: each BGP speaker tells all its other neighbours about what it has learned if the new learned information alters the local view of the network. This scenario is a lot like a social rumour network, where everyone who hears a new rumour immediately informs all their friends. BGP works in a very similar fashion: each time a neighbour informs a BGP speaker about reachability to an IP address prefix, the BGP speaker compares this new reachability information against its stored knowledge that it gained from previous announcements from other neighbours. If this new information provides a “better” path to the prefix, then the local speaker moves this prefix and associated next-hop forwarding decision to the local forwarding table and informs all its immediate neighbours of a new path to a prefix, implicitly citing itself as the next hop. BGP keeps track of the propagation of route advertisements across the inter-domain space by recording the sequence of network *Autonomous Systems* (ASs) that propagate the route in a route attribute called the *AS Path*. A “better” route is one with a shorter AS path, and a loop is detected when a BGP speaker sees its own AS in the received AS Path (Figure 1).

Figure 1: The Propagation of a route in BGP

In addition, there is a withdrawal mechanism, where a BGP speaker determines that it no longer has a viable path to a given prefix, in which case it announces a *withdrawal* to all its neighbours. When a BGP speaker receives a withdrawal, it stores the withdrawal against this neighbour. If the withdrawn neighbour happened to be the currently preferred next hop for this prefix, then the BGP speaker examines its per-neighbour data sets to determine which stored announcement represents the best path from those that are still extant. If it can find such an alternative path, it copies this path into its local forwarding table and announces this new preferred path to all its BGP neighbours. If there is no such alternative path, it announces a withdrawal to its neighbours, indicating that it no longer can reach this prefix.

Across the deployment lifetime of BGP-4, the IPv4 Internet has grown from an average of 20,000 distinct routing entries in 1993 to almost 1 million routing entries in 2021.^[12] Figure 2 shows the growth of the size of the Internet IPv4 routing table over time.

Figure 2: Internet IPv4 Routing Table Size, from [12]

BGP and TCP

BGP is not a link-level topology maintenance protocol. It assumes the existence of a relatively robust IP forwarding environment at the link level between BGP peers. This assumption has allowed BGP to use the *Transmission Control Protocol* (TCP) as a reliable transport protocol to support the transactions of the protocol across a BGP peer session.

TCP manages reliable message delivery and flow control between the BGP peers and allows BGP to operate across end-to-end connections whether they reside on the same subnet or across the Internet. There is no requirement for BGP speakers to be connected on a common media connection, and the choice of TCP allows this flexibility of connectivity by requiring only that a BGP peering session is supported by an IP network.

The TCP stream is divided into messages using BGP-defined markers, where each message is between 19 and 4096 octets long, extensible to 65,535 octets.^[11] The use of a reliable transport service implies that BGP itself need not explicitly confirm receipt of protocol messages, removing much of the protocol overhead seen in other routing protocols that sit directly on top of a media-level connection. There are no message identifiers, no message number initiation protocols, no explicit acknowledgement of messages, nor any provision to manage lost, reordered, or duplicated messages. TCP handles all of that. The use of a reliable transport protocol also obviates the need for BGP to periodically refresh the routing state by automatically reflooding the entire routing information set between BGP speakers. After the initial exchange of routing information, a pair of BGP routers exchange only incremental changes to routing information.

BGP Messages

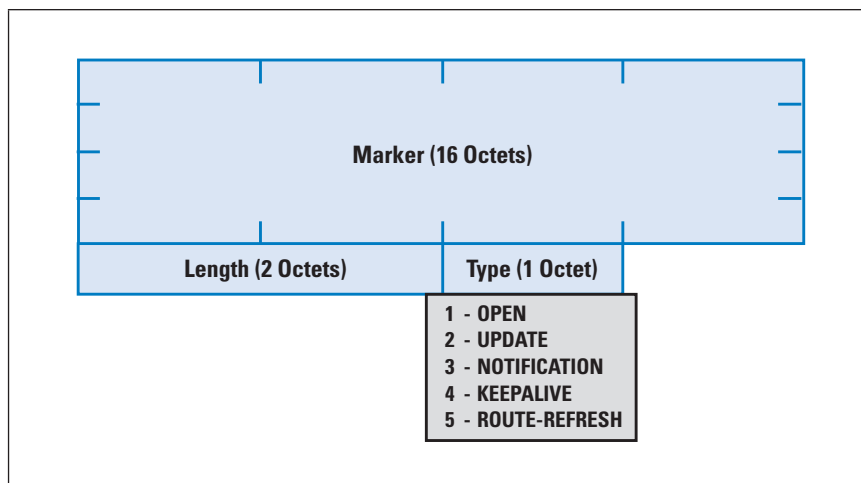

Because TCP is a *stream protocol* rather than a *record-oriented protocol*, BGP uses record marking within the TCP stream to delineate logical protocol units, or *messages* with a 16-byte marker as the BGP message delimiter. A 2-byte length and a 1-byte type field follow the marker, making the minimum BGP message size 19 bytes. The repertoire of defined messages follows:

- An OPEN message to start a BGP session
- An UPDATE message to exchange reachability information
- A NOTIFICATION message, which is used to convey a reason code prior to termination of the BGP session
- A KEEPALIVE message, used to confirm the continued availability of the BGP peer
- A ROUTE-REFRESH request message to request a resend of the routing information.

Figure 3 on the next page shows the common format of BGP messages.

BGP uses an explicit OPEN message to commence a BGP peering session. This message exchange confirms the identity of the BGP speakers and includes the option for a capability negotiation to understand what optional or extended capabilities each BGP speaker supports. A session is active only when both BGP speakers have sent their OPEN messages and neither has rejected the other's offered capabilities through a NOTIFICATION response.

Figure 3: BGP Common Header Message Format

When the session is active, BGP operates via the exchange of UPDATE messages. Each UPDATE message contains a set of address prefixes that are unreachable (withdrawals), followed by a set of common route object attributes and a set of address prefixes that share this set of attributes (announcements). The withdrawn prefixes are those prefixes where the local BGP speaker sees no reachability, and now wants to withdraw a previous advertisement of reachability. No routing attributes are associated with these withdrawn prefixes.

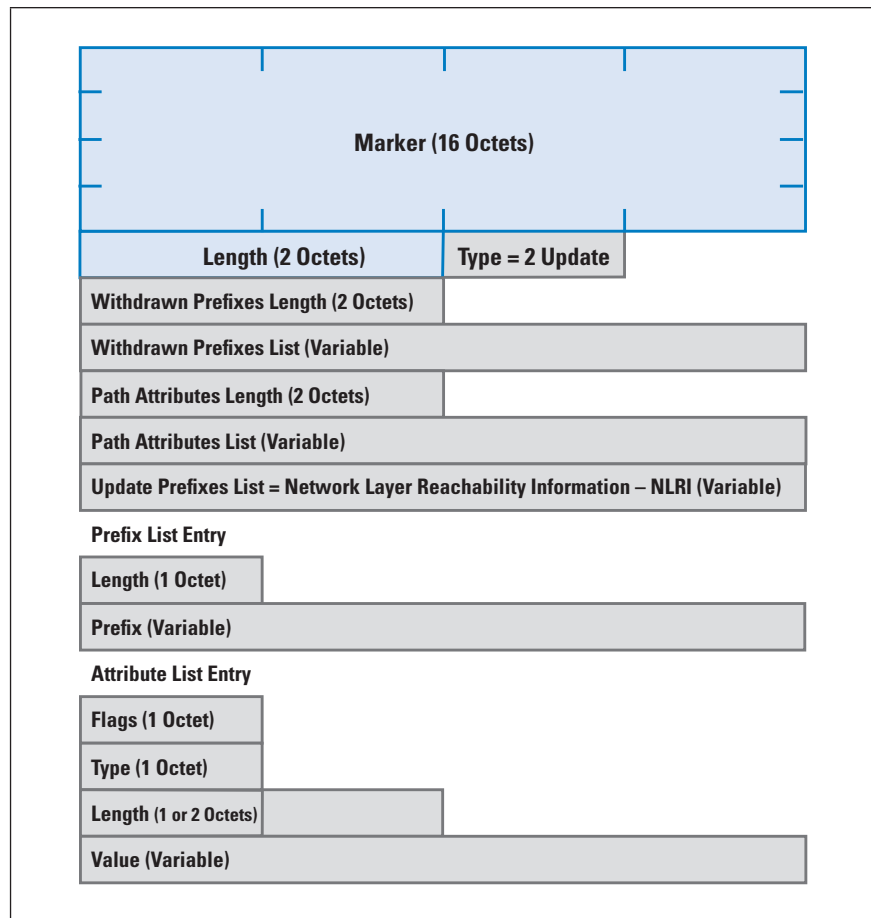

The announced prefixes are those prefixes where the local BGP instance has an updated view of the reachability of a prefix that was previously withdrawn or unannounced or has an updated view of the routing attributes of the locally selected “best” route for a prefix. BGP may group multiple prefixes together in a single UPDATE message but can do so only if all the updated prefixes share a common set of attributes. Within an UPDATE message, the withdrawn prefix set or the announced prefix set may be empty, but not both. Figure 4 on the following page shows the layout of the BGP UPDATE message.

AS Path Attribute

BGP binds together the concept of network address blocks and autonomous systems into a path vector-based routing technology. Every route object represented within a BGP-4 route database contains an address prefix and an associated path vector of AS values. BGP does not indicate the precise path a packet should follow within an AS, nor does it maintain a complete map of the topology of the Internet at a link-by-link level. BGP uses a level of abstraction that views the Internet as a set of per-AS routing domains, and the role of BGP is to maintain a routing map of the network at this AS level, associating every reachable address prefix with an AS transit path from the current location to the originating AS of the address prefix.

One of the most important route object attributes in BGP is the AS Path attribute of UPDATE messages that contain announced routes.

Figure 4: BGP UPDATE
Message Format

As address prefix reachability information traverses the Internet in the form of individual route objects in BGP, this BGP routing information is augmented by the list of autonomous systems that have processed this route information thus far, forming the AS Path attribute of a route object. Each BGP speaker adds its own AS value to the AS Path attribute of the route object when passing the route object through an *External BGP* (eBGP) session.

This AS Path attribute allows straightforward suppression of the looping of routing information, using the simple algorithm that a local AS will reject any forwarded route object that already contains its own AS in the AS Path attribute. Also, the length of the AS Path vector forms the BGP route metric. A local BGP system, when attempting to select one from numerous potential route objects that refer to the same address prefix, will, in the absence of any local policy directive, prefer the route object with the shortest AS Path length.

In addition to undertaking the role of path metric and loop detector, the AS Path attribute serves as a versatile mechanism for policy-based routing, where a local AS can alter the default preferences for route selection based on local policy settings coupled with pattern-matching rules to be performed on the AS Path.

Withdrawals have no associated AS Path.

BGP Route Selection Process and Routing Policies

A BGP speaker may receive two or more announcements for the same address prefix from different peers. The “best” announcement is selected as the locally used announcement, and this announcement is the one that is announced to its BGP peers. BGP defines an ordered sequence of comparisons to determine which route object is selected by the local BGP speaker as the preferred route to use:

- Prefer the route object with the highest value for LOCALPREF attribute value.
- Prefer the route object with the shortest AS PATH attribute length.
- Prefer the lowest origin value.
- Prefer the lowest MULTI EXIT DISCRIMINATOR attribute value.
- Prefer the minimum *Interior Gateway Protocol* (IGP) cost to the NEXT HOP address given in the route object.
- Prefer eBGP over *Interior BGP* (iBGP)-learned routes.
- If using iBGP, prefer the lowest *BGP Identifier* value.

Although network administrators usually employ routing policies depending on their needs,^[14,15] within the generic BGP route selection process the highest-priority selection rule is that a route for a more specific address prefix is to be preferred over that of a covering prefix.

The BGP Threat Model

One approach to providing a taxonomy for threats in routing in general, and BGP in particular, is to view a BGP peer session as a conversation between two BGP speakers and pose numerous questions relating to this conversation. These questions include:

- *How do we talk?* The manner in which the BGP session between the BGP speakers is secured such that the conversation is not altered, disrupted, or hijacked and is protected from unauthorised eavesdropping
- *Whom am I talking to?* Verification of the identity of the other party and verification that they are authorised to speak for the routing entity that they purport to represent.
- *What are you saying?* Verification of the authenticity and completeness of the routing information being passed in the BGP session.
- *Why should I believe you?* Verification that the routing information represents the current state of the forwarding system.
- *How recent is your information, and is it still valid?* Verification of how long routing information is valid and whether the information is still current.

You can further deconstruct each of these security questions to a set of specific objectives, as well as recognise a set of specific threats.

Securing a BGP Session

A BGP session between two BGP speakers is assumed to have some level of integrity at the session transport level.

BGP assumes that the messages one party sends are precisely the same messages the other party receives, and that the messages have not been altered or reordered, have not had spurious messages added into the stream, or have messages removed from the conversation stream in any way, and given that BGP uses a TCP transport session, some of these assumptions are reasonable but others less so.

As with any long-held TCP session, a BGP peer session is vulnerable to eavesdropping, spurious session reset, session capture, message alternation, and *Denial-of-Service* (DoS) attacks, all through what we might think of as conventional TCP attack vectors.

The threat at the BGP level is that a third party may attempt to break into the TCP session as an interception attack in the middle, and thereby alter the BGP message flow between the two end points. One form of threat is by injection, where the attacker injects spurious messages into the BGP session. Direct on-the-wire interception allows the attacker to have knowledge of the TCP sequence numbers, thereby making injection a trivial task. Even if the attacker is not able to intercept or eavesdrop the BGP session, it is still possible to attempt to guess the current sequence number.

While this guessing is often impractical in the case of injecting data into the session, if all that is to be injected is a TCP Reset, then the sequence number guess only has to sit within the current TCP window in order to be recognised as a valid reset TCP message.^[16] Another form of threat is by active intermediation, where the attacker sits on the connection between the two BGP speakers and intercepts all traffic in both directions. In this case, the attacker has complete control of the BGP message stream and can perform any form of message alteration. A variation of this form of threat is *session hijacking*, where the third party intrudes upon an active BGP session and injects its own traffic into the message stream—and that traffic allows the third party to take over the session and masquerade as one of the parties to the BGP session. Because timing is important in the overall performance of BGP, another form of attack at the session level is to delay messages. Although the content of the messages is unaltered, the implicit timing signals within the message stream are altered by this form of intervention, potentially causing the local BGP speaker to behave differently and fall out of sync with its routing peers.

Another form of attack is a *replay attack*, where older BGP messages are replayed into a hijacked TCP session. One form of this replay attack could be to replay a pair of messages that withdraw and then announce the same address prefix.

Route Flap Damping (RFD)^[17,18] is a widespread defensive BGP configuration that monitors the frequency of BGP updates for a given prefix from each peer, and if the update rate exceeds a locally set threshold, the advertisement of this prefix by the peer will be locally suppressed for a damping interval. The replay of updates could be used to trigger an RFD response in the remote BGP speaker.^[19] If a route is fully dampened through RFD, the BGP speaker will not advertise updates for this prefix for a damping interval (commonly 60 minutes), possibly causing a route disruption within that time frame. Another form of replay attack is to replay a route advertisement for a previously withdrawn prefix, possibly in conjunction with some form of prefix hijack attack.

Another form of threat is withholding traffic. BGP uses keepalive timers to determine remote end “liveness.” By intercepting and withholding all messages for the hold-down timer interval, a third party can force the BGP session to be terminated and reset. This action causes the entire route set to be re-advertised upon session resumption so that repeated attacks of this form can be an effective form of denial of service for BGP.

It is also possible to undertake a *saturation attack* on a BGP speaker by sending it a rapid stream of invalid TCP packets. In this case, the processing capability of the BGP speaker is put under pressure, and the objective of the attack is to overwhelm the BGP speaker and cause the BGP session to fail and be reset. This type of attack is particularly problematic if the BGP session uses *Message Digest 5* (MD5) or *Internet Protocol Security* (IPsec) as session protection protocols, because the cryptographic function overhead also applies to the injected packets, increasing the processing overhead on these spurious injected packets.

The underlying aspect of the BGP protocol is that BGP itself has no enforced minimum level of message protection. BGP messages are, by default, placed into the TCP stream without encryption or additional message wrapping of message sequencing. Any threat that is applicable to long-held TCP sessions applies to this default mode of BGP operation.

Verifying BGP Identity

BGP sessions commence by passing the local AS to the remote end of the session in the BGP OPEN message and receiving the AS of the remote end in the received OPEN message. BGP itself does not verify these asserted AS identities, and it is theoretically possible for a remote party to masquerade itself as another AS and assert an identity in BGP that the other party cannot directly verify by, and neither can any third party that subsequently receives this routing information. Most BGP implementations provide a level of protection against this threat by applying a constraint that the local BGP speaker will initiate a peer session only with a configured remote IP address, and reject all other TCP connection attempts.

Furthermore BGP will not complete the BGP OPEN message exchange if the AS in the OPEN message does not match the AS number associated with the remote end IP address in the configuration.

This approach places a heavy reliance on the out-of-band process of BGP configuration, and if an attacker can compromise or take control over BGP equipment connected to the Internet or use social engineering to convince a network administrator to configure incorrect information into the BGP configuration, then it is possible to masquerade as a different party in BGP and potentially inject incorrect information into the routing system.

The real question here is: “Are you really who you claim to be?” Here it is necessary for the BGP speaker to be able to confirm the validity of the peer claim that it is speaking for an AS.

Verifying BGP Information

The objective here is to verify the authenticity and completeness of the routing information being passed in the BGP session. The intention of BGP is that a local BGP speaker provides to all its BGP peers a complete feed of its locally selected route objects.

When a session is opened with a remote BGP speaker, the local BGP instance believes everything it is told without further qualification. The threat is that a BGP peer can deliberately feed false information to the local BGP instance, which BGP itself will be unable to detect as false. The false information could be in the form of suppression of routing information, or alteration of the route object that is being passed, or the invention of spurious route objects. The BGP speaker could be asserting that an AS Path is genuine when it reflects an artificial path, or that it has the authority to originate an advertisement for a prefix when, in fact, no such authority exists.

A BGP speaker may preserve all the attributes of a route object, but alter the prefix set to be the equivalent collection of more specific prefixes. The deliberate alteration of routing information can cause the local BGP instance to make an incorrect choice of a local best path and also cause the local BGP instance to propagate this incorrect information to its neighbours.

Not only could the BGP speaker be passing incorrect attributes for an address prefix in order to bias the local route selection process, but it also could be providing incorrect information regarding the prefix itself. The prefix that is the subject of the route object could be a prefix that has never been allocated and should not be legitimately routed, or the prefix could be an aggregate address prefix that spans both allocated and unallocated address space.

Prefix hijacking is a major threat to the integrity of the BGP routing. The fundamental weakness here is that BGP provides no explicit means of verifying the authenticity of the address prefixes that are listed in a BGP UPDATE message, nor the authenticity of the attributes of the prefix, including the origination information and the AS Path vector. The threat here is that by deliberately altering this information, the local BGP speaker can be induced to make incorrect route selection decisions and thereby make incorrect forwarding decisions for IP traffic.

A known common problem illustrative of exploiting this vulnerability is operational misconfiguration,^[20] which could result in propagating more specific routes and other forms of route leakage, or withholding that may affect the routing decisions made by other BGP speakers. This form of verification of intentionality by a remote BGP speaker is far more challenging—while these forms of security mechanisms are intended to verify that the received information matches the original information that was passed into the routing system, they are incapable of verifying that such information is consistent with the true intent of the originator of the information.

Verifying Forwarding Paths

The overall intention of the BGP protocol is to distribute the current binding of address to location such that individual routers can make accurate judgements about how to populate their local forwarding tables and hence make optimal local decisions for each packet that passes along the shortest path to its ultimate destination.

BGP does not provide any ability for a local BGP speaker to validate that the route advertisements it receives from a BGP peer accurately represent the current state of the network forwarding system. The threat model here is that a bad actor in the routing system may make a different forwarding decision to that being advertised in the routing system.

This situation can represent a subversion of local policies, theft of carriage capacity, deliberate denial of service, or the potential to eavesdrop on a conversation or support the interception and alteration of application-level transactions. Even a completely secured control plane does not avert such vulnerabilities.^[21]

The Consequences of Attacks on the Routing System

The ability to alter the routing system provides a broad array of potential consequences.^[3] The consequences fall into numerous broad categories, which are briefly described here:

1. *The ability to eavesdrop.* The forwarding system can be altered so as to pass all traffic to a class of destination addresses through a certain path. This change allows the attacker to attempt to pass all such traffic through an eavesdropping location prior to conventional delivery. In such a case the parties may not be aware that an eavesdropping attack is taking place.

2. *Denial of service.* The simplest form of a DoS is where traffic to an address prefix is passed to a point where it is then discarded. Routing loops also are a form of DoS, where not only will the traffic to a destination address prefix never reach its intended destination, but the traffic will be held in the loop for the life of the packet *Time to Live* (TTL) field. For sufficiently short loops the potential exists for the loop to act as a link load amplifier, where the traffic on the loop is several times the traffic load being addressed to the affected destination address prefix.
3. *The potential to masquerade.* Subversion of routing allows sites to masquerade as other sites; the routing system misdirects the traffic to the masquerading site. The consequences of such an attack can vary from the specific, where a particular site is targeted, to the more generic, where authoritative *Domain Name System* (DNS) servers are the subject of the masquerading attack, and the DNS responses are believed to be authentic. In this case if the masquerading occurs at the root level of the DNS hierarchy, incorrect information can be provided to any query, allowing for the attack to then be extended to any site.
4. *The ability to steal addresses and obscure identity.* Routing an unallocated address is subtly different from routing an already allocated address. Here the consequence is not displacement of traffic forwarding to incorrect locations in the network, but the assertion of the existence of addresses and forwarding paths to those addresses that should not exist in the network in the first place. The consequence is the ability to use addresses on the network that have no allocation registration information associated with them, allowing the originator of the routing attack some degree of ease to mount an anonymous attack at the application level. Such forms of attack have been observed to be associated with SPAM and botnet controllers where anonymity of the attack coordinator is desired.

Security Requirements

The primary requirements for securing BGP are securing both the transmission of the data payload of the BGP protocol and the semantics of that payload.

The security requirements for transmission are such that the data that a BGP speaker receives can be cryptographically verified to have been sent by the BGP peer, the data is not a replay of previously transmitted data, and no data has been removed from the transmission.^[22]

There is no strict requirement for encryption of the BGP payload, because the routing information being exchanged is not intrinsically confidential to the two parties involved. The security requirements for the semantics of the payload concern specifically some selected fields (transitive attributes) of the BGP UPDATE message. The BGP speaker must be able to verify that the advertised prefix is valid, and that the originating AS has been duly authorised by the legitimate right-of-use holder for that prefix.

The BGP speaker should also be able to validate that the AS Path in the UPDATE represents a valid inter-AS transit path through the network in terms of inter-AS topology and AS transit policies, and that the prefix reachability information has been propagated along the reverse inter-AS Path.^[22]

It is noted that route withdrawals and nontransitive announcement attributes are local, and thus do not need to be transitively protected in a similar fashion to route origination and the AS Path attribute of announcements. You can adequately protect withdrawals and local attributes with BGP peer session protection.

The associated requirements for a secure inter-domain routing system include that the additional use of security credentials and verification of routing information should not alter the temporal properties of the BGP protocol, and that authentication of the security credentials should occur in the same time frame as the BGP message processing operation. It is also a requirement that piecemeal incremental deployment should be feasible.^[23,24,25] A secure operational mode should be a capability negotiation with each BGP peer, with the ability to support backward compatibility with those BGP peers that do not recognise such a capability. It seems to be a good idea to start deployment of BGP security on the most-connected nodes and incrementally deploy it towards least-connected nodes.

Additionally, it suggests the question: How does a party that uses security credentials deal with information arriving from a peer that does not use any security credentials? Having no security credentials does not necessarily mean that the information is wrong, of course. But importantly, in these piecemeal deployment scenarios there should be some incremental benefit of piecemeal deployment to those actors who choose to supply such security credentials and those who choose to validate routing information using these credentials.

A routing system, secure or otherwise, should never make route selections that include routing loops. It is preferred that in a fully secured environment a secure routing system would be able to converge on best paths that are either identical to or no worse than an unsecured BGP speaker would select, assuming that such paths can be validated in a secure environment. In an environment of partial adoption of secure routing systems, it is recognised that a BGP speaker may use local preference settings that prefer sub-optimal paths that have preferred security credentials over unsecured paths.

The trust model of routing appears to involve two forms of trust. The first is a trust environment related to the public network and the legitimacy of use of a public address and a public AS number. It is necessary to be able to verify that a particular party has the right to use these number resources in a public context. The closest fit in the form of a trust model for verification of this assertion of right of use is a public authority that can provide authoritative information on the distribution of these numbers.

This approach leads to a rooted hierarchy model of trust, where the trust anchor is this public authority.

The second form is a trust environment in private contexts, where the use of an address or AS number is bounded by a specific context of use, and the trust in an assertion of a right of use is one made in the context of this bounded environment. In this environment, there is no clear ability to use public authorities as a trust anchor, and other means of trust that may involve reputation, or web of trust concepts may be appropriate.

A general security approach to BGP should be able to encompass that diversity of deployment environments and the corresponding diversity of authority models.

Tools for Securing BGP

The vulnerabilities of BGP arise from four fundamental weaknesses in the BGP and inter-domain routing environment, including:

- No mechanism to protect the integrity, currency, and source authenticity of BGP messages
- No mechanism to verify the authenticity of an address prefix and an AS origination of this prefix in the routing system
- No mechanism to verify the authenticity of the attributes of a BGP UPDATE message
- No mechanism to verify that the local cache *Routing Information Base* (RIB) information is consistent with the current state of the forwarding table

The other observation about BGP security is that it appears that by far the most straightforward form of attack is to obtain control and configuration access to a deployed router and use this compromised platform as the base for launching attacks on the routing system. In the face of such an encompassing attack on the control instruments of the routing system, BGP session-level security needs to be placed in some perspective. It is not possible to prevent routers from attempting to generate false information as long as routers themselves are in a position to be compromised.

The consequent vulnerability on the routing system, as distinct from a narrower view of BGP, is that there is no mechanism that limits the extent to which a misbehaving routing element can make inaccurate claims about reachability in the routing system.

The Security Toolset for BGP Session Protection

The available tools for securing BGP start at the level of the BGP TCP session and encompass the tools that are used to protect TCP and the two ends of the TCP session.

The TCP protection mechanisms include the generalized TTL security mechanism,^[26,27] which is intended to limit the effective radius of potential attack on the session to hosts that lie on or within the worst-case hop-count radius between the two BGP speakers and host-level defences against TCP SYN attacks.^[28] In many ways, this form of defence is effective when using multi-hop BGP sessions in that the attacker cannot subvert the defence, but it still leaves the session vulnerable to any attacker that lies within the TTL radius.

You can get greater levels of session protection by using cryptographic protection. Over time the IETF has worked on three approaches to protect the BGP TCP through cryptographic protection. They include:

- The use of IPsec.^[29] IPsec has not been widely used for BGP sessions, and the reasons why relate to the complications for rekeying *Internet Key Exchange* (IKE)/IPsec sessions and the potential *Distributed Denial-of-Service* (DDoS) vector.^[30]
- The *TCP MD5 Signature Option*.^[31] Although the MD5 signature option has some potential weaknesses when compared with IPsec,^[29] MD5 is considered preferable to no form of TCP protection at all, particularly with respect to the TCP Reset injection attack. However, there are issues with re-keying a long-held session, and the BGP speakers probably need to use graceful restart mechanisms in conjunction with MD5 to perform a re-key of the session.
- The *TCP Authentication Option*,^[32] which the IETF has marked as a replacement for the earlier MD5 approach. The *TCP Authentication Option* supports stronger crypto algorithms compared to MD5. It uses a two-fold security approach that reduces the critical reliance on a user-configured key. This approach also allows the configuration of up to 64 keys for a session and provides a simple key coordination mechanism by giving the ability to change keys (move from one key to another) within the same connection without causing any TCP connection closure. By comparison, changing TCP MD5 keys during an established connection might cause a flap or restart in the connection, which in the context of BGP may have operational implications.

From time to time the topic of BGP over *Transport Layer Security* (TLS)^[33] is raised, and it is possible that sooner or later we might hear of BGP over *Quick UDP Internet Connections* (QUIC).^[34,43] The salient question is one of balancing the additional burden of adding more transport choices to BGP implementations with the likely benefits that these additional choices may provide. As we've seen in the IPv6 transition and more recently in the increasing diversity of choices for encrypting DNS transactions, adding more options can offer just confusion and impede adoption instead of accelerating it.

However, the most important guideline in securing BGP sessions is to use multi-hop BGP and multi-access LAN sessions sparingly and preferably use a direct 1:1 channel connection when such a choice is available.

The Security Toolset for BGP Message Protection: RPKI

In addition to message integrity protection that transparent session-level protection mechanisms provide, the tools to provide protection of the integrity of BGP messages relate to the use of digital signatures to provide a set of credentials that allow relying parties to verify the correctness of the information carried as the message payload in BGP.

The reason for the use of digital signatures as opposed to an integrity check using some form of shared secret was obvious after the observation that the number and identities of all eventual recipients of the information are not known in advance, and non-repudiation is desirable.^[3] Verification of the contents of a message is not only a test of whether the message has been altered in any way during its transit between BGP speakers, but also a test of whether the message represents correct origination information and correct operation of the processing of the message during the message propagation (*authenticity*).

This requisite implies a need to establish a means of verification of information where the author of any security credentials relating to origination and propagation is not necessarily known to the relying party that is attempting to validate the information. This need typically invokes a form of validation that relies upon third-party transitive trust, where the relying party is attempting to build a testable chain of trust between its trust anchor and the party or action that is the subject of the verification operation. Conventionally, this requirement implies the use of some form of *Public Key Infrastructure* (PKI). In this case, we are not looking to use such a PKI to validate claims of identity, authority to perform a particular function, or some form of verifiable attribution. We need some form of mechanism to associate a public key with an IP address prefix or an AS number in a sense of functional control, where the certification authorities in this PKI are attesting that the certified subject has *functional control* of a collection of IP number resources (AS numbers and IP address prefixes). The associated certificate issuance practices are intended to support transitive trust in such attestations of association.

We have adopted a structure using X.509 public key certificates and a certificate extension that uses a canonical list of IP address resources and AS numbers^[35] as the foundation for this *Number Resource PKI* (RPKI).^[36] Verification of a digital signature entails a test of the authenticity and current validity of the associated certificate that describes the public key of the address or AS number holder in the context of a structured set of signed relationships between certificate issuers and subjects. In other words, the holder of the matching private key is the current functional controller of those IP addresses and AS number and can digitally sign authorities and attestations about such number resources on the basis of that functional control.

Given that the discourse of BGP messages is about address prefixes and AS numbers, the RPKI provides a solid foundation for digital signatures to be associated with various routing actions that are described in BGP messages.^[37] It does not attest in any way to the identity of these number resource holders.

Anchoring the model of authority and trust in the RPKI certificate structure has resulted in a framework where the issued certificates are aligned with the IP address and AS number allocation and assignment framework. If an Internet Registry has issued a set of IP addresses and AS numbers to an entity, then this registry would be able to publish a public key certificate that associates a private key provided by the entity with the IP resource set. Further allocations from a registry to a registry address holder would result in re-issuance of the certificate for the address holder with a larger resource set, while reduction in this set would result in both re-issuance and revocation of the previous certificate. This certificate framework would allow auditing of the certificate state by inspecting the registry contents of the Internet Registries, because the intention of this PKI is to mirror the overall state of the number registries with the set of issued certificates.

The RPKI is different from many other PKIs because the requirements related to adding digital signatures to the routing domain are different from many other PKI deployment environments. The common question that the PKI attempts to answer is: “Is this data authentic?” The data is signed with a digital signature, and the key used to generate that signature is described in a certificate. The validity of that certificate can be ascertained by using a collection of certificates and *Certificate Revocation Lists* (CRLs), such that a relying party may validate the data by using its local trust anchor(s) and constructing a *validation path* of issuer-subject chained certificates from a trust point to the digital signature. If this collection of certificates is bundled with the digital signature and the data itself, then the only data items that need to be distributed outside the data flow are the PKI trust anchors.

Distributing the RPKI Data Collection

When the RPKI is combined with a use case for the routing domain, we are looking at a design space that is somewhat atypical in the PKI world. For example, in the WebPKI the certificates that are passed between server and client in the initial exchange of a *Transport Level Security* (TLS) session are related to the particular domain name used in the TLS session being established.^[33] The critical distinction here between the secure client/server transactions using the WebPKI and the promulgation of routing information in the routing system using RPKI is that the routing system continuously presents the *entire* routing domain to each relying party. Each relying party needs to have continual access to the entire RPKI certificate and CRL collection, rather than the TLS practice of processing individual signatures and certificates on an as-needed basis.

This requirement for all participating entities to have access to all the RPKI data at all times poses a design challenge about how to manage this RPKI and use it in a routing protocol such as BGP.

A basic approach here is for each Internet Registry to publish its certificate products in its own publication point. This paradigm is analogous to the pre-*Content Delivery Network* (CDN) model of web content publication, where each element is independently published. Of course, in this case while publication is easy, the onus is shifted to the relying party client, or BGP validator, who has to assemble a local cache of all RPKI signed data. It becomes the task of clients of the RPKI to maintain a local cache of the entire RPKI by continuously sweeping across these publication points looking for, and retrieving, changes, and validating all such signed objects as they are received.

At this point BGP updates could be passed to this local RPKI engine, and the data in the update can be compared against the validated information contained in the local RPKI cache. If RPKI validation was performed at the point of acceptance into the local cache (that is, discarding all RPKI products that cannot be validated within the framework of the RPKI validation procedures), then you could verify the route information against the assembled (and validated) crypto data without a high on-demand crypto processing overhead. An alternative approach is to express the validation outcomes from the local RPKI cache as a filter list. If this list were maintained on a router, then the overheads in passing route objects through such a filter would be little different from the many other routing policy maps used in operational configurations.

The drawback in this distributed approach is the need for these clients to constantly sweep all the RPKI publication points to ensure that their local cache is up-to-date. The meaning of “up-to-date” is relative here, but it is worth remembering that the average time to propagate a BGP update across the global Internet depends on the average AS path length (around 4 to 5 autonomous systems on average at present) and the interaction with the BGP *Minimum Route Advertisement Interval* (MRAI) timers. Whereas the worst case would be 300 seconds (assuming that the full MRAI delay would be applied on each eBGP session), the fastest case is well under a second. So how quickly should the local cache be populated to keep up with the propagation of routing information in BGP? Before leaping to a target time, it is also worth remembering the scaling question. With around 100,000 distinct ASs in the Internet routing system, today’s worst-case scenario is some 100,000 RPKI clients performing a sweep across 100,000 distinct RPKI publication points every few seconds (or even more frequently if the RPKI system is intended to be highly responsive).

In some ways, this scenario puts the load on the wrong side of the information distribution process. By making the relatively infrequent publication process one that involves a local action without any associated notification of a change, then the burden is shifted to the client set, that has to poll every publication point continuously just to ascertain if anything has changed. To put it as plainly as possible, this particular information distribution design is completely broken! If the client set is known in advance (such as is the case in the DNS in synchronising the information across primary and secondary authoritative services), you could use notification mechanisms. But in the case of the RPKI system, the publishers of authoritative information have no information as to who the clients who need to be notified of a change in the part of a *Certificate Authority* (CA) of the RPKI data collection even are. Hence, notification is not a viable option in this framework.

You can mitigate these relatively formidable scaling issues by changing the publication behaviour, in a manner analogous to the way in which CDNs have improved web performance by shifting content publication models to various permutations of anycast-related models of content replication. In the context of the RPKI, these permutations could entail the use of a smaller set of RPKI publication points that many RPKI certificate issuers share, or a reduction in the number of independent CAs who each publish their own products through the extensive use of *Registration Agents* (RAs). The information being published is signed, so there is no particular benefit to retrieving the data from any particular publication point. As long as the client can validate the data, the client can be assured that the data it has retrieved is most likely to be genuine, irrespective of the location used for the retrieval. It is possible to use third-party aggregators in such a role; these aggregators would take on the task of continuous monitoring of all RPKI CA publication points and publish an aggregated data set of all current RPKI data. You could take this model further into a *push* model by having clients register their interest in updates from the intermediary and allow the intermediary to send them information updates as they are received from the primary CA publication point sources.

Again, it must be noted that the information is signed, so the potential that the intermediary could alter the RPKI information is limited. The design gap in such mediated distribution approaches is to provide a mechanism for clients of these aggregated intermediaries to be assured that the collection the intermediary has provided is the entire collection of RPKI data, and any credible intermediary approach would need to explicitly address this problem of *information completeness*.

However, although these approaches reduce the load imposed on the RPKI clients by increasing the load on information publication, such aggregated publication models also create critical points of concentration of routing data, and a sustained denial-of-service attack against such aggregate publication points could significantly affect the routing system as the local RPKI caches lose currency and coherency.

These approaches have their own strengths and risks. Highly distributed publication models impose undue costs on clients because the clients need to maintain an aggregate and current data collection in their local cache. Aggregate data-publishing models relieve load from clients but have some unresolved issues in terms of assured completeness of the aggregated data collection; they also run the risk of creating new points of vulnerability in terms of the consequence of DOS attacks launched against these aggregated publication points.

The current RPKI operational framework that is used in the *Route Origination Validation* (ROV) tool^[38] uses the approach of an *out-of-band* RPKI *pull* system together with some use of aggregated RPKI publication points. The local cache currency performance level of an RPKI client is phrased in units of minutes rather than seconds, and the overall system operates at a level of coherency that is at a time scale of hours rather than minutes. The initial design of this RPKI distribution system is for each client to operate autonomously and maintain a local cache to keep synchronised with the current state of all the RPKI publication points using the *rsync* protocol^[39] together with the concept of a manifest.^[40] This manifest allows a client to ensure that it has retrieved the entirety of the data available at each RPKI publication point. The *rsync* protocol was subsequently found to be a poor choice for this role,^[41] and these days the *RPKI Repository Delta Protocol* (RRDP) is the preferred RPKI repository synchronisation tool.^[42]

In terms of the application of the RPKI to the BGP environment, we should ask an obvious question here: If the intent of the flooding system is to provide a reliable and efficient way to flood current information to all clients, then why not just use BGP itself? BGP is an Internet-wide information flooding protocol using a *push*-based approach that is intended to ensure that all BGP speakers have a consistent and current collection of reachable route objects. If the set of clients that want to maintain an up-to-date synchronised local cache is isomorphic to the set of BGP speakers, then adding a BGP message payload type in the same manner that *Address Family Indicator/ Subsequent Address Family Indicator* (AFI/SAFI) indicators are already used in Multi-Protocol BGP today seems only logical.

Part of the reason why the RPKI has had to re-invent this particular wheel of reliable flooding lies in the strictures imposed on the standardisation effort in the IETF, where the *Secure Inter-Domain Routing* (SIDR) Working Group was constrained from proposing changes to the BGP protocol itself.

In retrospect, this constraint appears to have been a rather suboptimal and, in hindsight, extremely poor piece of guidance from the *Internet Engineering Steering Group* (IESG) at the time.

If we could contemplate changes to BGP, then one approach to the RPKI distribution tasks is to maintain the association of the validation material with the data, and in the context of the routing environment it would staple a collection of certificates (and CRLs) to each route object. In a sense this approach would attempt to reproduce the TLS model in BGP, where each prefix being updated would have a subset of the RPKI certificates stapled to the update that would permit an associated signed attestation to be validated within the framework of the RPKI. This method is not without additional impositions, and it would impose costs on the operation of the BGP protocol and BGP speakers. Stapling crypto credentials to BGP updates would bloat both the volume of stapled data (through the use of long validation chained paths and long-term certificate issuance policies which, in turn, create extended CRL lists) and the amount of crypto processing of these stapled digital credentials. There would be a significant level of the retransmission of certificates on a pair-wise basis in such a system if the protocol were to bundle the entire RPKI validation chain data with every routing protocol update. The validation processing load would also likely be beyond the processing capabilities of most routers, and there are considerations of the maximum message size in the BGP protocol itself (which, until RFC 8654,^[13] published in October 2019, was 4,096 octets), which limited the amount of attached data that can be placed into BGP.

None of these issues is intractable, and many proposals have been made to attempt to optimise such additional loads and processing demands. We will look at some of these proposals in Part 2 of this survey.

Coming in Part 2

In Part 2, we will take these various requirements and tools and look at the various proposals that have been published for securing BGP. We will also evaluate the current state of the effort in the IETF to standardise a secure BGP Framework.

GEOFF HUSTON, B.Sc., M.Sc. A.M., is the Chief Scientist at APNIC, the Regional Internet Registry serving the Asia Pacific region. He has been closely involved with the development of the Internet for many years, particularly within Australia, where he was responsible for building the Internet within the Australian academic and research sector in the early 1990s. He is author of numerous Internet-related books, and was a member of the Internet Architecture Board from 1999 until 2005. He served on the Board of Trustees of the Internet Society from 1992 until 2001. At various times Geoff has worked as an Internet researcher, an ISP systems architect, and a network operator. E-mail: gih@apnic.net

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

I have spent some time in recent months studying the history and development of the world-wide telephone network. Broadly speaking, the telephone network has evolved in two directions away from the traditional system of interconnected public and private telephone switches and their associated hard-wired telephones. First, starting in the mid-1980s we saw the introduction of mobile devices and networks, eventually leading to what we refer to as “smartphones” today. Secondly, many of the traditional telephone networks have been augmented or completely replaced by numerous systems that employ *Voice-over Internet Protocol* (VoIP) technologies. In spite of the differences in technologies, it is still possible to place and receive voice calls to *telephone numbers*, an addressing system that has proved remarkably resilient to growth and technological evolution since its introduction some 130 years ago. (The first commercial telephone exchange was installed in 1892 in La Porte, Indiana.) Unlike IP addresses, telephone numbers are not fixed-length, nor are they managed by a single global entity, but for such a system to work we do rely on a unique set of country codes and numerous interconnection agreements, thus there are some similarities to the way the Internet operates.

I have also been reading numerous recent postings to the “internet-history” e-mail list, operated by The Internet Society. If you’re interested in hearing from Internet pioneers such as Vint Cerf, Brian Carpenter, Noel Chiappa, Jack Haverty, and many others, this list is a great place to start. You can find further details here:

<https://elists.isoc.org/mailman/listinfo/internet-history>

In our previous issue, Geoff Huston presented Part 1 of “A Survey on Securing Inter-Domain Routing.” He described the design and operation of the *Border Gateway Protocol* (BGP), the threat model, and the requirements from a security framework for BGP. In this issue, Geoff concludes the survey by looking at the various proposals to add security to the routing environment and evaluates the current state of the effort in the *Internet Engineering Task Force* (IETF) to provide a standard specification of the elements of a secure BGP framework.

A Survey on Securing Inter-Domain Routing

Part 2 – Approaches to Securing BGP

by Geoff Huston, APNIC

The *Border Gateway Protocol* (BGP) is the inter-domain routing protocol of the Internet, and after some thirty years of operation it is now one of the more venerable of the core protocols on the Internet. One of the major ongoing concerns related to BGP is its lack of effective security measures, and as a result the routing infrastructure of the Internet continues to be vulnerable to various forms of attack.

In Part 1 we looked at the design of BGP, the threat model, and the requirements from a security framework for BGP. In Part 2 we will look at the various proposals to add security to the routing environment and also evaluate the current state of the effort in the *Internet Engineering Task Force* (IETF) to provide a standard specification of the elements of a secure BGP framework.

The approaches to securing BGP can be further classified in the same fashion as the security requirements: securing the operation of BGP and securing the integrity of the BGP data.

Securing the Operation of BGP Sessions

BGP uses a long-held *Transmission Control Protocol* (TCP) session, and you can use the same approaches to secure any TCP session^[1] in the context of a BGP session. These approaches fall into two categories: those that simply attempt to protect the TCP session from disruption via injection of spurious traffic, and those that also attempt to protect the TCP session from eavesdropping and alteration by encrypting the payload.

Generalized TTL Security Mechanism

The *Generalized TTL Security Mechanism* (GSTM), originally described in [2] and updated in [3], is based on the observation that the overall majority of BGP peering sessions are established between routers that are directly connected. The technique is to configure each BGP IP packet to be sent with a *Time To Live* (TTL) field value in the IP header of 255, and for the BGP receiver to discard all packets with an inbound TTL of less than a set threshold value. For a direct connection, the inbound TTL value should be 255, so the receiver can discard all inbound TCP packets within this session with a TTL of 254 or less.

The motivation for this approach is that spoofing of the TTL field in an IP header is challenging for an unassisted remote attacker. This TTL packet filter is a lightweight defensive measure intended to add some protection to the BGP session from efforts to intrude into the session using remote attacks.

You can use this GTSM approach for multi-hop BGP peer sessions, as well as directly connected BGP sessions, but it is not all that robust in terms of its security properties because of the additional variables introduced with TTL changes due to routing changes and the potential to mask the conventional TTL behaviour with tunnelling techniques.

TCP MD5 Signature Option

A more robust approach to protecting the TCP session is through the use of cryptographic protection of the TCP session. While these crypto approaches can be highly resilient to intrusion attempts, they also expose the BGP speaker to potential *Denial of Service* (DoS) attacks if the processing load of the cryptographic functions to detect bogus packets is sufficiently high. The target still has to process bogus packets just to ascertain that they are bogus.

The TCP *MD5 Signature Option*^[4] uses message authentication codes—which are a class of cryptographic hash algorithms applied to messages of arbitrary length that produce a *message digest* of the message—intended to protect the integrity of the message. The desired property of a message digest is that it is infeasible to generate two messages that have the same message-digest value, and equally infeasible to generate a new message that has a particular message digest value. The *Message-Digest 5* (MD5) algorithm^[5] is intended for digital signature applications where a message digest is generated over the combination of a message and a secret shared key value. The message and the digest value can be transmitted openly, and the receiver can use a local copy of the secret key and apply the message-digest algorithm to the combination of the received message and the key. If the digest value matches the received value, then the receiver can be assured that the message has not been altered in transit, and that the message was generated by a party who also has knowledge of the key.

The TCP MD5 Signature Option is a TCP extension where each TCP segment contains a TCP option that contains the 128-bit MD5 digest of the combination of the TCP pseudo header, the TCP segment payload excluding TCP options, and a connection-specific key. This combination establishes a cryptographically secure signature of the packet. Without knowing the key, it is very challenging to construct a TCP segment with a valid signature, and it is not readily possible to alter the packet without causing the signature to be invalidated. The receiver calculates the MD5 digest across the received data, using a locally held copy of the key, and rejects the segment if the digest value fails to match that provided in the packet. In the context of BGP, the TCP session is resistant to various forms of intrusion attack unless the attacker has knowledge of the shared secret key value. The TCP MD5 specification does not specify how the shared key is passed between the two BGP speakers, nor how the key value can be changed during the session. This latter problem is significant in that continued use of a key weakens its integrity, and it is conventionally advised that MD5 session keys be changed every 90 days or so in this type of use context^[6].

With a mechanism for in-band key change, this advice implies the need for a BGP session reset every 90 days or so, which is counter to conventional operational practice in BGP, where sessions are held up for as long as possible. Even with tools such as BGP *Graceful Restart*, deliberate BGP session resets are generally avoided in the operational community.

TCP Authentication Option

A somewhat different approach—the *TCP Authentication Option* (AO)^[7]—uses a *Message Authentication Field* in the place of the MD5 message digest, where the final bit of the length field of the option determines whether or not a key ID has been appended to the *Message Authentication Code* (MAC). The message-digest algorithm in this case is specified as HMAC-MD5-96, although you can use other algorithms if you configure them in advance. This approach relies on a similar form of out-of-band provisioning as the original MD5 approach, where each end of the conversation must configure a *TCP Security Association Database* before using this mechanism. This database contains a description of the supported TCP connections, the key set, the MAC algorithm, and MAC length.

IPSec

Internet Protocol Security (IPsec) is a suite of protocols that operate at the IP level of the protocol stack; these protocols secure all communications between two endpoints^[8]. The functionality of IPsec includes methods for protection of IP packet headers, methods for protection and encryption of IP payloads, and key management services that allow key rollover during long sessions. This implementation is one of public/private key cryptography, and it can ensure the confidentiality and integrity of all IP messages passed between two hosts. You can use IPsec to secure BGP sessions, and it provides greater levels of assurance than MD5 offers.

However, IPsec is not widely used in the public Internet for the purpose of securing BGP sessions^[7,9], and no generally accepted profile of IPsec for BGP has been standardised so far, with earlier efforts along these lines not progressing within the standards process. The perceived problem with IPsec relates to the complications for rekeying *Internet Key Exchange* (IKE)/IPsec sessions, and the observation that processing load to detect bogus packets is considerably higher with IPsec than with MD5. Using IPsec for BGP exposes a DoS attack where a stream of bogus IPsec packets directed at a BGP speaker may be capable of exercising the processor into a fully saturated mode of operation, causing degradation of other concurrent router functions.

More Options

As was observed in Part 1 of this survey, there are many alternatives here, including *Transport Layer Security* (TLS)^[80] and *Quick UDP Internet Connections* (QUIC)^[81], but more choice is not a substitute for better quality.

These session-level encryption approaches that applications use provide no better answer to dynamic rekeying, and they follow a now well-established Internet tradition of adding more options to divert attention from the observation that the common fundamental problems are inadequately addressed. The design goal of such application-level session approaches is protection for transient short-duration sessions, while the vulnerabilities associated with long-held BGP sessions are somewhat different.

The best advice today is that a combination of TCP AO and GTSM is as good as it gets at present. However, it's also highly desirable to avoid multi-hop BGP wherever possible and directly attach the two BGP speakers. That way reduces considerably the radius of potential eavesdroppers and attackers.

Securing the Integrity of Routing Information Passed in BGP

One of the earlier recognised works that addressed routing security was the 1988 study on *Byzantine Robustness* by Radia Perlman^[9]. If failure or malicious behaviour on the part of one or more entities in the system occurs, all correctly operating entities should reach a mutually consistent decision regarding the validity of each message in finite time. This study was in the area of link-state protocol design, and the work described a protocol that satisfied the properties for Byzantine Robustness. It categorised route validation in three approaches:

- *Bound* or just in time — validation occurs the same moment a route is announced, and appropriate measures are taken immediately. Credentials must be available immediately.
- *Unbound* or just in case — validation occurs only if a new router takes part in the system. Credentials are retrieved on arrival of this router.
- *Interrogative* or just too late — validation occurs sporadically, requesting validation or credentials from a remote system when necessary.

Although the link-state approach described in this paper does not exactly match the inter-domain routing environment, the concept of validation of routing information is a consistent theme in all BGP security architectures.

Subsequent work by Smith and Garcia-Luna-Aceves^[10,11], published in 1996, attempts to address session security by modifying the BGP protocol. This work proposed the protection of BGP control messages using message encryption at the BGP level, with session keys exchanged at BGP session establishment time. It also proposed the addition of a message sequence number to protect against replay attacks and message removal. This approach also proposed a predecessor path attribute that indicated the *Autonomous System* (AS) prior to the destination AS for the current route and proposed digitally signing all fixed fields in the UPDATE message. The predecessor attribute constructs a means of validation of the AS Path attribute.

These proposed changes to the BGP protocol required comprehensive adoption and deployment in order to be effective, because partial adoption would create gaps in any assurance that a predecessor attribute could provide. Their approach was similar to the earlier *Interdomain Routing Protocol* (IDRP) work^[12]. IDRP eschewed the use of TCP and included a reliable flow-controlled transport into the IDRP protocol, also including numerous message integrity protection options.

A contemporary proposal to the Smith and Garcia-Lunes-Aceves proposal for securing BGP was based on leaving the BGP protocol unchanged, but augmenting the BGP data flow with access to credential information. This additional information was intended to allow a BGP speaker to confirm the authenticity of origination information in BGP UPDATE messages by validating the binding of address prefixes to originating ASes^[13]. This proposal, *Network Layer Reachability Information* (NLRI) *Origin AS Verification*, used the *Domain Name System* (DNS) as the distribution mechanism for origination information, where a BGP speaker could perform a DNS query to validate the prefix size and authorised originating AS information contained in a BGP route object. Informally, it was intended to allow a DNS query to answer the question: “Which ASes have been authorised by the address holder to originate a route for this prefix?” The proposed framework assumed that the reverse DNS space was securely associated with the holder of the address prefix, and the DNS response was verifiable [using a *Domain Name System Security Extensions* (DNSSEC)-signed DNS record and DNSSEC validation^[14], presumably, although this work was contemporaneous with DNSSEC and did not use it in this proposal]. This proposal assumed that the performance of DNS queries was within the same order of timescale as the propagation of BGP messages within BGP. It also assumed that there was no circularity, where a DNS recursive resolver or authoritative name server that the BGP speaker used was located within an address prefix that was being validated prior to local acceptance of the route associated with that prefix.

The DNS delegation hierarchy would need to be precisely aligned to the address allocation framework, so that the zone administrator of each of these origination authentication zones was in fact the duly delegated holder of the addresses, and this alignment should, preferably, be capable of third-party validation. Meeting these requirements would create a digital signature hierarchy embedded in the DNS that would be aligned to the address allocation framework.

The *Internet Routing Registry* (IRR)^[82] pre-dates most other efforts in this space, dating back to the routing work of the early 1990s in the *Routing Arbiter* project that was part of the US *National Science Foundation Network* (NSFNET), and a project coordinated under the auspices of the RIPE IRR in Europe. The IRR objective was to provide a set of routing policy databases populated by the ASes themselves that described the addresses that they intended to announce in the routing system and the routing policies that they intended to apply to these announcements^[83].

The Routing Registry was a response to the need described in RFC 1787^[84] for improving global consistency by allowing providers to share routing policies. Each participating AS submits policy data, encoded using the *Routing Policy Specification Language* (RPSL)^[27,28]. Clients may use the registry to determine the stated policies for a particular AS, including what ASes (and possibly prefixes) are suitable for import or export, potentially using the data to populate filter sets on their BGP feeds. Additional information that an AS provides to the IRR could include policy concerning the configuration of BGP communities and the policy responses associated with particular community settings.

However, the utility of the IRR for securing routing is quite limited. First, the IRR does not provide information about current routes, only about potential routes. Some potential routes may be legal according to the IRR, but undesirable from a more global point of view. Next, the IRR has many security vulnerabilities concerning the integrity of registry contents and authorization of changes to the registry. There is no intrinsic authority model that constrains which party can publish data about addresses and ASes in an IRR. Moreover, some policy information concerning agreements between peering ASes is not intended for broader public distribution and the IRRs did not normally implement any form of limited disclosure rules. Efforts to improve the controls over the authority framework in registries and access frameworks^[85] never really gained traction. The IRR system is a misnomer, in that there is not a single IRR but many IRRs. The contents of these IRRs are not necessarily mutually consistent, and there is no clear way to resolve any such conflicts. Not only is there no authority model ensuring that only authorised parties may publish routing policy data about their own address prefixes and ASes, but there is also no way to describe the intended lifetime of the information. Old information that is no longer current or relevant sits alongside current information, and this current information sits along with contingency information that may never be actually used.

Although the overall approach of providing an out-of-band commentary on routing, enumerating all the cases of authorised (or valid) route objects has been a useful tool for many operational environments, IRR tools are only truly useful in the context of being able to detect and filter routing anomalies if the information is verifiable and authentic, current, and complete. In other words, IRRs are most useful if they are carefully and continuously managed, and the accuracy and usefulness of the information rapidly declines if the information in the registry is neglected. Our experience with IRRs suggests that it would be somewhat foolhardy to automatically apply IRR data to populate route filters, given the risks of incorrect outcomes—both positive and negative. In addition, although there have been good counter examples in some operational communities, the broader judgement for IRRs being capable of supporting a robust whole-of-Internet role for route integrity is somewhat negative^[86].

It looks like the common requirements in this space appear to relate to *authenticity*, *currency*, and *completeness*.

Digital signatures can provide strong assurance related to authenticity and currency of information, assuming that the enrollment practice that governs the authority to generate such signatures is robust. Given such a practice, the consequent observation is that whether or not this digital signature framework is placed into the DNS via a DNSSEC framework^[15] or into a framework of X.509 certificates and an associated *Public Key Infrastructure* (PKI) is, at one level, an isomorphic transform of the same information. The issue of the choice of DNS (and DNSSEC) or X.509 certificates (and certificate-based validation) is then an issue of the performance requirements of these systems.

Completeness is a more challenging requirement. The identification of invalid routing information in the partial adoption case of this approach is unclear. When a query to an information source has a negative response, it is unclear whether the route object that was the basis of the query is not valid (such as a bogus prefix or a bogus AS), or the database being queried is incomplete.

Let's now move forward in time to review some more recent proposals to secure BGP.

Secure BGP

Secure BGP (sBGP)^[16] offered a relatively complete approach to securing the BGP protocol by placing digital signatures over the address and AS Path information contained in routing advertisements, and defining an associated PKI for validation of these signatures.

sBGP defines the “correct” operation of a BGP speaker in terms of a set of constraints placed on individual protocol messages, including ensuring that:

- No protocol UPDATE messages have been altered in transit between the BGP peers
- The UPDATE messages were sent by the indicated peer
- The UPDATE messages contain more recent information than has been previously sent to this BGP speaker from the peer
- The UPDATE was intended to be received by this BGP speaker
- The peer is authorised to advertise information on behalf of the peer AS

In addition, for every prefix and its originating AS, the prefix must be a validly allocated prefix, and the prefix “right-of-use” holder must have authorised the advertisement of the prefix and the originating AS to advertise the prefix.

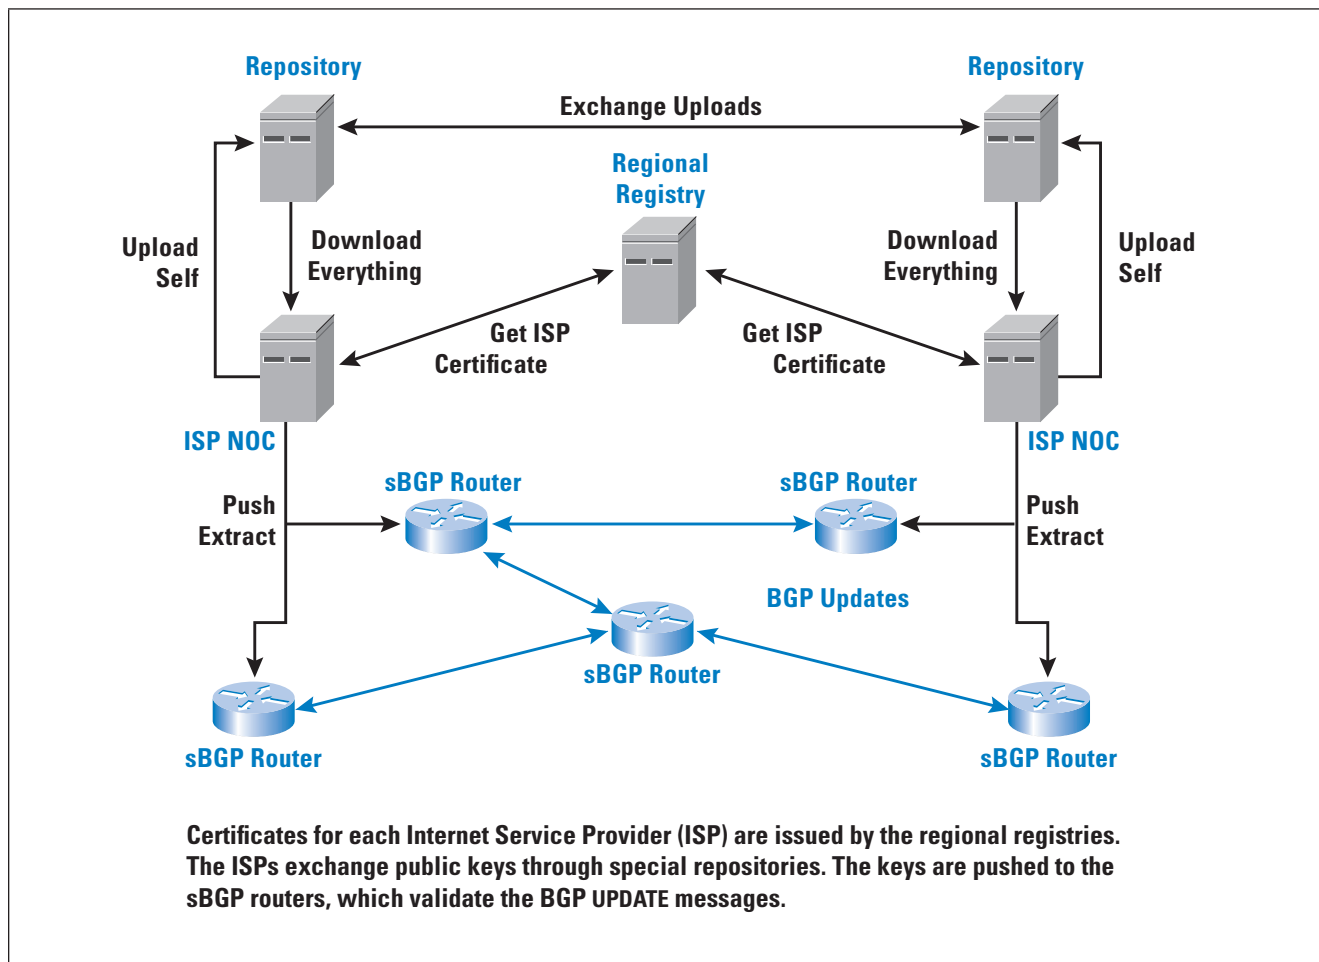

The basic security framework proposed in sBGP is that of digital signatures, X.509 certificates, and PKIs to enable BGP speakers to verify the identities and authorisation of other BGP speakers, AS administrators, and address prefix owners.

The verification framework for sBGP requires a PKI for address allocations, where every address assignment is reflected in an issued certificate^[17]. This PKI provides a means of verification of a “right-of-use” of an address. A second PKI maps the assignment of ASes, where an AS number assignment is reflected in an issued certificate, and the association between an AS number and a BGP speaking router is reflected in a subordinate certificate. In addition, sBGP proposes the use of IPsec to secure the inter-router communication paths.

sBGP also proposes the use of *attestations*. Produced by an address holder, an *address attestation* authorises a nominated AS to advertise itself as the origin AS for a particular address prefix. A *route attestation* is produced by an AS holder; it attests that a BGP speaker is an authorised member of that AS and that it has received a specified route. The address and AS PKIs, together with these attestations, allow a BGP speaker to verify the origination of a route advertisement and verify that the AS Path as specified in the BGP UPDATE is the path taken by the routing UPDATE message via the sequence of nested route attestations.

Figure 1 shows inter-operation and information exchange between sBGP elements.

Figure 1: sBGP

sBGP proposed to distribute the address attestations and the set of certificates that compose the two PKIs via conventional distribution mechanisms outside of BGP messages. For route attestations, it is necessary to pass these attestations via path attributes of the BGP UPDATE message, as an additional attribute of the UPDATE message.

Numerous significant issues have been identified with sBGP, including the computation burden for signature generation and validation, the increased load in BGP session restart, the issue of piecemeal deployment and the completeness of route attestations, and the requirement that the BGP UPDATE message has to traverse the same AS sequence as that contained in the UPDATE message^[18,19].

Secure Origin BGP

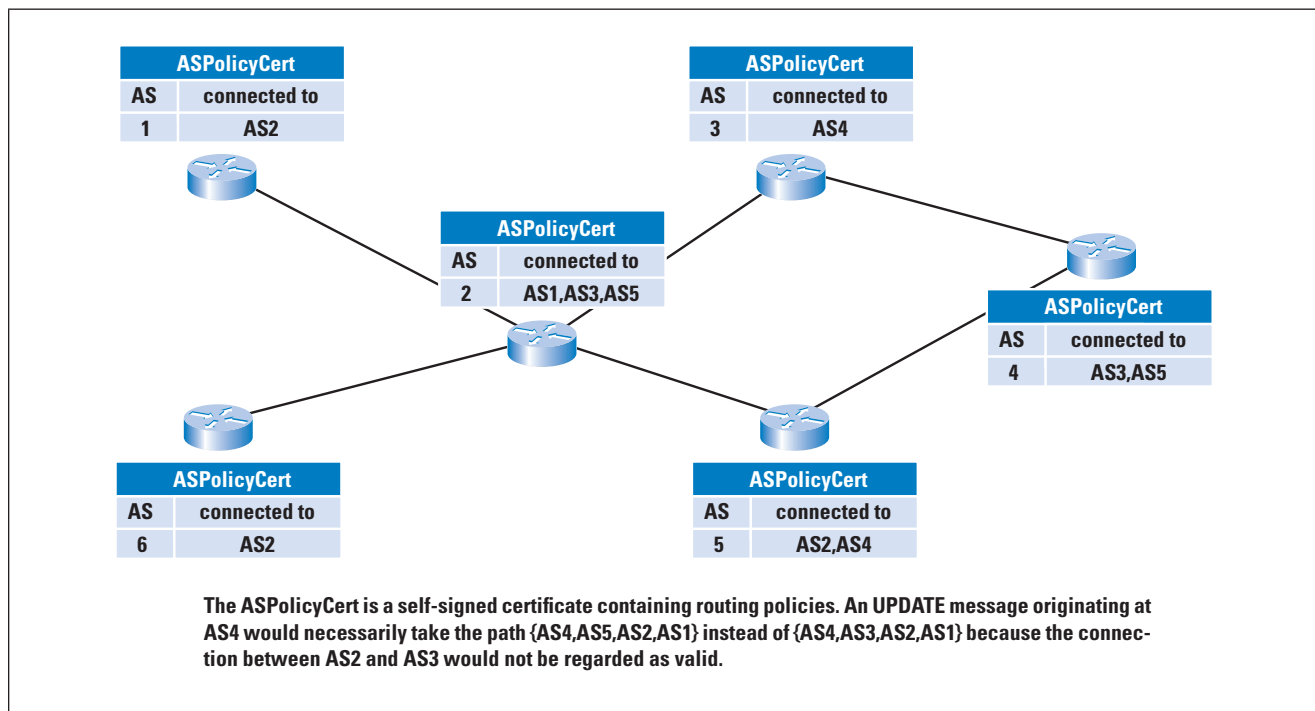

Secure Origin BGP (soBGP)^[20,21] was a response to some of the significant issues that were raised with the sBGP approach, particularly relating to the update processing load when validating the chain of router attestations and the potential overhead of signing every advertised UPDATE with a locally generated router attestation.

The validation questions that soBGP posed also included the notion of an explicit authorisation from the address holder to the originating AS to advertise the prefix into the routing system. soBGP AS Path validation is quite different from that of sBGP, in that soBGP attempted to validate that the AS Path, as presented in the UPDATE message, represents a feasible inter-AS Path from the BGP speaker to the destination AS. This feasibility test is a weaker validation condition than validating that the UPDATE message actually traversed the AS Path described in the message.

soBGP avoids the use of a hierarchical PKI that mirrors the AS number distribution framework and nominates the use of a web of trust, or a reputation mechanism, as the means of validation of these certificates. At the time of its development, no Address or AS PKI had been devised or deployed, so this web-of-trust approach was a pragmatic response to this critical omission. soBGP uses the concept of an *AuthCert* to bind an address prefix to an originating AS. This *AuthCert* is not signed by the address holder, but by a private key that is bound to an AS via an *EntityCert*. soBGP deliberately avoided the use of a PKI that was derived from the established AS and address distribution framework. This consideration appears to have been pragmatic at the time, because no such PKI existed then, and it was unclear if the various address registries were in a position to undertake this type of role of administering such a specialised PKI in any case. This situation left open the problem of how to establish trust anchors for validation of these signed objects, a rather significant deficiency in the validation framework of soBGP.

Instead of sBGP route attestations, soBGP used the concept of an *ASPolicyCert* as the foundation for constructing the data for testing the feasibility of a given AS Path. An *ASPolicyCert* contained a list of the AS local peer ASes, signed by the AS private key. An AS peering was considered valid only if both ASes list each other in their respective *ASPolicyCerts*. Figure 2 depicts a possible soBGP peering network.

Figure 2: soBGP Peering Network

The overall approach proposed in soBGP represented a different set of design trade-offs to sBGP, where the amount of validated material in a BGP UPDATE message is reduced. This approach was intended to reduce the processing overhead for validation of UPDATE messages. In soBGP each local BGP speaker assembles a validated inter-AS topology map as it collects ASPolicyCerts, and each AS Path in UPDATE messages is then checked to see if the AS sequence matches a feasible inter-AS Path in this map. soBGP proposed to use BGP itself to flood ASPolicyCerts through the network, using a new BGP message type (a *Security Message*) for this function.

The use of *Web of Trust* and the avoidance of a hierarchical PKI for the validation of AuthCerts and EntityCerts could be considered a weakness in this approach, because the derivation of authority to speak about addresses is very unclear in this model, but this absence occurred because the protocol was developed prior to the completion of the work on the *Resource PKI* (RPKI).

It is clear that soBGP could be readily adapted to use the RPKI as its trust and authority framework.

The fact that soBGP used BGP itself to flood the security credentials through the network represented an interesting approach to the problem of distributing such credentials, but it also at the time raised some unanswered questions relating to partial deployment scenarios. Interest in continuing work on soBGP waned in the early 2000s, most likely because the level of operator demand was inadequate to sustain the development effort.

Pretty Secure BGP

Pretty Secure BGP (psBGP)^[22] put forward the proposition that the proposals relating to the authentication of an address in a routing context must either rely on the use of signed attestations that need to be validated in the context of a PKI or on the authenticity of information contained in Internet Routing Registries.

The weakness of routing registries is that the commonly used access controls to the registry are insufficient to validate the accuracy or the current authenticity of the information that is represented as being contained in a route registry object. The information may have been accurate at the time the information was entered into the registry, but it may no longer be accurate at the time the relying party accesses it.

The psBGP approach was also motivated by the proponents' opinion that a PKI could not be constructed in a deterministic manner because of the indeterminate nature of some forms of address allocations. This opinion led to the assertion that any approach that relies on trusted sources of comprehensive information about prefix assignments and the identity of current right-of-use holders of address space is not a feasible proposition. Accordingly, psBGP rejected the notion of a hierarchical PKI that could be used to validate assertions about addresses and their use.

Interestingly, although psBGP rejected the notion of a hierarchical address PKI, psBGP assumed the existence of a centralised trust model for AS numbers and the existence of a hierarchical PKI that allowed public keys to be associated with AS numbers in a manner that could be validated in the context of this PKI. This notion exposed a basic inconsistency in the assumptions that lie behind psBGP, namely that a hierarchical PKI for ASes aligned to the AS distribution framework was assumed to be feasible, but a comparable PKI for addresses was not. Given that the same distribution framework has been used for both resources in the context of the Internet, it is unclear why this distinction between ASes and addresses was necessary or even appropriate.

psBGP used a rating mechanism similar to that used by PGP^[23], but in this case the rating was used for prefix origination. An AS asserted the prefixes it originated and also could list the prefixes originated by its AS peers in signed attestation.

The ability of an AS to sign an attestation about prefixes originated by a neighbour AS allowed a psBGP speaker to infer AS neighbour relationship from such assertions, allowing the local BGP speaker to construct a local model of inter-AS topology in a fashion analogous to soBGP. One of the critical differences between psBGP and soBGP was the explicit inclusion of the *strict* AS Path validation test, namely that it was a goal of psBGP to allow a BGP speaker to verify that the BGP UPDATE message traversed the same sequence of ASes as is asserted in the AS Path of the UPDATE message. The AS Path validation function relies on a sequence of nested digital signatures of each of the ASes in the AS Path for trusted validation, using a similar approach to sBGP.

However, psBGP allowed for partial path signatures to exist, mapping the validation outcome to a confidence level rather than a more basic sBGP model of accepting an AS Path only if the AS Path in the BGP UPDATE message was completely verifiable.

The essential approach of psBGP was the use of a reputation scheme in place of a hierarchical address PKI, but the value of this contribution was based on accepting the underlying premise that a hierarchical PKI for addresses was infeasible. It is also noted that the basis of accepting inter-AS ratings in order to construct a local trust value was based on accepting the validity of an AS trust rating, which, in turn, was predicated upon the integrity of the AS hierarchical PKI. psBGP appeared to be needlessly complex and bears many of the characteristics of making a particular solution fit the problem, rather than attempting to craft a solution within the bounds of the problem space.

The use of inter-AS cross certification with prefix assertion lists introduces considerable complexity in both the treatment of confidence in the assertions and the resulting assessment of the reliability of the verification of the outcome. psBGP does not consider the alternate case where the trust model relating to addresses is based on a hierarchical PKI that mirrors the address distribution framework. In such a case, the calculation of confidence levels would be largely unnecessary. The major contribution of psBGP relates to the case of partial deployment of a security solution in relation to AS Path validation, with the calculation of a confidence rating in the face of partial security information.

Inter-domain Route Validation

All of the approaches to securing the semantics of BGP described in this section so far entail changes to the operation of BGP itself and operate most effectively in an environment of universal deployment. In practical terms this scenario is unlikely, and the experience with the uptake of modifications to BGP that supported 32-bit AS number values suggests that the public Internet has considerable inertia and is very resistant to adopting changes to BGP^[24]. In a system as large as the public Internet, long-term piecemeal deployment is a far more likely scenario.

The approach proposed with *Inter-domain Route Validation (IRV)*^[25] is not to modify the BGP protocol in any way, but to define a companion information-distribution protocol.

The intent here was to attempt to provide legacy compatibility and incremental deployment capability. The IRV approach replaced the concept of simultaneously feeding both routing information and associated credentials in BGP with the concept of moving the provision of credentials into a query response framework where the receiver of a route object can query the originating AS about the authenticity of a received route object, or request additional information relating to the object in a similar fashion to the information contained in an *Internet Routing Registry (IRR)*^[26].

In IRV, each AS is responsible for providing an IRV server capable of providing authoritative responses relating to prefixes originated by this AS. IRV is envisaged as being used to provide routing policy information, using the *Routing Policy Specification Language* (RPSL)^[27,28] structure that the IRRs already use, community configuration information, contact information, a local view of the routing system in terms of received route advertisements and withdrawals, and route updates that have been sent to neighbouring ASes.

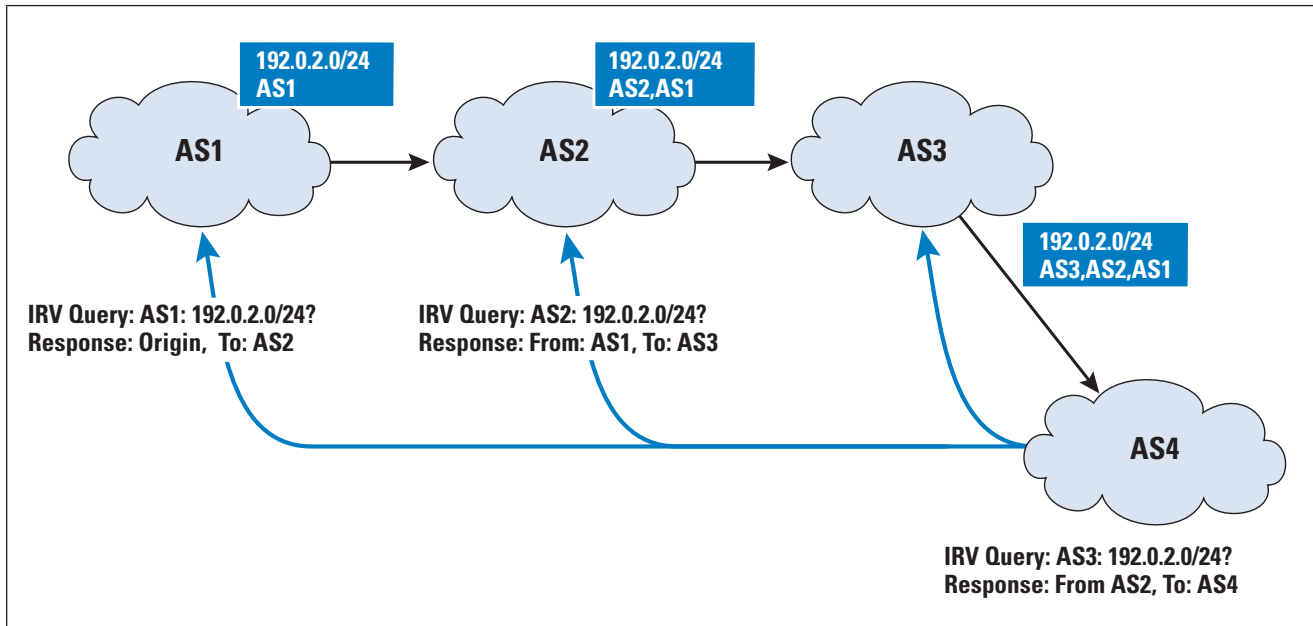

Assuming that there is a way to reliably query a per-AS IRV server and receive a response that can be validated, then AS origination validation in the IRV framework is a case of querying the originating AS IRV server with the origination query for the prefix in question and verifying the response. In a similar fashion, AS Path validation is a case of querying each IRV server of the AS in the AS Path, confirming that an advertisement was received from the previous AS in the AS Path, and that an advertisement has been sent to the next AS in the AS Path (Figure 3). This approach is midway between a strict AS Path test that validates that the UPDATE message was passed along the AS sequence described in the AS Path, and AS Path plausibility that validates that a set of AS peer connections that correspond to the AS sequence exists. Here the validation test is that each AS in the sequence is currently advertising this prefix to the next AS in sequence.

This IRV architecture has numerous issues that are not completely specified, including IRV discovery, IRV query redirection, authentication of queries and responses, selective responses, transport layer protection, and imposed overheads. It is unclear how an IRV response is to be validated, and how the relying party can verify that the received response originated from the IRV server of the AS in question, that the response has not been altered in any way, and that the response represents the actual held state in the queried AS. A similar concern lies in the estimation of additional overhead associated with performing a query to each AS in the AS Path for every received BGP UPDATE. Whether or not the query and response are preconditions to the local acceptance of a BGP route is also unspecified. While making validation of a route, a precondition for acceptance of a route would appear to offer a more robust form of security. It is also true that the IRV associated with the originating AS may be reachable only via the prefix being advertised, in which case the IRV would be unreachable until the route is accepted. It is also unclear to what extent the additional information that the IRV could provide would be useful within strict real-time constraints.

The IRV approach is essentially an extension of the IRR concept that further decentralises the publication point of routing information to individual ASes. It extends the IRR in a manner that is intended to provide adequate assurance that received responses are responses to the original query, that the response was formed by the authoritative IRV for an AS, that the response is complete and has not been altered in any way, and that the response is an accurate representation of the state of the remote AS, using DNS-style chained look-ups.

What is unclear here is whether this decentralisation has superior performance and security properties compared to an alternative approach of further augmentation to the existing IRR framework.

Figure 3: AS Path Verification Using IRV

A similar approach within the IRR framework that integrates the concept of an address and AS PKI could make provision for signed responses in a way that allows the IRR client to authenticate that the response is accurate, current, and contains information that has been digitally signed by the AS or prefix holder. In such a model of publication, the relying party is able to validate the authenticity of the IRR object independently of the manner in which the object was published or the manner in which it has been retrieved^[29].

Secure Path Vector Routing for Securing BGP

Secure Path Vector Routing for Securing BGP (SPV) is another proposal that explores the feasibility of using symmetric cryptographic operations to secure the AS Path in BGP UPDATE messages^[30] using hash chains and trees. The SPV study identified the following classes of path attacks:

- *Forgery*, where false paths are associated with routes in order to influence local route selection decisions
- *Modification*, where the path is altered in order to hide the UPDATE from a target AS or influence local route-selection decisions
- *Denial of Service*, where the attack attempts to overwhelm the intended victim's resources
- *Worm-holing*, where colluding adversaries assert false AS-to-AS links

The first two classes are attacks via BGP, whereas the second two could be more accurately classified as attacks on the routing system itself through multiparty collusion. SPV takes the approach of tree-authenticated hash values and applies it specifically to AS Path validation as an alternative to the nested digital signature structure proposed as the AS Path validation mechanism of sBGP. The SPV study paper claims significantly improved processor performance using this technique, based on the difference in computational complexity for asymmetric cryptography from symmetric cryptography as used in hash functions.

This proposal falls into the category of proposals that call for changes to the operation of the BGP protocol. In this case, the significant change is the requirement that all routes must be re-advertised to peers within a fixed time interval. This requirement is the weakest part of the approach in terms of performance evaluation, because much of the leverage in terms of scaling BGP is based on the use of a reliable transport protocol for BGP messages which, in turn, obviates any need for a BGP re-advertisement function. The need to regularly re-advertise the entire routing table to all peers has some adverse implications in terms of the performance of the protocol and its scaling capabilities.

SPV also assumes that the originating AS has knowledge of the private key associated with an address, as distinct from the more logical approach that an originating AS need only be able to produce an authority from the address allowing the AS to originate the advertisement. This approach, while efficient on processing speed, requires more storage; a higher level of time synchronisation; higher update rates within the BGP protocol, coupled with some form of loose time synchronisation; and complex key pair distribution. It has also been observed^[31] that SPV does not sufficiently protect against route forgery and eavesdropping or collusion attacks.

Signature Amortisation and Aggregate Signatures

If the signature load of sBGP is the problem, then how can this load be reduced? Numerous papers have addressed this question.

It may be possible to amortise the cost of signature validation over many messages^[32]. The technique signs a subset of the connected topology over which an UPDATE flows and places a topology description as a vector in an equivalent of an AS connectivity attestation that is flooded to all relying parties. The AS Path signing can then be generalized such that the same vector is reproduced in the signed data, with the AS neighbours who were passed the UPDATE messages marked in the bit vector. All AS neighbours can now receive the same UPDATE.

Related work^[33] combines the time-efficient approach of signature amortisation with space-efficient techniques of aggregate signatures to propose a set of constructions for aggregated path authentication that improve on the sBGP requirements for processing throughput and memory space.

Aggregate signatures apply to a collection of UPDATE messages that are to be sent to a peer. Instead of signing each UPDATE separately, the UPDATE messages are hashed into a *Merkle* hash tree^[34] and the root of the tree is signed, and the UPDATE and the root of the hash tree are sent as the signed UPDATE to each peer. This technique improves upon [35], which uses bilinear maps instead of Merkle hash trees.

Exploiting Path Stability

You also can mitigate the validation overhead by caching validation outcomes and reapplying the outcome if the same update information is received within the cache lifetime. A study by Butler, McDaniel, and Aiello^[36] noted that across a 1-month period less than 2% of advertised prefixes were advertised using more than 10 paths and less than 0.06% of prefixes were advertised with more than 20 paths.

Their paper proposed combining numerous approaches to reduce the AS Path validation workload. The first was the use of hash chains and signature aggregation, where a BGP speaker sends all local viable paths to its peers along with the tokens that represent hash chain anchors, allowing route change to be represented by an authentication token that can be validated by hash operations. The second part of the approach was to use Merkle hash trees to sign across a set of UPDATE messages that are queued awaiting the *Minimum Route Advertisement Interval* (MRAI) timer. The third part of the approach was to exploit the stability of path advertisements to amortise cryptographic operations over many validations by caching the cryptographic proofs. The paper asserted that simulations point to a reduction of the computational costs by as much as 97% over existing approaches using this approach.

Another approach, termed *pretty good BGP* (pgBGP)^[37], analyses path stability over a longer period of time and builds a local database that is then consulted in order to detect anomalous routes. The idea is that origin ASes usually do not suddenly change over time for certain prefixes, and such a sudden change might indicate an attack to the routing system. pgBGP does not provide completely automated security, because it does not eliminate any route advertisements, but rather puts them into quarantine for 24 hours (similar to route flap damping), giving operators the time to decide how to classify the event. You can deploy this proposal incrementally, and it imposes little overhead on the routing system. It is a method to mitigate effects of an attack to the routing system, not an effective mechanism for prevention of such attacks.

Detecting Prefix Hijacking

One special case of routing attacks that is considered a major threat and evokes high interest in the research community is *prefix hijacking*. A considerable amount of research has been undertaken to provide security against this single form of attack. The approaches describe possible methods of detecting prefix hijacking^[38,39,40,41], as well as complete systems and implementations of prefix hijacking detection in order to possibly react to the attack.

These systems^[42,43,44,45] rely on existing external route-monitoring databases like *Route Views*^[46] or need special routing registries to be deployed to detect prefix hijacking. The quality of such prefix hijack detection systems is strongly dependent on the quality of the route databases, all of which have some level of perspective bias given that all views of the BGP routing system are relative to the location of the collector.

Another method to detect prefix hijacking is to look for *Multiple Origin AS* (MOAS)^[47,48], which can be either a sign of multi-homing an AS or of bogus route announcements, thus prefix hijacking.

A different approach is presented for *iSPY*^[49], which tries to detect prefix hijacking by continuously probing known transit ASes in order to detect whether the prefix owned by the probing AS has been hijacked through a path change in the routing fabric to reach the address prefix.

Secure BGP and BGP Dynamics

If securing BGP is a case of applying cryptographic operations to BGP UPDATE messages, then the other approach to reducing the security overhead is to exploit the dynamic behaviour of these messages.

The BGP update pattern is addressed in [50], where a study of BGP update dynamics showed that a cache of 10,000 prefix and AS Path validation outcomes, or less than 5% of the total number of distinct routed entries, would achieve a cache rate of between 30% to 50% using a simple *Least Recently Used* (LRU) cache-replacement algorithm.

When distance-vector algorithms react to a change in prefix reachability, many UPDATE messages are generally observed before the routing system reaches a stable state. A study of BGP convergence across the global Internet concluded that the severity of path exploration and the convergence speed depend on the relative positions of the event origin and the observer^[51].

This study aligned the originator and the observer in terms of the “tiering” of *Internet Service Providers* (ISPs) and noted that these extended convergence times and larger path exploration events occurred at lower levels of the tiering hierarchy. It hypothesised that the richer inter-connectivity that was typically prevalent at such lower levels in the tiering hierarchy was a major contributing factor here. Fail-over and new route announcements converge in similar times, while route withdrawals have far longer convergence times.

A similar study on BGP path exploration characteristics proposed modifications to the BGP UPDATE message intended to identify and limit the path exploration behaviour of BGP^[52].

If a significant level of update load is related to path exploration and a significant level of AS Path security overhead is related to validation of short-term transient routing states associated with path exploration, then another direction in terms of reducing security overheads is to limit path exploration behaviour. An approach to do so by selective damping of BGP updates that are characteristic of BGP path exploration following a withdrawal at source is described in *Path Exploration Damping*^[53,54].

Further study of BGP update behaviour has explored the level of determinism that exists in the BGP route-selection process and noted that in the absence of the *Multiple Exit Discriminator* (MED) and *Route Reflectors*, the process can be considered to be a deterministic one^[55]. The paper suggests some refinements to BGP that could achieve a similar outcome to MEDs and Route Reflectors while preserving the deterministic route-selection property. The question this paper raises is that most security proposals view AS Path validation as an “after-the-event” activity because of the assumed lack of predictability in BGP. This paper questions this basic assumption and raises the possibility of path security as a provisioning activity, which, in turn raises some interesting performance optimisations for BGP path security as a provisioning exercise rather than a reactive task.

Securing the Data Plane

Securing BGP is not only a matter of securing the control plane, but also of securing the data plane^[56] and ensuring that the status of the forwarding table is consistent with the advertised BGP routing information.

A study by Mao et al.^[57] showed that up to 8% of the paths advertised through the control plane do not match the actual paths in the data plane. The data plane is subject to not only attacks that try to subvert the routing system, but also to synthetic BGP announcements from network operators that could enable the theft of carriage capacity. It is, therefore, necessary to provide security for the whole data path, not only on a next-hop basis as *Stealth Probing*^[58] intends to, because carriers might span over multiple ASes and synthesise false routing information that spans multiple AS hops.

Proposed approaches focus mainly on probing the full data path through packet injection, trying to detect and isolate malicious routers. In “Secure Traceroute”^[59], a modified *traceroute* is used to control which path data packets actually take and compares it to the actual AS Path of the routing table, effectively detecting malicious ASes. Secure Traceroute comes with the overhead of a PKI and related key exchange and no chance for piecemeal deployment.

The Fatih approach^[60] instead focuses on using traffic summary functions, and comparing their results with those of other routers, allowing detection of ASes that provide anomalous values. These traffic summary functions seem to be prone to inaccuracy because of a variety of applications running on routers that might alter the packet flow, and their application appears infeasible in routers with very high packet volumes.

The solution proposed as *Listen and Whisper*^[61] tries to detect inaccuracies in the data plane (the Listen part) but focuses also on control-plane security (the Whisper part) and aims to provide an almost complete BGP security solution, combining both parts. Compared to sBGP, Listen and Whisper should be classified as a “just-too-late” solution for BGP security, like many solutions that try to ensure data plane/control plane consistency. Like other data-plane security solutions, this approach seems infeasible, because it tries to detect data-plane anomalies by analysing individual TCP flows, and scaling this approach to the high-speed core of the Internet presents some practical challenges.

An approach that aims towards high performance and possible partial deployment is described in [62]. Its focus is to ensure that the data path always conforms to the announced AS Path, and is achieved by probing data paths by injecting tagged IP packets, or by using IP options. Similar to pgBGP, it leaves the decision of which action to take towards a malicious router to the network operator and builds up a small database to detect possible malicious routers. It deploys the roles of *verifiers* and *provers* on certain ASes, with the verifier being an AS that wants to verify a certain route, and the prover being an AS that helps the verifier in the process by replying on probe data.

Even though all these approaches intend to provide a certain level of data-plane security, and also a certain level of control-plane security, none provides comprehensive data-plane security. Authenticity of a data path from start to end could easily be forged by two ASes deploying tunnels between them, and thus disabling the possibility to effectively verify the data path by a third party.

IETF Activity – RPKI, ROV, BGPsec, and ASPA

Following numerous efforts to make progress in this area, the IETF charted a *Routing Protocol Security Requirements Working Group* (RPSEC) in 2002 to develop a common set of security requirements for routing protocols. The activity concluded in 2009. In terms of the study of inter-domain security requirements, the work stalled on some fundamental and evidently irreconcilable disagreements over the issue of the requirements for AS Path security^[63,87], and the BGP-related working drafts from the RPSEC Working Group were never published as RFCs.

Based on the initial RPSEC work on security of route origination, the *Internet Engineering Steering Group* (IESG) chartered the *Secure Inter-Domain Routing Working Group* (SIDR) in 2006^[64]. The charter for this effort presented some problems, in that it was stalled in assuming security requirements for AS Path validation and had to await results from the RPSEC activity. Given that RPSEC was unable to agree on a requirement for AS Path security, the initial work in SIDR was concentrated on securing the origination of routing information rather than its propagation through the inter-domain space.

Notably in retrospect, SIDR was also constrained from making any changes to the BGP protocol, implying that any security framework applied to the operation of BGP was to be positioned as an overlay rather than a basic change to the BGP protocol itself. This decision turned out to be very important because it precluded some design decisions that would turn out to be critical for the SIDR design work.

The initial SIDR products were a collection of specifications that described a profile for a PKI for IP addresses and AS numbers (the RPKI), as well as a model for publication and maintenance of local cache, discussed earlier in Part 1 of this survey. From this foundation, the SIDR Working Group moved on to Route Origination Validation.

Route Origination Validation

Route Origination Validation (ROV) builds upon the earlier work in the Routing Registry effort, where a prefix holder is able to publish information as to how an address prefix is to be announced into the routing system by nominating the AS number(s) that are permitted to originate a routing announcement for the prefix. In the RPKI framework this information is published as a signed *Route Origin Authorization* (ROA)^[65,66].

A ROA, which is signed by a prefix holder, denotes a permission given by the address prefix holder for an AS to originate a route.

Many additional implications are associated with publishing a ROA. The first is that no other AS has permission to announce that prefix when a cryptographically valid ROA exists in the RPKI system. If the prefix holder wishes to authorize multiple ASes to originate a route for this prefix, the prefix holder must generate multiple ROAs, meaning that an address holder can declare that a prefix should not be routed at all by issuing a ROA that provides a permission to AS0. Secondly, the ROA denies permission for any AS to originate a prefix that is more specific than the prefix listed in the ROA. You can use a *MaxLength* attribute of a ROA to define a range of more specific prefix lengths than a ROA permits. Thirdly, there is no acknowledgement of the ROA on the part of the AS. A prefix holder may publish a ROA providing a permission to an AS that is unaware of the permission.

The RPKI framework has no symmetric instrument relating to the AS holder. An AS holder does not have the ability to issue a signed attestation that lists all the prefixes that it intends to originate in the routing system.

One more important component of the ROV framework is the *RPKI to Router Protocol* (RTR)^[67]. This protocol allows you to remove a crypto engine from a router and operate on a dedicated platform. The result of this local processing of ROA data is expressed in the form of a filter list, which is implemented as a shared state between a RTR server and one or more RTR client routers. This mechanism offloads most of the RPKI overheads from the router and leaves just a residual filtering function on the router.

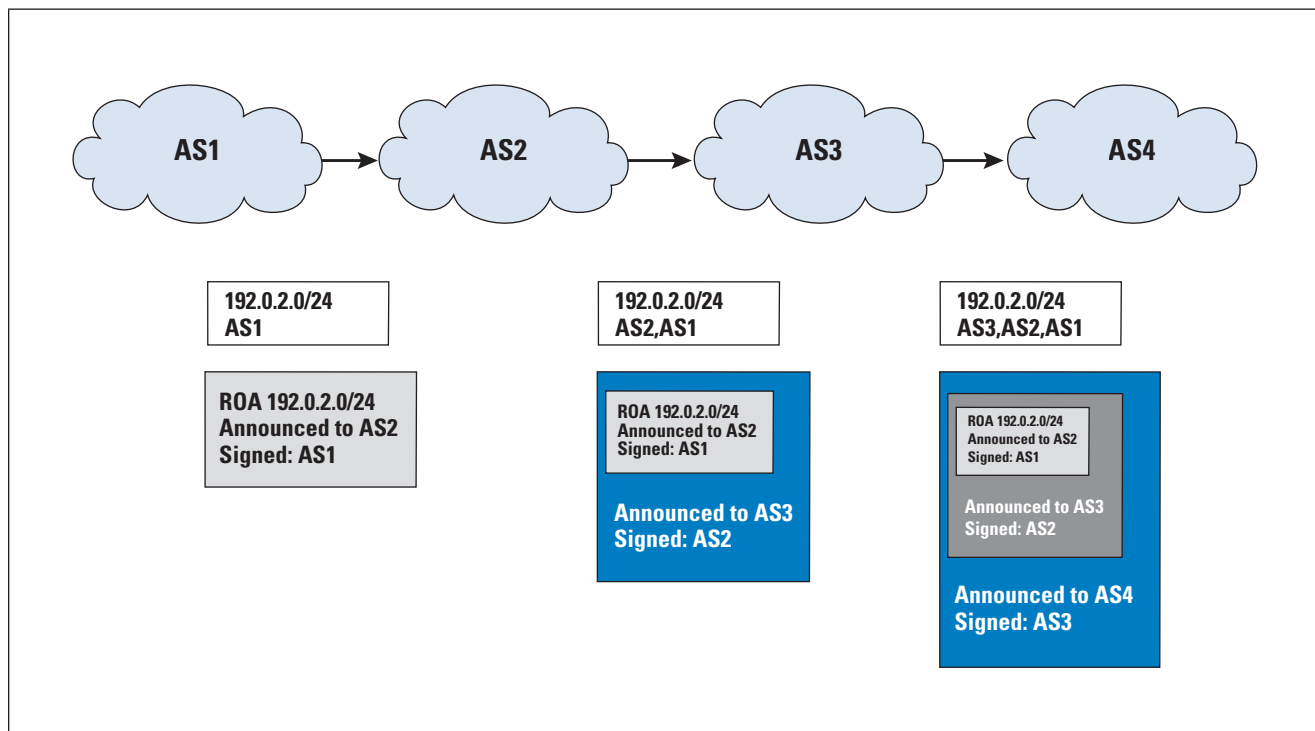

BGPsec

The SIDR working group commenced work on an extension to BGP what would allow validation of the AS Path attribute in 2011, and the standard track specification of BGPsec was published in 2017^[68].

Unlike ROV, BGPsec is not implemented in an off-router mode but is implemented through the definition of nontransitive BGP AS Path attributes. These attributes carry the digital signatures produced by the AS that propagates a BGP UPDATE message. These signatures, signed by the AS, provide confidence that every AS listed in the AS Path attribute has handled the propagation of this prefix, that the order in the AS Path is the exact order of propagation of the UPDATE message through the inter-domain routing space, and that each AS listed has explicitly authorised the propagation of an UPDATE message to its eBGP peer.

BGPsec appears to be solidly based on the concepts described in the earlier sBGP work^[8]. In essence, each eBGP speaker generates a digital signature that covers the information it received (including that digital signature) and the AS number to whom this UPDATE is to be sent (Figure 4). There is a wealth of detail behind this simple overview, but it can be summarised by the observation that this mechanism ties the AS Path in the UPDATE message to the sequence of ASes that handled the propagation of the route object. A detailed exposition of BGPsec design decisions is available in [69].

Figure 4: BGPsec Handling of AS Path Signature Structure

Stepwise AS Path validation cannot tolerate AS Sets in this approach, nor AS Confederation Sets, nor sets that are in the process of being deprecated in response to this limitation^[88]. In a similar vein, BGP Route Reflectors require special processing, as do private AS numbers.

This design approach has numerous consequences.

The first, and perhaps the most important consequence, is that piece-meal incremental deployment is simply not possible in BGPsec. When an UPDATE is passed from a BGPsec BGP speaker to a non-BGPsec BGP speaker, all BGPsec attributes are lost, meaning that if the UPDATE is further propagated to a BGPsec BGP speaker, the initial BGPsec information is unavailable. In today's Internet, the consequences of this highly constrained deployment scenario are prohibitive factors for adoption.

This approach also places a high crypto processing load on BGPsec-aware BGP speakers. There is some scepticism that this load is a feasible impost on the routing infrastructure of the Internet, and this scepticism guided the design of the ROV RTR approach. However, for BGPsec, not only are routers expected to process the BGPsec messages, but they also hold secure private keys to perform signing in real time for outgoing UPDATE messages.

Thirdly, while this approach can provide some assurance regarding the "correct" operation of the BGP protocol and can detect efforts to tamper with update messages, there is no protection against spurious WITHDRAW messages, no ability to ascertain the alignment of the route object with the forwarding state of the network, and no protection of alignment of the UPDATE with the policy state. In other words, route leaks can still occur in BGPsec.

In summary, BGPsec represents a relatively high overhead to pay for a limited set of assurances and a limited protective capability. Furthermore, a more extreme view says that BGPsec cannot achieve any of the security properties because of the fundamental design principles of BGP and BGPsec. In one research paper^[70], it is asserted that routes can still be hijacked in BGPsec, and routing loops can still appear. The authors of the paper hope to stimulate further dialog to rethink the fundamental tenets of BGP and BGPsec designs by publishing their analysis of the observed shortcomings of BGPsec.

Autonomous System Provider Authorization

The issue with the overall SIDR approach to BGP security is that if BGPsec is impractical, we cannot rely on ROV alone. All a determined routing attacker would need to do is tack on the originating AS to a synthesised AS Path and then could place any AS sequence in the AS Path attribute of a synthetic route.

ROV represents a substantial effort to get the infrastructure deployed, but without any form of AS Path protection the level of protection ROV offers is minimal at best.

The conclusion is that ROV needs to be accompanied by some form of AS Path validation if it is to be useful.

Many proposals to address this shortfall have been made. An interesting approach is *Peer Lock*^[71], which is based on the observation that the core of the routed Internet is a small set of Tier 1 ASes, and no customer of an AS should be announcing a route where the AS Path includes any of these Tier 1 networks. Secondly, no more than two of these Tier 1 ASes should appear in any AS Path, and if there are two such ASes in the AS Path they should be adjacent. This approach does not necessarily catch much in the way of deliberate efforts to generate a synthetic AS Path, but it can be effective in catching many common forms of route leaks, and its implementation is quite simple and very lightweight.

Can we do better?

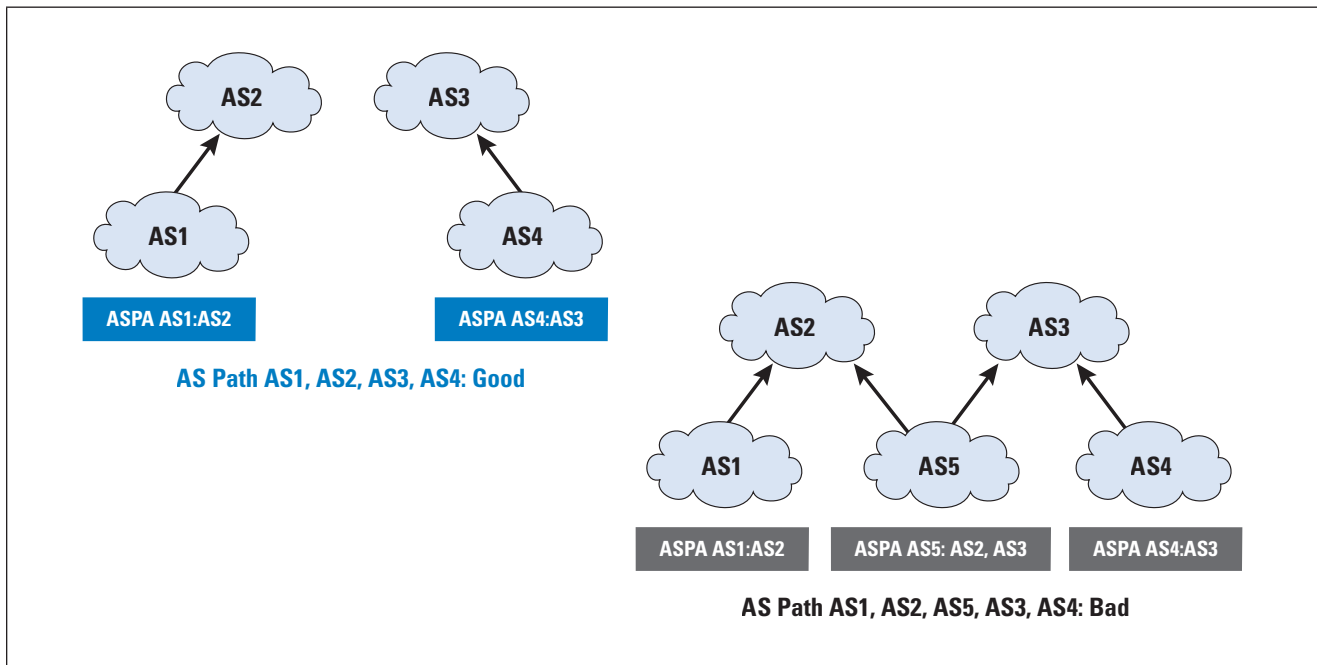

In what appears to be a replay of the situation from around 2000 when soBGP was proposed as a lighter weight response to the crypto load associated with sBGP in the area of AS Path validation, a proposal to use RPKI-signed AS adjacency attestations as a response to the issues with BGPsec has been made.

The proposal has a slight twist, however, which is different from soBGP in that an element of routing policy is also used in the *Autonomous System Provider Authorization* (ASPA) proposal^[72]. Instead of an AS listing its adjacent ASes in the inter-domain routing space and requiring both ASes to list each other as BGP neighbours before accepting the AS adjacency as valid, the ASPA framework requires an AS to list only its adjacent ASes that act in a transit provider role to the issuing AS. Given that a common criticism of BGPsec, sBGP, and soBGP was that these proposals were incapable of identifying route leaks (because route leaks represent a violation of route policy as distinct from a violation of the BGP protocol itself). ASPA provides a means of identifying such route leaks.

The ASPA relationship is a graph fragment in the directed graph that describes the inter-AS topology^[73]. The property that the ASPA proposal uses is described as “valley-free” AS Paths. All AS Paths can be characterised by zero or more paired relationships from customer-to-provider (up), zero or one peer-to-peer relationships (flat), and zero or more provider-to-customer relationships (down). In other words, all viable AS Paths are a sequence of customer-to-provider (up) AS pairs, then a peer AS pair, and then a set of provider-to-customer (down) AS pairs. Any AS sequence that contains a down and then an up (or a “valley”) represents a customer AS leaking routes learned from one provider to another (Figure 5).

ASPA requires any AS that issues an ASPA object to comply with the constraint that the providers listed in an AS ASPA are the complete set of providers for that AS.

Figure 5: ASPA and Route Leaks

ASPA still provides some benefit, even in scenarios of partial deployment. After an AS issues an ASPA, a routing attacker can include this AS in a synthetic AS Path attribute only if it also includes an adjacent provider AS, and the synthetic AS pair can be inserted in the “front part” of the AS Path (customer-to-provider) only if the order is preserved, and in the “back part” of the AS Path (provider-to-customer) in reverse order. Like soBGP, the use of ASPAs does not necessarily prevent the synthesis of AS Paths by a routing attacker, but it limits what you can use to make such synthetic paths, and the greater the use of ASPAs the more it becomes the case that the only AS Paths that can be synthesised are viable BGP AS Paths in any case. soBGP termed this constraint *AS Path Plausibility*, and the same condition applies to ASPA.

It’s evidently still early days for ASPA, and after 3 years the work remains a study item in the *SIDR Operations* (SIDROPS) Working Group of the IETF. Part of the issue here is that the SIDROPS Working Group has had its collective attention diverted away from the issues of BGP security mechanisms and AS Path validation and has taken on the role of the RPKI operational maintenance working group. In addition, in the area of RPKI operations the topic that presently takes up the working group’s attention is not the PKI itself, but the ongoing ramifications of the original design decision to use an out-of-band client-pull credential distribution mechanism for RPKI distribution. The emerging observation is that this original design choice is sufficiently flawed that the efforts in the working group to adjust the parameters of this distribution system will in all likelihood be unable to adequately address the operational issues that accompany scaling up the use of the RPKI credential system.

It may be productive at this point in time to reopen the question of how to use BGP itself to perform a *just-in-time* push-based distribution of BGP security credentials, but within the structure of the IETF it is difficult for an operationally focussed working group to perform protocol development work. However, it's an equally difficult ask for the IETF to reopen a protocol design effort on BGP security so soon after the closure of the original SIDR effort. The protracted and painful saga of the DNSSEC development effort in the IETF is one that many participants in the IETF are unwilling to repeat for BGP security.

Open Questions on Securing BGP

It appears to some observers that no current solution to routing security has found an adequate balance between appropriate security and acceptable deployment overhead^[74,75], and that's an observation that I can agree with. We are just not there yet.

Current research on BGP performance is focused on topics related to scalability, convergence times, stability, and consistency, while the questions on security research have been focused on the integrity, authenticity, authority, and verifiability of routing information. These two fields of research are inherently connected, in that a more stable routing system that can provide clear indications when convergence to a stable routing state is achieved is believed to also provide clear indications of when verification of routing information is appropriate.

In exploring the threat model for BGP, it is noted that BGP was designed to support inter-domain routing between trusted networks, while today's networks operate in a looser confederation that does not exhibit the same mutual trust properties. Not only are the TCP sessions that BGP uses vulnerable to attack, and the messages that BGP uses vulnerable to alteration that would disrupt the network routing system, the integrity of the operation of BGP is also threatened by misconfiguration, where incorrect information is injected into the routing system unintentionally, and by router vulnerabilities where a compromised routing system can exploit its trusted role and intentionally inject false information into the routing system.

Some of these attacks are intended to overwhelm a BGP speaker and force its reset, because BGP is a method of directly accessing the processing unit of a router and a saturation attack can cause processor and memory overload. Other attacks are aimed at altering the forwarding state of a router, generating an incorrect or unintended forwarding state for one or more prefixes. Other forms of attack are aimed at causing a BGP speaker to become unstable and thereby disrupt the forwarding function and impact on applications. A BGP session that is being continually reset will cause large local traffic bursts as neighbouring BGP speakers continually resend their routing tables upon each reset, and the continued instability will trigger a flap damping response in other BGP speakers.

The factors that contribute to these vulnerabilities include a lack of BGP message integrity checks, an as yet partial ability to check the authority of an originating AS to actually originate an advertisement for a prefix, and an inability to verify the accuracy, completeness, and authenticity of AS Path attributes of a routing advertisement. The use of the RPKI to support address attestations, as in ROAs, provides a very robust means of detecting incorrect origin route objects, as long as the RPKI itself is accurately aligned to the address distribution framework and as long as the RPKI is generally, if not universally, used.

In contrast, robust solutions to the problem of AS Path authentication have been elusive so far. BGPsec provides a robust method of path validation but has been assessed to be significantly expensive in terms of processor and memory cost, and also detrimental to BGP convergence times, and it requires comprehensive adoption to be effective. Efforts to substitute AS Path plausibility in place of actual AS Path validity, as is the case with ASPA, offer a different level of robustness that appears to be more practically achievable.

The study of approaches to securing BGP has raised several questions about the behaviour of inter-domain routing and the most effective approach to securing BGP. These questions include consideration of security topics and raise the issue of whether it is possible to secure the routing information to the extent that the routing information being presented is tightly aligned to the associated forwarding state^[76]:

- Is it possible to secure this association of routing information to the chained forwarding state? Can a BGP speaker validate that not only the AS path as presented in a BGP route advertisement matches the BGP propagation path taken by the prefix advertisement, and also that the current forwarding state of the network to reach the address prefix is aligned to this AS Path and this alignment can be validated? To put it simply, can a router validate that a route matches the forwarding path? This question is not one that is directly addressed within any of the current set of inter-domain routing security measures.
- A related issue concerns the overheads of securing BGP and the scaling properties of BGP. Is BGP too monolithic a protocol even before adding security capabilities? BGP simultaneously performs the functions of exchanging reachable prefixes, maintaining an inter-domain network topology, binding prefixes to paths, and implementing routing policy. Would inter-domain routing be more scalable if these functions were performed by separate protocols? Adding security and authentication within BGP, as in the sBGP model, increases the complexity of the protocol and may diminish its long-term prospects for scalability across ever larger and denser inter-domain topologies. At the same time, using a separate mechanism to flood security credentials in a manner that is entirely distinct from BGP itself, as used in the Route Origination Validation framework, becomes a source of additional operational complexity and potential vulnerability, even though the BGP protocol itself is unaltered.

Following are several practical and some more fundamental questions relating to securing BGP:

- The first is a practical question relating to the inevitable design trade-off between the level of security and the performance overheads of processing security credentials. The question concerns what aspects of securing BGP should be considered essential and what is simply desirable, but not essential. Our level of understanding as to what aspects of BGP performance and load are critical for the robust operation of network applications and what are not so critical appears to be less than comprehensive. The impact of performance trade-offs in BGP in terms of time to converge, the size of the routing space, the router memory and processing load, and scaling capability are not well understood to the extent that there is a commonly accepted answer here.
- The next question is whether verification of the correct operation of the BGP protocol is sufficient, or whether the policy intent of the routing environ is equally critical. For example, if a stub network were to leak the routes it learned from one transit network to another transit network, this route leak would, in the normal situation, be regarded as contrary to routing policies, but there is no violation of the BGP protocol itself. If we want to also include alignment to routing policies, then the question arises as to how such policies are to be expressed, who has the authority to express them, and how BGP speakers reconcile local routing policies with external routing policies when the policies differ.
- The next question is whether securing the operation of the BGP protocol (securing the control plane) is sufficient in and of itself to adequately mitigate the vulnerabilities in the overall routing system, or whether it is also necessary to include mechanisms that extend the security model to validate that the routing information represents current forwarding state in each routing element in the network (securing the data plane). One answer to this question is that securing one element of a system with multiple components does not necessarily address the underlying vulnerabilities of the entire system. The more common outcome is that such work exposes the residual vulnerabilities in other components, and that an effective security system needs to address all components of the routing system. While it may be possible for a BGP speaker to be able to validate that the originating AS did indeed originate the prefix advertisement and that the AS Path accurately represents the propagation path of this advertisement through the network, that is not the basic question in terms of the properties of the overall system.
- The more basic question here is whether a BGP speaker can verify that if it decides to forward a packet on the next hop along a path indicated by the routing system as the optimal path to a destination, is this choice indeed the optimal local choice, and does this next-hop decision pass the packet “closer” to the destination address?

- If a comprehensive security framework is proving to be elusive in terms of deployment considerations, then could a less comprehensive approach offer acceptable outcomes? Many security frameworks demonstrate a profile of diminishing returns, where the incremental cost of deploying additional security capabilities increases, while the incremental benefit in terms of risk mitigation decreases. In the case of securing BGP, could an approach of reducing the security credential generation and validation workload, through reducing the amount or timeliness of validated information, represent an acceptable trade-off? We see a practical form of this question today, where the capabilities the Route Origination Validation offer can mitigate some forms of routing incidents but are ineffectual against other forms of route manipulation that preserve the origination data. Practically, is this mitigation enough? Or do we need to also deploy some mechanism that allows detection of various forms of AS Path manipulation? A similar question relates to the comparison of the earlier soBGP and sBGP models. Is Path Plausibility sufficient? Did the mechanisms of soBGP exercise sufficient levels of constraint such that any synthesised path is close enough to a viable network path that the difference is of little consequence from a security perspective? This question is being replayed today when we consider the relative merits of the ASPA approach against the heavier weight of the BGPsec fully signed AS Path attribute.
- A final question here concerns the practicalities of deployment. The Internet is now far too large to sustain the concept of a *Flag Day* for deployment of any technology, and it is not possible to assume that a technology would be universally adopted without a protracted period of piecemeal deployment as part of a transitional interval. Indeed, as the Internet continues to grow and the diversity within the Internet increases, the anticipated transitional periods become indefinite, and piecemeal deployment becomes a continuing factor rather than a temporary transitional factor. The questions to consider include whether it is even possible to deploy high-integrity security using partial deployment scenarios, or whether the BGP protocol is too incomplete in terms of its information-distribution properties to allow robust validation of the intended forwarding state? Does securing forwarding imply carrying additional information relating to the routing and forwarding state coupling in addition to routing that would be entirely impractical in a partial deployment scenario?

Conclusions

BGP has proven surprisingly resilient in terms of its longevity of useful operational life, despite early predictions of its imminent demise in favour of IDRP^[12]. BGP-4 has routed the inter-domain Internet since late 1993, and the number of routed elements for the IPv4 Internet “default-free zone” grew from under 20,000 distinct prefixes to some 1,000,000 distinct prefixes by mid-2021, with a further 130,000 prefixes in the IPv6 network^[10].

Despite the changes in the IPv4 address infrastructure due to exhaustion of the registry free pools, the growth in the number of routing IPv4 prefixes appears to continue unabated, and together with the continued deployment of IPv6, these numbers are expected to continue to rise in the coming years.

Because of its extensibility and large installed base, BGP-4 will likely remain the only inter-domain routing protocol in the foreseeable future for the Internet (although the term “foreseeable” is prudently measured in units of years and perhaps not in decades). So far, BGP has not changed in any substantive manner, including in its security properties.

There is ample evidence from reports of use of unregistered addresses^[77] or of “routing incidents”^[78] that BGP is the subject of various forms of accidental inattention and possibly deliberate forms of abuse. Current efforts at mitigation of these forms of abuse appear in the inter-domain routing space to be less than fully adequate, and the ease with which unauthorised or bogus route objects can be injected into the inter-domain routing system remains a continuing threat issue for the security, stability, and utility of the Internet. We appear to be getting very comfortable in operating a network that experiences a continuing stream of routing incidents, both intentional and unintentional, and the longer this situation persists the more we are resigned to just accept it as the status quo for the Internet and place the onus on applications and content-distribution systems to defend themselves from routing attack. Like many unintended outcomes, it's not the outcome we would prefer to have, nor is it necessarily the optimal outcome in terms of collective cost and benefit, but it's the outcome many of us have simply accepted. All change comes at a price, and the more we resign ourselves to operating networks in the face of a poorly secured routing system the greater the effort required to make the case that the cost of a change to improve this situation will be money and effort widely spent.

GEOFF HUSTON, B.Sc., M.Sc. A.M., is the Chief Scientist at APNIC, the Regional Internet Registry serving the Asia Pacific region. He has been closely involved with the development of the Internet for many years, particularly within Australia, where he was responsible for building the Internet within the Australian academic and research sector in the early 1990s. He is author of numerous Internet-related books, and was a member of the Internet Architecture Board from 1999 until 2005. He served on the Board of Trustees of the Internet Society from 1992 until 2001. At various times Geoff has worked as an Internet researcher, an ISP systems architect, and a network operator. E-mail: gih@apnic.net

FCC Launches Inquiry To Reduce Cyber Risks

On February 25, 2022 the *Federal Communications Commission* (FCC) Chairwoman Jessica Rosenworcel shared with her colleagues a proposed action to help protect America's communications networks against cyberattacks. Earlier that week, the Department of Homeland Security warned U.S. organizations at all levels that they could face cyber threats stemming from the Russia-Ukraine conflict. The proposal would begin an inquiry into the vulnerabilities of the Internet's global routing system.

If adopted by a vote of the full Commission, this action, called a *Notice of Inquiry*, would begin a proceeding by seeking public comment on vulnerabilities threatening the security and integrity of the *Border Gateway Protocol* (BGP), which is central to the Internet's global routing system. The inquiry would also examine the impact of these vulnerabilities on the transmission of data through email, e-commerce, bank transactions, interconnected *Voice-over Internet Protocol* (VoIP), and 911 calls—and how best to address these challenges.

BGP is the routing protocol used to exchange reachability information among independently managed networks on the Internet. BGP's initial design, which remains widely deployed today, does not include explicit security features to ensure trust in this exchanged information. As a result, a bad network actor may deliberately falsify BGP reachability information to redirect traffic. Russian network operators have been suspected of exploiting BGP's vulnerability to hijacking in the past. "BGP hijacks" can expose Americans' personal information, enable theft, extortion, and state-level espionage, and disrupt otherwise-secure transactions.

Working with its federal partners, the Commission has urged the communications sector to defend against cyber threats, while also taking measures to reinforce the nation's readiness and to strengthen the cybersecurity of vital communications services and infrastructure, especially in light of Russia's actions inside of Ukraine. Chairwoman Rosenworcel also recently shared with her colleagues a Notice of Proposed Rulemaking that would begin the process of strengthening the Commission's rules for notifying customers and federal law enforcement of breaches of *Customer Proprietary Network Information* (CPNI). The inquiry under consideration would build on those efforts. For more information, visit: <https://www.fcc.gov>

APNIC Announces "hybrid" APNIC 54 Conference in Singapore

The *Asia Pacific Network Information Centre* (APNIC) is pleased to announce that APNIC 54 will include a face-to-face event in Singapore in September 8–15, 2022. The conference will provide full online participation support so all attendees—online or in-person—receive the best possible conference experience. The *Asia Pacific Regional Internet Governance Forum* (APrIGF) and the *Asia Pacific School on Internet Governance* (APSIG) intend to co-locate their 2022 meetings with APNIC 54.

This will be the first time an APNIC conference has included a face-to-face component since APNIC 49 in March 2020 held in Melbourne, Australia, in conjunction with the *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT).

As previously announced, the usual “rotation” of the location of APRICOT and APNIC conferences has been suspended since the start of the pandemic, but a decision to restart it will be considered by APNOG and APNIC in the coming months. When the conference rotation restarts, the first face-to-face APRICOT will be held in Manila, Philippines. More information about APNIC 54, including the venue, dates, online participation options, partner meetings and other details can be found here: <https://conference.apnic.net/54/>

Our Privacy Policy

The *General Data Protection Regulation* (GDPR) is a regulation for data protection and privacy for all individual citizens of the *European Union* (EU) and the *European Economic Area* (EEA). Its implementation in May 2018 led many organizations worldwide to post or update privacy statements regarding how they handle information collected in the course of business. Such statements tend to be long and include carefully crafted legal language. We realize that we may need to provide similar language on our website and in the printed edition, but until such a statement has been developed here is an explanation of how we use any information you have supplied relating to your subscription:

- The mailing list for *The Internet Protocol Journal* (IPJ) is entirely “opt in.” We never have and never will use mailing lists from other organizations for any purpose.
- You may unsubscribe at any time using our online subscription system or by contacting us via e-mail. We will honor any request to remove your name and contact information from our database.
- We will use your contact information only to communicate with you about your subscription; for example, to inform you that a new issue is available, that your subscription needs to be renewed, or that your printed copy has been returned to us as undeliverable by the postal authorities.
- We will never use your contact information for any other purpose or provide the subscription list to any third party other than for the purpose of distributing IPJ by post or by electronic means.
- If you make a donation in support of the journal, your name will be listed on our website and in print unless you tell us otherwise.

Check your Subscription Details!

If you have a print subscription to this journal, you will find an expiration date printed on the back cover. For the last couple of years, we have “auto-renewed” your subscription, but now we ask you to log in to our subscription system and perform this simple task yourself. The subscription portal is here: <https://www.ipjsubscription.org/>

Thank You!

Publication of IPJ is made possible by organizations and individuals around the world dedicated to the design, growth, evolution, and operation of the global Internet and private networks built on the Internet Protocol. The following individuals have provided support to IPJ. You can join them by visiting <http://tinyurl.com/IPJ-donate>

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

According to Wikipedia, the *Border Gateway Protocol* (BGP) “...is a standardized exterior gateway protocol designed to exchange routing and reachability information among *Autonomous Systems* (ASs) on the Internet. BGP is classified as a path-vector routing protocol, and it makes routing decisions based on paths, network policies, or rule-sets configured by a network administrator.” We’ve covered numerous aspects of BGP in this journal, most recently in our two-part article by Geoff Huston entitled “A Survey on Securing Inter-Domain Routing.” In this issue, a team of engineers from Juniper Networks describes a method for running BGP processing in parallel using a concept known as *sharding*.

In our second article, Geoff Huston takes a closer look at the transport and network functions in today’s ever-changing Internet. Many network elements such as firewalls and *Network Address Translators* (NATs) use the transport protocol *header* to make decisions on how to handle traffic, but concerns about pervasive monitoring and information leakage have led to various forms of encryption-based solutions and an ongoing debate within the Internet technical community and beyond.

Using the Internet for teleconferencing or telephony is not a particularly new idea. I fondly remember taking part in experiments between the *Norwegian Defence Research Establishment* (NDRE), MIT’s Lincoln Laboratories, *University of Southern California’s Information Sciences Institute* (USC-ISI), and *University College London* (UCL) as early as 1977 when I was doing my military service at NDRE. You can find out more about these early developments by searching for the article “Linear Predictive Coding and the Internet Protocol.” *Voice over IP* (VoIP) as we know it today became a reality in 2002 with the publication of RFC 3261, which describes the *Session Initiation Protocol* (SIP). In our final article, Jonathan Rosenberg gives a retrospective on 20 years of SIP.

Publication of *The Internet Protocol Journal* is made possible by the generous support of numerous individuals and organizations. Please consider making a donation or getting your company to sign up for a sponsorship. As always, we welcome your feedback and suggestions on anything you read in this journal. Letters to the Editor may be edited for clarity and length and can be sent to ipj@protocoljournal.org

Parallel BGP Protocol Processing

by Sanjay Khanna, Jaihari Loganathan, and Ashutosh Grewal, Juniper Networks

Managing large inter- and intra-*Border Gateway Protocol* (BGP) domains places a large computational load on the CPU of a router, adversely affecting its performance and increasing the BGP convergence time. To address these problems, we have architected a solution that splits a *BGP Routing Information Base* (RIB) across concurrently running BGP threads. These parallel running threads run the same code on multiple CPU cores concurrently. Each of these threads maintains a *RIB shard*, a subset of the RIB. This parallel BGP processing improves the read-side performance of processing incoming UPDATE messages. A set of parallel running I/O threads generate outbound UPDATE messages and improve the write-side performance of BGP. This entire design uses a lockless mechanism to allow parallel processing on each CPU core independently. A testbed representing a Tier 1 service provider *Route Reflector* network was used to verify and quantify the performance of the implementation. BGP in this topology receives several copies of the global Internet routing table (~800,000 routes). Our results show that performance improves as parallelism and scale are increased. The speedup we can attain gets better as more CPU cores are available for RIB sharding. These gains are bounded by the extent to which the BGP update processing can run in parallel.

Terms and Definitions

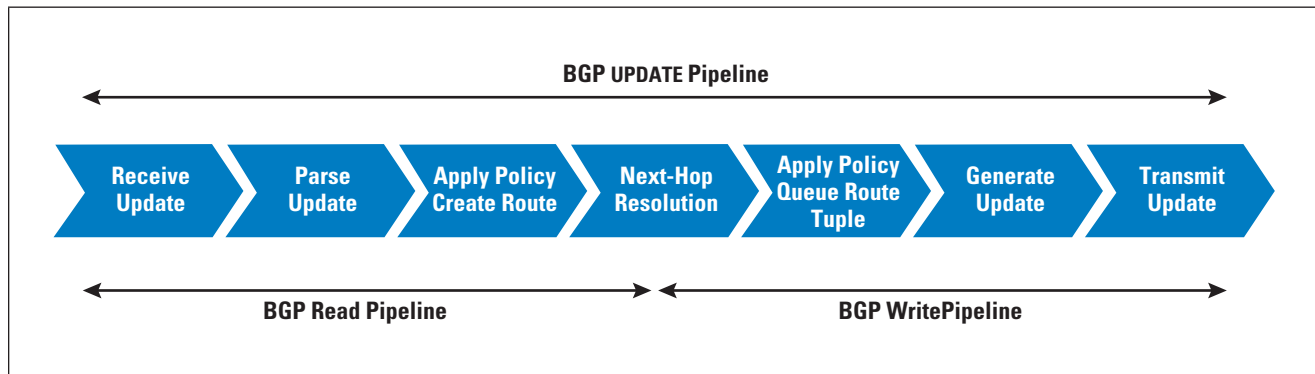

The BGP RIB conceptually consists of four parts:

- *Adj-RIBs-In*: Stores unprocessed routing information that has been learned from BGP updates received from peers. The routes contained in Adj-RIBs-In are considered feasible routes.
- *Loc-RIB*: Contains the routes that the BGP speaker has selected by applying the decision process (route selection, import policy) to the routes contained in Adj-RIBs-In. These routes populate the routing table (RIB) along with routes that other routing protocols discover.
- *Adj-RIBs-Out*: Contains the routes that the BGP speaker advertises to its peers in BGP UPDATE messages. Export routing policies determine what routes are placed in Adj-RIBs-Out.
- *Outbound Route Tuple* is a route in Adj-RIBs-Out. Every tuple consists of a prefix, associated BGP metrics, and information about peers in a peer group that will be sent to this tuple in an UPDATE message.

BGP Update Processing Pipeline

Figure 1 illustrates the BGP^[1] UPDATE message processing pipeline. This pipeline can be further subdivided into the *Read-Side Pipeline* to identify the inbound processing of an UPDATE message, and the *Write-Side Pipeline*, which concerns generation of outbound UPDATE messages to be sent to peers.

Figure 1: BGP Pipeline

The read-side pipeline consists of the following stages:

- *Receive Update*: Routes are advertised between BGP speakers in an UPDATE message. Multiple routes that have the same PATH attributes are advertised in a single UPDATE message. This message is received over an established *Transmission Control Protocol* (TCP) socket.
- *Parse Update*: A BGP UPDATE message is parsed for prefixes, and PATH attributes are canonicalized into a local state after validating the data in *Protocol Data Units* (PDUs).
- *Apply Import Policy and Create Route*: BGP stores routing information learned from the inbound UPDATE messages in a RIB called *Adj-RIB-In*. BGP applies the import policy on incoming BGP routes and—if permitted by policy—performs a best-route selection. The best routes are used to populate the local RIB, called *Loc-RIB*. These routes are then used to program a *Forwarding Information Base* (FIB) and generate outbound updates to BGP peers.
- *Next-hop Resolution*: BGP uses a local routing table to find the reachability information for a BGP next-hop, which may be several hops away. For example, *Interior Gateway Protocol* (IGP) metric, intermediate address, and outgoing interface are parts of resolving reachability for the BGP next-hop. BGP may have several routes to the same IP destination that have different degrees of preference. Although all accepted routes are installed in Loc-RIB, BGP may choose one route or multiple routes (BGP multipath case) as active routes.

The write-side pipeline consists of the following stages:

- *Apply Export Policy and Queue Outbound Route Tuple*: BGP applies export policy to routes in Loc-RIB and generates outbound RIBs called *Adj-RIBs-Out*. Adj-RIB-Out stores information that BGP uses to generate an outbound route tuple. Generally, several peers with the same policies are grouped into a *peer group*, and a single outbound route tuple is generated for each peer group.

- *Generate Update*: Route information in the outbound route tuple is converted into an UPDATE message. Destination prefixes that share the same PATH attributes are packed in a single message. This prefix packing reduces the number of UPDATE messages sent over TCP. Sending fewer messages improves local performance and does not impose extra work on the peer BGP routers.
- *Transmit Update*: UPDATE messages that were generated in a prior stage are sent over a TCP socket to a remote BGP peer. The same BGP UPDATE message is sent to multiple BGP peering sessions that share a common export policy, thereby amortizing the cost of UPDATE message generation.

BGP *convergence time* is the time taken by the router to process the incoming BGP UPDATE messages, passing them through the read pipeline in Figure 1, and distributing the results by generating UPDATE messages to its peers. As networks scale up in the number of peers, the number of parallel inbound feeds, and the size of the network in terms of the number of prefixes, this convergence time can become very high. The result can be slower convergence of the entire network when device and link failures occur. The slower convergence generally leads to traffic loss and a traffic black-hole in the network. Most operators of large networks want a faster convergence to reduce these downtimes. To help improve the convergence time of a router, and to exploit multi-core CPUs available on routing engines, we decided to run the previously mentioned pipeline functions in parallel. We encountered several hurdles to running BGP update processing in parallel:

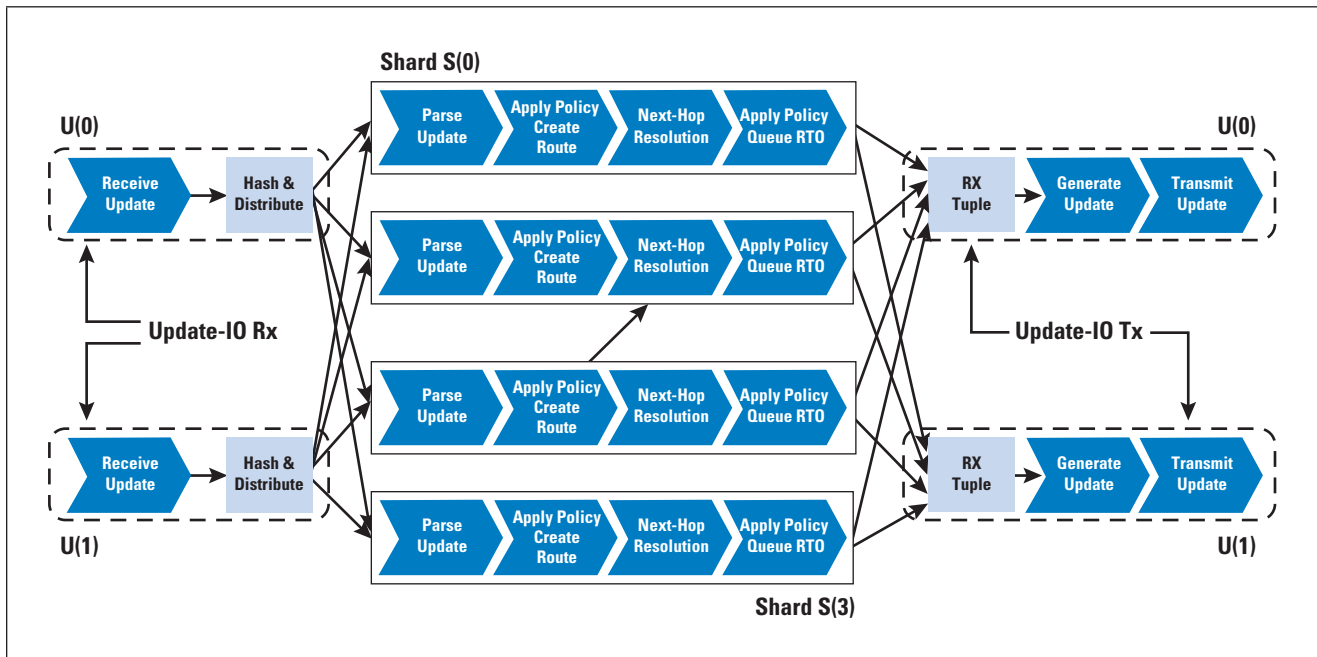

- RIBs are generally a shared collection of routes, and concurrent updates to RIBs need locks.
- Locking in general reduces concurrency and increases complexity.
- BGP next-hop resolution is a shared function and requires synchronization between parallel running threads.
- Prefix packing in outgoing UPDATE messages deteriorates because each concurrent pipeline produces more frequent and smaller UPDATE messages with fewer prefixes.
- Other protocols in an IP router need active BGP routes to implement other useful functions like *Layer 3 Virtual Private Network* (L3VPN) and programming the FIB.
- Interface state (like links and IP addresses) is a shared collection too, and concurrent threads meant more locking across concurrently running threads.

The BGP software architecture described in the following sections addresses these concurrency limitations and improves the BGP convergence time at very high scales. This solution performs better when input scale increases and the required number of concurrent pipelines increases.

Parallel BGP Protocol Processing

Figure 2 illustrates the high-level architecture of parallel BGP processing. The pipeline is broken into three logical parts running concurrently on two kinds of threads of execution: “Shard(S)” and “Update-IO(U)” threads. Shard threads process a subset of UPDATE message prefixes, execute most of the BGP read pipeline, and generate a tuple for an Update-IO thread. An Update-IO thread processes a tuple for a set of BGP peers in a peer group. Update-IO threads also receive the UPDATE message from peers (over TCP sockets) and distribute the messages to shard threads. These threads process tuples from shard threads and generate UPDATE messages to transmit to peers.

Figure 2: Parallel Processing of BGP UPDATE Messages

- *Update-IO Rx Processing:* Running in an update-IO thread, this stage receives update messages from peers, sanity checks the messages, and computes a hash on every prefix in the message to determine which shards will receive the message. In the best possible scenario a single shard gets the entire message, and in the worst-case scenario the same message is shared with every shard thread.
- *Shard Processing:* A shard thread receives a copy of the message and processes prefixes that it owns (ignoring the ones that it doesn't). The ownership of a prefix is decided by computing the hash on the prefix. Thereafter each shard will follow the entire read pipeline on its prefixes and generate tuples for the Update-IO thread matching the peer group.
- *Update-IO Tx Processing:* An Update-IO thread receives tuples and processes them into BGP UPDATE messages. These messages are sent towards the peer via TCP sockets. This stage is responsible for packing tuples from several shard threads into UPDATE messages to improve the packing of prefixes.

This architecture exploits the *Single Program Multiple Data* (SPMD) model of parallelism to do concurrent read and write pipeline processing. Concurrently executing threads do not share any state with each other, thereby eliminating any need for locks. Shards and Update-IO threads maintain a parallel ecosystem of collections of objects (like BGP peers, peer groups, RIBs, interfaces, configuration, etc.). Wherever needed, message passing is used to achieve eventual consistency of the routing state in the system. At any point of time, concurrently executing functions running at different rates may be in different states. However, all these functions executing on different cores will eventually reach the same final state as if there were a single executing pipeline. Reaching eventual consistency quickly is an important outcome of this architecture.

Sharding Several Kinds of BGP RIBs

This architecture requires all routes (BGP and otherwise) with the same IP address to always be assigned to the same shard so that the best active route calculation for all routes matching an IP address is handled in a single shard. This requirement guarantees the correctness of the active route selection algorithm. *Multiprotocol BGP* (MP-BGP) extensions^[2] allow BGP to carry routing information for multiple network layers and address families. BGP routes for each of these address families are saved in several RIBs, and each RIB has its own network prefix in a route. For example, the IPv4 Unicast RIB has the IPv4 address and prefix mask length as the route destination. The L3VPN RIB has the IP address, route distinguisher, and mask length as the route destination. For shard assignment, the hash is computed only on the address and prefix length part of the route destination, and the rest is ignored.

Next-Hop Resolver

The main job of the resolver is to translate protocol next-hops into forwarding next-hops using *helper routes*. A protocol next-hop is an IP address of a remote BGP peer, most commonly an *Interior BGP* (IBGP) peer. A protocol next-hop, by itself, is insufficient to make a forwarding decision. To forward a packet, a router needs to know the directly connected next-hop. This information is derived from helper routes that provide reachability information for the protocol next-hop. Since the resolver is a central function and the concurrent shard threads also need the services of this resolution, a mechanism is needed to distribute resolver information to shard threads. One way to achieve this distribution is to run the resolver as a service and all shard threads to register next-hop IP addresses for resolution. BGP in each shard gets reachability notifications for registered IP addresses. These notifications populate the local BGP neighbor reachability information of the shard and trigger routing updates local to a shard. These updates can activate a BGP route when a next-hop is reachable, change the BGP route if reachability changes, and inactivate the BGP route if a next-hop is unreachable.

VPN and Sharding

You can apply sharding to *Virtual Route Forwarding* (VRF) and *Virtual Private Network* (VPN)^[3] routing tables also. Each shard thread hosts a slice of the VPN and VRF RIB table as determined by the hash. The *Route Distinguisher* (RD) of VPN routes is excluded from hash calculations to allow routes with the same prefixes but different RDs to be correctly processed in the associated shard. VPN label allocation is a central service because a single pool of *Multiprotocol Label Switching* (MPLS) labels is generally available to send out. A shard thread that wants an MPLS label for a VPN route requests this centralized service for labels. Target routes—needed for VPN processing—are stored in a separate RIB. Since this RIB is smaller, it is duplicated in all shard threads.

Large Peer Groups and Update-IO Parallelism

A peer group is usually assigned to an Update-IO thread that manages packing and generation of updates for that group. Multiple groups get assigned to different update threads for parallelism. In certain use cases, one or more large peer groups can include a very large number of BGP peers, and as a result we would not be able to distribute the load of such peer groups over several Update-IO threads effectively. To handle such a special case, we split such configured peer groups into several logically split peer groups. Each split group is allocated a subset of peers from a large peer group and assigned to an Update-IO thread.

BGP Graceful Restart Handling with RIB Sharding

BGP *Graceful Restart* (GR)^[4] processing requires sending of an *End-of-Rib* (EOR) notification after initial download of routes to a peer that is coming up after a failure. Shard threads contribute to the initial download of routes to a peer independently and in parallel. But the EOR message is sent in a coordinated fashion from the main thread after all shard threads complete the initial download of their slices of RIB to the peer. Likewise, consumption of an inbound EOR requires coordination from shard threads. The inbound EOR message is sent to all shard threads.

BGP Optimal Route Reflection and Sharding

You can configure BGP *Optimal Route Reflection* (ORR)^[5] with *Intermediate System-to-Intermediate System* (IS-IS) and *Open Shortest Path First* (OSPF) on a Route Reflector to advertise the best path to the BGP ORR client groups. Configuration is done by using the IGP metric after calculating the *Shortest Path First* (SPF) from a client's perspective. For BGP ORR to work in a Route Reflector, BGP requires assistance from an IGP implementation to calculate an IGP metric for a prefix from a client's perspective. In a sharded BGP architecture, ORR must be built as a service like a resolver. Shard threads register ORR reachability to this service, and in turn receive notifications about reachability of the registered prefixes.

Configuration, CLI Show Commands, Telemetry, SNMP, and Sharding

The shard architecture requires that each shard thread processes configuration independently of other shard threads. This way each shard has its own configuration state to work with. To present a consistent view to the user, some of the *show* commands in a router must collate information about RIBs from all shard threads and present a system view of the RIBs to the user. The same is true about telemetry streaming and the *Simple Network Management Protocol* (SNMP) get/walk of tables in a shard. For debugging purposes, we also implemented a view into the RIBs of each shard thread.

Routing and BGP RIB Sharding

Figure 3a illustrates an approximate high-level view of how routing protocols were implemented in the JUNOS *Routing Protocols Daemon* (RPD) before BGP RIB sharding was implemented. It shows a single thread that runs all routing protocols (including BGP), and INFRA, which includes interfaces, routing tables, next-hop tables, route resolution, and FIB programming. When BGP RIB sharding and Update-IO are configured, then additional threads are spawned, as shown in Figure 3b.

Figure 3a: Single Threaded Routing Protocol Daemon

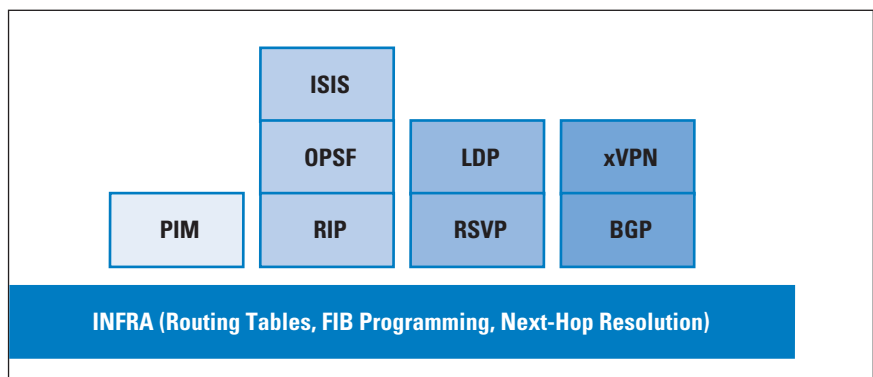

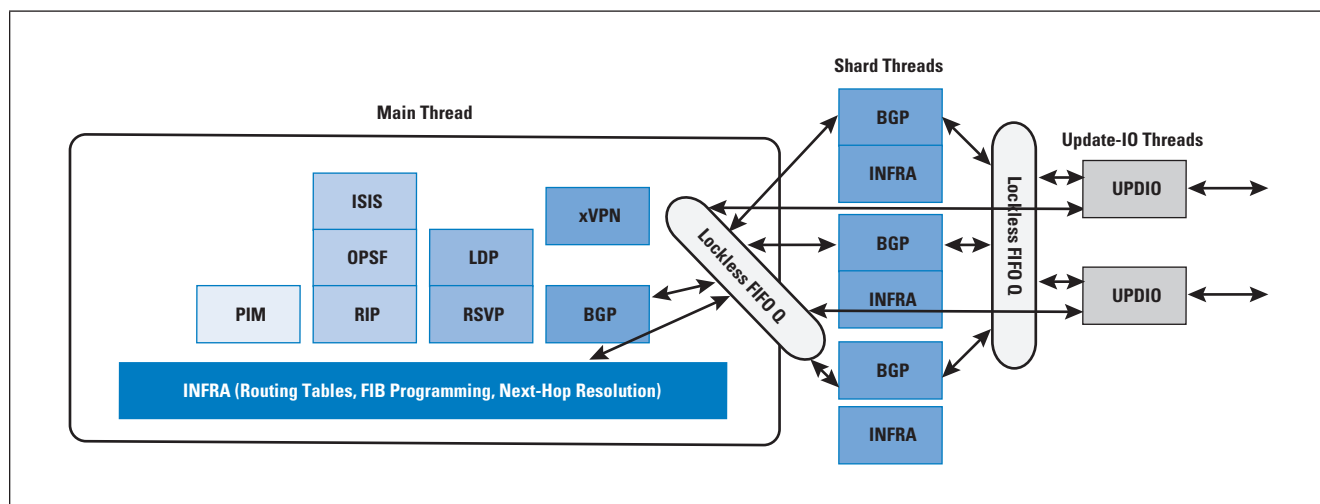

Figure 3b: Shard Routing Protocol Daemon

Main thread shards and Update-IO threads do not share any mutable state, and as a result no locks or critical sections are executing between these threads. As explained earlier, shard threads do the read-side processing of incoming messages in parallel and Update-IO threads do write-side processing of outgoing messages in parallel. Shard and Update-IO threads like the main thread process the routing configuration independently in a lockless manner. Coordination of peer state, interface state, and RIB routes and counters between main and other threads is done via *Interprocess Communication* (IPC) messages. These messages are sent over an IPC channel consisting of a pair of lockless *First-In, First-Out* (FIFO) queues. To allow for state compression, IPC channel queue depths are kept small. Socket read/write readiness is used for IPC channel back pressure between threads. Overall, all message passing between threads is very fast and efficient.

The following message types are sent from the main thread to the shard threads:

- Interface state, such as link information, address families configured, IP address, and state of the links is used by routing tables code and the BGP protocol. As a result, each shard has its own copy of interface state information.
- Route messages for non-BGP routes are distributed to a shard that is found via hash computation on the IP prefix of the route. Also, the entire route target RIB is sent as route messages to all shard threads.
- Configuration indications are sent as messages to signal availability of the updated configuration database.
- When *show* commands, SNMP *get* requests, and telemetry requests are sent, responses from shards are sent to the main thread to service the *Command-Line Interface* (CLI), SNMP requests, and telemetry streaming.
- BGP peer state transition messages are sent from the main thread to the shard threads. A handler in shard threads takes appropriate actions on BGP peer objects local to the shard.
- Next-hop resolution messages are sent from the resolver service in the main thread to shard threads. Shard threads register with this service for a BGP next-hop.
- VPN label messages are sent to shard threads whenever the main thread receives a request from a shard.

BGP in the main thread also shares state with Update-IO threads via IPC messages. These messages follow:

- The BGP peer *Finite State Machine* (FSM) in the main thread sends peer state messages to Update-IO threads. Such messages result in state changes for BGP peer objects in the Update-IO threads.
- *Route tuple messages*: Outbound BGP route messages are sent from the main thread to one of the Update-IO threads. Update-IO threads consume these messages to generate BGP UPDATE messages for a set of peers.

Shard threads send the following messages to the main and Update-IO threads:

- Route messages are sent from the shard to send active BGP-only routes to the main thread. The main thread adds these received routes to its RIB.
- Shards send *show*, SNMP, and telemetry responses to the main thread to assist in supporting these administrative functions.
- Shards send resolver registration requests for BGP next-hops, and they get resolver responses from the main thread.
- VPN label requests are sent to the main thread to get a pool of labels to support VPN functions in the shard threads.
- Outbound route tuples are sent to Update-IO threads per peer group.

When a shard thread receives UPDATE messages, it does the PDU processing on the prefixes that it owns and ignores those it does not. This processing uses the same hashing scheme that Update-IO threads use for distributing inbound prefixes. As a result, BGP routes are added to the RIBs of a shard thread. If the active route for a prefix in a shard is a BGP route, then it must be added to the FIB. Queueing points are used on the shard send side (before the IPC) to dampen the route churns due to link and peer flaps. The active route is added to the queue and then distributed (via IPC) to the main thread.

The main thread can program the FIB. Any subsequent state changes associated with BGP prefixes in shard threads may result in changes to the current active route in the shard. When this active route changes or is deleted in a shard, a new message is queued to be sent to the main thread.

The main thread centralizes answering BGP next-hop resolution, and it also programs the FIB. Any changes in the next-hop reachability are announced to shard threads. Shard threads react to such announcements and cause the necessary state changes in the Update-IO threads and the active route redistribution to the main threads. Update-IO threads generate outbound UPDATE messages and announce the prefix changes to their neighbors. In the end all threads, the FIB, and the network will have the consistent view of any prefix.

When a shard thread has run the BGP export policy and decided which BGP peers across all peer groups will receive a route, a new set of IBGP route announcement tuple messages (tuples) are queued for Update-IO threads. Shard threads multiplex several tuples back to an Update-IO thread. These tuples carry state about the BGP PATH attributes and prefixes. These PATH attributes are assumed immutable and are shared in a reference-counted manner between threads.

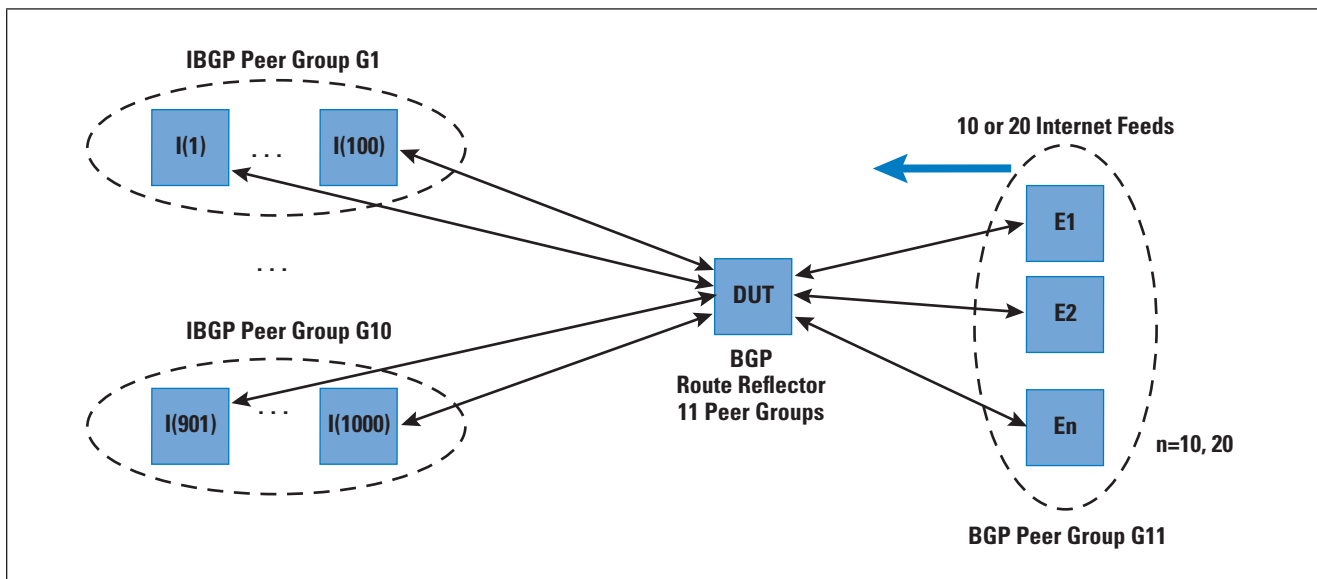

The Update-IO thread puts many tuples with the same BGP PATH attributes in a single BGP UPDATE message for transmission. Packing helps ensure that the number of BGP UPDATE messages is limited to prevent flooding of the local TCP/IP stack with too many send calls. Also, packing ensures that downstream BGP routers are not flooded with excessive messages. It ensures that gains from concurrent read processing in the shard threads to CPU overhead are not lost by handling more I/O messages.

Various queueing points are present in the main, shard, and Update-IO threads in our routing implementation. As these routes are learned and selected to distribute, the queueing points help us compress fast occurring state changes and reduce the churn from spreading from a source to the consumers. This churn reduction is very important when operating at scale and with several producers and consumers. Shard threads compress route changes for prefixes being redistributed to the main thread. For example, a route addition followed by a route deletion nullifies both. The main thread has a similar queueing logic to compress state churn when downloading routes to the FIB. Shard threads have a queue towards Update-IO threads to dampen the tuple churn in the BGP. Similarly, the Update-IO threads also use tuple queues to pack and suppress state before final state is disseminated to the peers.

Performance Measurements

To measure the gains of the approach described previously, we used a testbed where the *Device Under Test* (DUT) is a scaled BGP Route Reflector (Figure 4).

Figure 4: Route Reflector Topology

The RR receives several Internet feeds (800,000+ routes per feed) from an *External BGP* (EBGP) peer group of 10 BGP peers and reflects the best path for each destination towards 1,000 BGP client peers divided among 10 peer groups. Thus, a total of 11 BGP peer groups are in this testbed.

This setup represents a high scale of incoming UPDATE messages, and even higher scale of outbound UPDATE message generation. We used Internet feed instead of canned routes from a protocol tester like IXIA to mimic the real-world scenario where routes have variable PATH attributes. The DUT is a Linux Ubuntu with 18 servers with 8 cores (Xeon CPU E5-2640 v3 @ 2.6 GHz) and hyperthreading is turned off. The RR server on the DUT runs in a Linux Docker Container. The RR clients were also running our BGP implementation, where these clients drop all incoming PDUs after checking them for validity. This modification was done to ensure these 1,000 clients are never a bottleneck when receiving UPDATE messages from the DUT.

Table 1. Read-Side Performance Measurements

Number of Shard Threads	Convergence Time (Seconds)	Scale Up (S)
0	73	1.00
1	76	0.96
2	42	1.74
3	31	2.35
4	26	2.81
5	20	3.65
6	18	4.06

Table 2. BGP Write-Side Performance (4 Shards)

Number of Update-IO Threads	Convergence Time (Seconds)	Scale Up (S)
0	352	1.00
1	259	1.36
2	141	2.50
5	67	5.25
10	54	6.52

Table 3. BGP Full Pipeline Performance (4 Shards)

Number of Update-IO Threads	Convergence Time (Seconds)	Scale Up (S)
0	347	1.00
1	282	1.23
2	161	2.16
5	93	3.73
10	77	4.51
11	78	4.45

The testbed was run in three modes:

- Add a discard export policy to the DUT to ensure that no tuples to Update-IO threads are generated and we can get the measurements of the read side of the BGP pipeline. Table 1 shows the performance numbers for this mode of measurement. We noticed a maximum scale-up of 4x on six shards, and beyond six shards our gains were not beyond 4x.
- After the DUT has all the inbound Internet feeds and the RIBs have settled down, we delete the discard export policy, and this deletion triggers generation of tuples towards Update-IO threads and update messages start streaming toward the 1,000 peers. This step emulates the write side of the BGP pipeline and helps us measure that performance. Table 2 presents the measurements for this mode with 4 shard threads. The numbers of Update-IO threads were chosen to ensure 10 peer groups map to an even number of threads. We noticed gains linearly increasing as the number of threads increased.
- To measure the full pipeline performance, we repeated the previous 2 modes of testing without any discard export policy. We ran tests with 4 shard threads and up to 11 Update-IO threads. As expected, we noticed several fold improvements in the performance of BGP convergence time as we increased the number of I/O threads, as shown in Table 3.

Conclusions

Sharding in databases, web servers, and parallel computing concepts of SPMD have been used many times in the industry. This article is the first one where both concepts are used with BGP. We have designed and implemented a solution of splitting BGP into read and write pipelines and data (the RIBs). Our technique of sharing nothing among threads implementing BGP read and BGP write pipelines yields significant gains in scale and performance without impacting the convergence properties of the BGP protocol. This design also maintains BGP prefix packing and reduces the impact on local and remote routers. Lastly, we have implemented a design that keeps providing performance gains as parallelism increases, but the gains are limited by Amdahl's Law^[6].

Transport Versus Network

by Geoff Huston, APNIC

One of the basic tools in network design is the so-called “stacked” protocol model. This model was developed in the late 1970s as part of a broader effort to develop general standards and methods of networking. In 1983, the efforts of the *Consultative Committee for International Telephony and Telegraphy* (CCITT) and *International Organization for Standardization* (ISO) merged to form *The Basic Reference Model for Open Systems Interconnection*, usually referred to as the *Open Systems Interconnection Reference Model*, or the “OSI Model”^[0]. This model included a seven-layer abstract model of networking that defined standard behaviours of both the overall network functions and the various components of the network (Figure 1).

Figure 1: OSI Reference Model

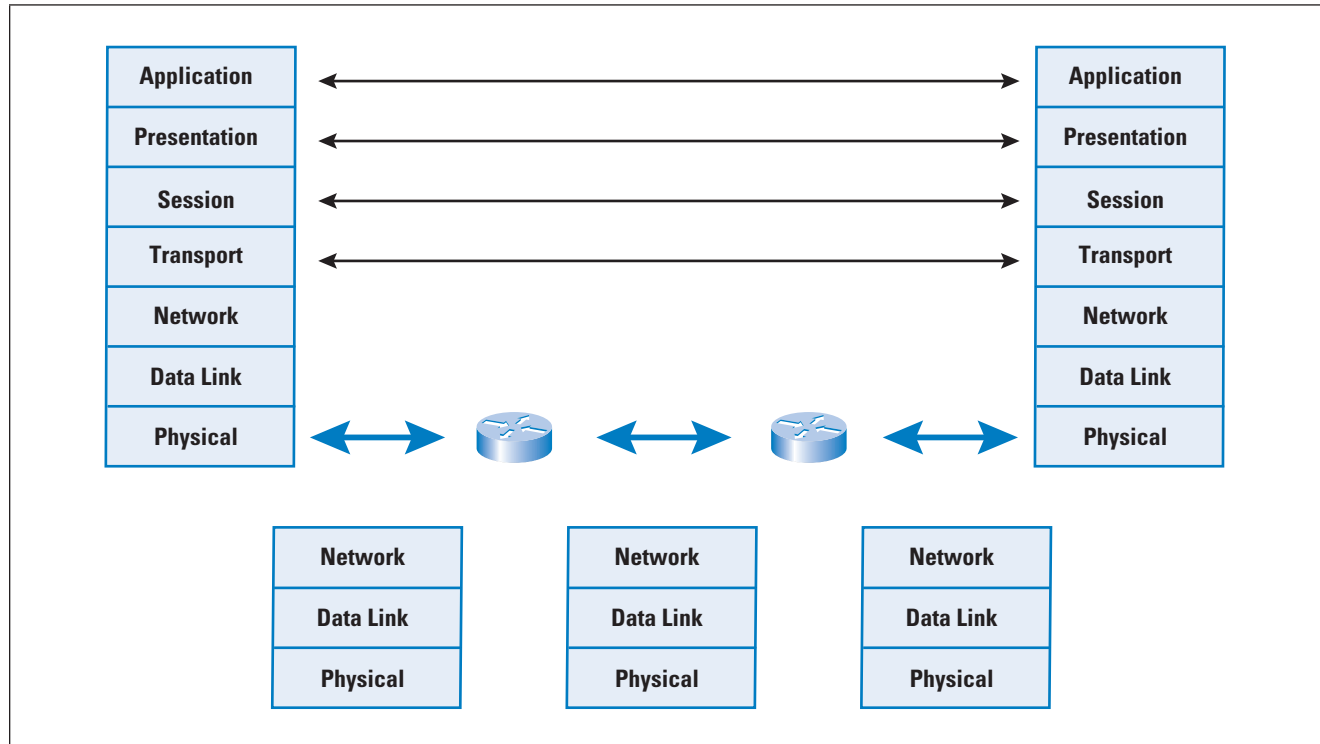

The model segmented functions into two parts:

- The *Media Layers* handle the encoding of binary data into the physical transmission media, the data link layer describes the data frames used between two inter-connected “nodes,” and the network layer manages a multi-node network, including addressing and routing behaviours that manage the transmission of data between attached hosts.
- The *Host Layers* concern functions on end hosts. These layers encompass the transport layer that performs data segmentation into packets, end-to-end flow control, packet loss recovery, and multiplexing. The layers above the transport layer in the OSI model are the session layer, the presentation layer, and the application itself.

In a model of a network as a collection of interior *nodes* and a set of attached *hosts*, the interior nodes use only the network layer to make forwarding decisions for each packet that it handles, while the hosts use the transport layer to manage the data flow between communicating hosts.

The implication of this model is that there is a delineation between node and host functions and a clear delineation of the data that they need to perform their functions. Nodes do not need to have any knowledge of the settings used at the transport level, and, similarly, hosts have no need to access the network layer (Figure 2).

Figure 2: Host and Node Functions

In the context of the Internet Protocol Suite, the network-layer function is encoded as the IP header of a data packet, and the transport-layer function is encoded as the transport header, conventionally as either a *Transmission Control Protocol* (TCP) or a *User Datagram Protocol* (UDP) header (although IP also defines other headers). In terms of the Internet architectural model, a packet should be deliverable through the Internet no matter what transport header it may have attached to it.

Therefore, it should not matter in the slightest what value you put in the IP Protocol field in IP packet headers. It's really none of the network's business!

The same almost applies to the *Extension Header* fields in IPv6, although this area is one where, inexplicably, IPv6 scrambled the egg and some extension headers are addressed to network elements, namely the *Hop-by-Hop* and *Routing* Extension Headers, while the remainder are ostensibly addressed to the destination host. If Extension Headers were defined exclusively as host (or destination) extensions, then the IPv6 networks should ignore them, while if they were intended to be network options, then hosts should ignore them. Perhaps it's another of those areas where theory and practice just don't align well.

In a strict sense the Protocol field in the IPv4 packet header need never have been placed in the IPv4 header in the first place. The particular transport protocol that the communicating hosts use is none of the network's business, in theory, meaning that if the two communicating hosts decide to deliberately obscure the transport protocol control settings from the network, then that should not matter in the slightest to the network.

In today's public Internet it appears to matter a lot that the transport protocol header is visible to the network. In fact, not only should the transport protocol be visible to the network, but the particular transport protocol that the hosts select also matters to the network. That is because many elements of today's network not only peek into the transport headers of the packets that they carry, but they also rely on the information in this transport header. Firewalls are a classic example of this reliance, but there are also *Network Address Translators*, *Equal-Cost Multi-Path Load Balancers*, and *Quality-of-Service Policy Engines*, to name a few. These network functions make assumptions about the visibility of transport headers in the IP packet in order to make consistent decisions about packet handling for all packets within a single transport flow. Often these network functions take it one step further and they process packets with the well-known transport headers (typically restricted to just TCP and UDP) and discard all else. It's even gone further than that, and we have reached the point that today's generally accepted rule is that unfragmented IP packets that contain a TCP transport header that includes one end using Port 443, and unfragmented IP packets that contain a UDP transport header where one end uses Port 53 stand the best chance of getting their data payload through to the intended destination. Every effort to augment this remarkably constrained set of packet profiles increases the probability of network-based disruption of communication.

Encrypted Transport Headers

If it is a self-limiting action to use a novel transport protocol in the public Internet, then why are we even considering the option of encrypting transport protocols to make all transport headers opaque to the network?

One answer is "Edward Snowden." When Snowden made his pervasive monitoring revelations^[1], the *Internet Engineering Task Force* (IETF) responded in what could be called a "like-for-like" reaction and came to a consensus position that "Pervasive Monitoring Is an Attack"^[2]. The general response to this form of insidious attack was to increase the level of encryption of Internet traffic to lift the degree of difficulty in carrying out network-based surveillance. Not only does this IETF response encompass the use of *Transport Layer Security* (TLS) to encrypt session payloads on the Internet wherever possible and shift the application behaviour profiles to make this the default action, but it also shifted our attention to other areas of Internet communication where compromise of the trust model was thought to be an issue.

The actions of the *Domain Name System* (DNS) protocol have been drawn into this IETF universal obfuscation effort, as has the transmission of transport protocol headers. We are long past the time when hosts were ill-equipped to perform encryption functions, and now robust encryption is not a luxury option with limited use, but rather something every user should reasonably expect to use as a minimum requirement. If the objective is to limit the information leakage in all aspects of the communications environment on the Internet, then the control meta-data is as important as the data itself. Applying confidentiality to transport header fields can certainly improve users' privacy and can help mitigate certain attacks or manipulation of packets by devices on the network path^[3].

However, I suspect that this privacy argument is only one part of the story, and while these measures to encrypt Internet traffic play to a popular concern of the surveillance state operating in a largely unchecked manner, they may not lie at the heart of why obscuring host functions from the network is a path that some parts of the Internet ecosystem vigorously pursue today with transport header encryption.

It's not clear that the objective is here, and as with all interdependent complex systems, deliberately obscuring one aspect of the system from another typically offers both benefits and downsides. In April 2019, the *Internet Architecture Board* (IAB) published RFC 8546, titled "The Wire Image of a Network Protocol"^[4]. It's a short document (9 pages) by today's RFC standards, but brevity does not necessarily imply clarity. This document appears to have cloaked its message in such a dense level of abstract terminology that it managed to say very little of practical use! The IAB document appears to have been prompted by the protracted debate in the QUIC Working Group over the use of the visible spin bit in the QUIC transport protocol^[5], and I suspect that it started as an effort to argue for some levels of transport behaviour visibility to the network, but the IAB's prognostications on the topic have offered little useful or informative comment apart from illustrating the level of collective angst that this issue has generated! The IAB is not the most prolific of commentators, and any matter that provokes an IAB response, no matter how cryptic that response may be, does illustrate that the topic is one of general concern rather than being just a rather esoteric tussle buried deep down in the design of a particular protocol.

This topic of encrypted transport headers is a transport topic, so it is natural to ask whether the IETF's *Transport Area* can do any better than the IAB in providing a clear and informed exposition of the issues here. The Transport Area Working Group of the IETF has completed an RFC on this topic, "Considerations around Transport Header Confidentiality, Network Operations, and the Evolution of Internet Transport Protocols"^[6]. To quote from its abstract: "This document discusses the possible impact when network traffic uses a protocol with an encrypted transport header. It suggests issues to consider when designing new transport protocols or features."

This document strikes me as an effort to produce a slightly more practically focused commentary on header encryption than the earlier IAB effort. At 49 pages it certainly cannot be considered a brief document, but does this extended commentary do any better in terms of clarity of the arguments being considered?

The document first looks at some rationales for the use of information on the network contained in headers. It cites the situation of link aggregation, and the problem of packet re-ordering in such scenarios. The common response to re-ordering is for the network to peer down into the transport header to gain a more granular view of a traffic flow than that which can be derived from source and destination IP address pairs. It is the IPv4 proxy for the IPv6 *Flow Label*. (Although the IPv6 Flow Label is so confused as to its intended role it's hard to understand how the IPv6 Flow Label field is useful in any case whatsoever!)

The document references differential service efforts that attempt to perform selective damage on traffic flows under the guise of "Quality of Service." (That "Quality" label always seems to me to have an Orwellian connotation, and a more honest label would be "Selective Service Degradation," or even just "Carriage Standover Services"). The document also enumerates the ways network operators can perform network analysis of using transport-level information, including traffic profile analysis, latency, and jitter and packet loss. However, the document strikes me as presenting a somewhat disingenuous set of rationales. For me, it is akin to a voice telephony operator justifying its eavesdropping on phone conversations on the basis of a baseless assertion that the information gathered by such wiretapping, or in other words knowledge of what people are saying to each other over a telephone connection, can be used to make the telephone network better! The document also uses the last recourse of the desperate, by invoking a nebulous concept of "security," claiming that if network operators were no longer able to eavesdrop on the transport parameters of active sessions, then somehow the operator's ability to run a secure network would be compromised in some unspecified way.

Obviously, none of the rationales presented in this document can withstand much in the way of close scrutiny.

It also appears to take a privacy-oriented stance in its analysis, and it seems to me that the privacy argument is largely an overt excuse for a more substantial difference of opinion between *content* and *carriage*. To a large extent, the issue from the perspective of the application is that the efforts of network operators to perform "traffic grooming" through transport header manipulation amounts to little more than inflicting damage on application data flows, and thereby pushes the network to a lower level of carriage efficiency. And this issue of the use of networks to selectively degrade transport performance in the name of network service quality is perhaps where we should look for the real tensions between networks and hosts in today's Internet.

Transport Protocol Meddling

To look down this path we might want to start with the tensions between hosts and networks on the Internet.

In the telephone world, the network operator controlled all traffic. What you leased from the network was either a virtual circuit capable of passing a real-time voice conversation, or a fixed-capacity channel between two end points. If you used one of these channels, you couldn't go any faster than the contracted speed, and if you went slower, you did not release common capacity for anyone else to use. Obviously, the network charged more for leases of higher capacity. Packet networks changed all that. The network had no enforcement, and various applications (or traffic flows) competed with each other for the common transmission resource. Networks that wanted to control the allocation of shared common communications resources to clients had a problem.

This allocation control was the motive for a large body of work on the Internet during the 1990s and 2000s over what was called *Quality of Service* (QoS)^[7]. The network operator wanted to offer (no doubt for some premium) a “higher-quality” service to some clients and some traffic profiles. But if a network has a fixed-capacity offering a larger slice of the network resources to some clients, inevitably it will offer less capacity to the others. One common theme of much of this work was that while it was possible for the network to disrupt a communication session in various ways to make it go slower, it was a lot more challenging (or even impossible in many ways) to make a session go faster.

Thus, in order to offer preferential treatment to a class of traffic flows, a good way was to make all the other flows go slower! The intended effect was to clear some space for sessions that were intended to be favoured to expand their sending windows and occupy this cleared network space. So-called *Performance-Enhancing Proxies* were not really able to make the selected TCP sessions go faster per se, but they were able to make other concurrent TCP sessions go slower, and thereby make some space for the selected sessions to have a lower packet-loss probability and hence achieve a higher data-throughput rate. One way of using this form is session throttling to drop packets. A subtler way, but also very effective, is to alter the TCP control parameters. If the offered TCP window size parameter is reduced, then senders will conveniently throttle their sending rate accordingly.

Pretty obviously, this selective behaviour of throttling active TCP sessions by networks was not something that applications viewed as a sympathetic act, and there have been two major responses from the application side. One is the use of a different congestion-control algorithm that is a lot less sensitive to packet loss and more sensitive to changes in the end-to-end bandwidth delay product across network paths. This method is called the *Bottleneck Bandwidth and Round-trip* (BBR) TCP control protocol, which is a relatively new TCP sender-side control algorithm.

But BBR is still susceptible to on-path manipulation of the TCP window size, and protecting the session from this form of network interference is where encrypted transport headers emerged and became an important objective. This response is the second one, executed by obscuring where the TCP control information is actually carried in the packet.

As we've already noted, you just can't remove a visible transport header from IP packets in the Public Internet, and even encrypting the TCP header would probably incur the same drop response from the network. But hosts have the option to ignore these transport header settings. So, while the host can't remove a visible transport header, they can make the headers meaningless.

One option is to use a "dummy" outer TCP wrapper as fodder for networks that want to peek at the transport layer and manipulate the session settings while hiding the real TCP control header inside an encrypted payload. There would be little in the way of a visible network signature that this manipulation is happening, apart from the observation that the TCP end hosts would appear to be unresponsive to manipulation of their window parameters.

However, the problem with this approach is that these days the application is actually trying not only to take control over its transport session parameters from a meddling network, but also to assert the same control over the platform in which the application is hosted. In theory, the application could use "raw IP" interfaces into the platform I/O routines, but in practice in deployed systems it is close to impossible. Platforms used in production systems tend to treat applications with suspicion. (Given the proliferation of malware, this level of paranoia on the part of the platform is probably warranted.) It is quite a challenge to disable all forms of how the platform handles the transport protocols and pass control of the transport protocol from the kernel into the applications space.

For this reason, it is logical to take the approach QUIC uses, where the shim wrapper of QUIC uses UDP as a visible transport header and pushes the TCP header into the encrypted payload part of the IP packet. UDP is close to ideal in this case as there are no transport controls in the protocol, just the local port numbers. QUIC looks to the network a lot like a UDP session that uses a TLS-like session encryption because in so many ways it is a UDP session that uses TLS. The change is that the end-to-end TCP flow control is now truly an end-to-end flow because only the two applications at the "ends" of the QUIC transport can see end-to-end transport-control parameters that are embedded in the end-to-end encrypted UDP payload. The host platform control over UDP packets is perfunctory, and the application is then allowed to assume complete control over the transport behaviour of the session.

Content Versus Carriage

Perhaps this shift to opaque transport headers goes a little further than just a desire for greater levels of protected autonomous control by applications. The shift that QUIC represents could be seen as the counter move by content providers to another round of a somewhat tired old game play by network operators to extract a tax from content providers by holding their content traffic to ransom, or, as it came to be known, a tussle over *Network Neutrality*.

There have been times when network operators have implemented measures to throttle certain forms of traffic that they asserted was using their network in some vaguely unspecified manner that was “unfair” in some way. The vagueness of all this discussion is probably attributable to a baser desire on the part of the carriage operator, which was to extort a carriage toll from content providers in a crude form of basic blackmail: “My network, my rules. You customer, you pay!”

I suspect that many carriage providers in this industry, who are witnessing the content providers take all the money off the table, believe that they are the victims here. Their efforts to restore some of their lost revenue base has meant that they are looking to restore a “fair share” of revenue in forcing the giants of the content space to pay for their share of carriage costs. However, if the enforcement mechanism of this extortion pressure is through playing with the transport-control parameters of the traffic that transits the carriage network (or, in other words, holding the traffic to ransom), then the obvious response is to push the transport controls under the same encryption veil as the content itself to prevent such real-time manipulation of the traffic profile. And this explanation of why QUIC is so important is perhaps a more compelling one.

If this situation is a tussle for primacy in the tensions between carriage and content, then it looks like the content folks are gaining the upper hand. Through encryption at every level in the host part of the protocol stack, including at the transport layer, the content folks are withholding information from the carriage providers that would allow the carriage providers to selectively discriminate and play content providers off against each other. If all that the network can do is limited to fully encrypted UDP packet streams, then one stream looks much like another, and selective discrimination is just not feasible. And if that’s not enough, then padding and deliberate packet variation can blur most efforts at traffic profiling.

But when I say “content” I really mean “apps,” and when I say “apps” I actually mean “browsers,” so in reality I am really talking about Chrome, and when I say Chrome, I mean Google.

The massive dominance of mobile traffic in the industry and the massive dominance of Android in the mobile device environment tilts this space to an extraordinary degree.

Given this inherent level of control of all mobile devices, coupled with control of the majority browser platform in this space, it is hard to conceive how Google could possibly lose in this tussle. However, it is likely that if Google wins this particular battle with the carriage providers, there will be further battles to come. It is highly likely that the carriage industry will follow the lead from traditional print media and head to politicians with the case that Google's destruction of the business model for the provision of national communications infrastructure is counter to national interests, and political intervention is necessary to restore some balance into the market and allow the market for carriage to be a viable investment vehicle. Or, to put in more crudely, if Google has destroyed the residual value of the contained carriage market, then Google should now pay carriage operators to restore its viability.

At this point all technical considerations of encryption and information leakage, and even all market considerations of the viability of various business models, just walk out the door, and in their place comes a bevy of lawyers and politicians. Strategic national interest is always a strong argument to make, and when we get over the various nebulous threats by actors to quit national markets, we then get down to the real question of: "What is a tenable business relationship between carriage and content?"

In such a politically charged space the choices at that point are either that the various market players will compromise and reach some outcome that they can all live with, or the politicians will attempt to impose an outcome that will in all likelihood be far more disagreeable for all!

Whatever the outcome in the next few years, it should be fun to watch this drama play out. Don't forget to bring popcorn!

SIP phones have replaced traditional telephones even in the offices of The Internet Protocol Journal.

20 Years of SIP — A Retrospective

by Jonathan Rosenberg, Five9

June of 2022 marked the twentieth anniversary of the publication of the *Session Initiation Protocol* (SIP), documented in RFC 3261^[1,2,3,4]. When it was published in June of 2002, it set records for the longest specification produced by the *Internet Engineering Task Force* (IETF), at 269 pages. The IETF produces the technology standards that make the Internet work. Protocols like *Internet Protocol* (IP), *Transmission Control Protocol* (TCP), and *Hypertext Transfer Protocol* (HTTP)—all now part of mainstream vernacular—came out of the IETF. It was a monumental effort to produce, involving a dedicated author team that worked full time for months to ensure that the specifications were correct, consistent, and complete. I had the great fortune to be the lead author of this document, an accomplishment that was the defining moment for my career.

The RFC 3261 author team included Robert Sparks, Jon Peterson, Alan Johnston, Allison Mankin, Jonathan Rosenberg, Gonzalo Camarillo, and Henning Schulzrinne.

In the 20 years (and almost countless extensions to SIP) that followed, it is hard to dispute that SIP has been a major success. At its core, SIP enabled the transformation of the telecommunications industry from one based on hardware to one based on software—colloquially known as *Voice over IP* (VoIP). A 20th anniversary is the ideal time for a retrospective, to consider both its positives and negatives. On the plus side, this transformation resulted in the re-engineering of the phone network, the creation of new markets and market categories, and the creation of jobs and livelihoods. On the negative side, it has exacerbated the scourge of robocalling.

The Phone Network Re-Engineered

Prior to SIP, the telephone network was built using telephone switches based on custom hardware. These switches were made by a small set of vendors and were a completely verticalized solution from the physical networking layer to the application layer software.

With the mainstream adoption of IP networks, it became possible to replace that hardware with general-purpose computers running SIP-based software applications. This replacement resulted in a dramatic reduction of cost compared to the prior generation. SIP further reduced this cost by enabling these software applications to run on machines in a small number of data centers that might be far away from the people talking to each other, while still keeping the audio delays to a minimum. This centralization of the software was a dramatic shift in how the phone network worked.

This new paradigm had the most immediate impacts on the way corporate phone systems were built. Before SIP, businesses needed to put hardware-based phone systems called *Private Branch Exchanges* (PBXs) in each building and wire them up on a separate network from the IP network used for everything else.

SIP allowed enterprise IT departments to ditch this separate network and reuse the IP network for voice. It also allowed them to put the software in their data centers and eliminate the hardware in each building. This development represented a huge improvement in costs and reduction in complexity. The final “icing on the cake” was that SIP enabled video, instant messaging, and presence too, spawning the creation of desktop applications—called *softphones*—that allowed users to place calls, have video meetings, and chat. Businesses far and wide adopted these phones. Today, almost all business phone systems are based on SIP.

With its success in corporations, pressure grew for the phone companies (that is, the telcos), to provide a way for businesses to connect their phone systems to the rest of the phone network using SIP. Prior to this time, businesses could use software within their corporate campus, but they needed to switch to hardware to connect to the rest of the world. And so, “SIP Trunking” was born, providing a way to send and receive calls into the traditional phone network using SIP-based software applications. Its adoption was rapid, and it was the first step in transforming the edge of the telco networks from hardware to software.

Around the same time, mobile phone operators were seeing an explosion in usage due to smartphones. These mobile phones had two distinct wireless connections—an old one just for voice, and a new one for data. To expand capacity, they needed to reclaim the voice channel and use it for data. They could do it by switching the voice to VoIP, which would require them to replace their own voice hardware with SIP-based software. The wireless industry produced an expansive set of specifications on how to build a SIP-based replacement for mobile phone networks, called the *Internet Multimedia Subsystem* (IMS). IMS was finally deployed in the late 2010s. Today, most mobile phone calls use a SIP client built into the phone and traverse a SIP network deployed and operated by the mobile carriers. This change is largely invisible to mobile phone users, but not entirely. SIP also enabled the usage of higher quality wideband voice for phone calls, creating an audio experience that is more like listening to music, and you may have noticed this difference in more and more calls you make.

In a similar fashion, wireline telco providers saw a surge in demand for data. To make the jump to next-generation data access technologies like fiber, they needed to get rid of their separate voice networks and move to voice over IP too. Today, if you have one of these higher speed data networks and still have an analog phone in your home, the analog signal is converted to VoIP using a SIP client in the modem at your house, and then processed by a SIP network that the carrier operates.

The final piece of the puzzle is how carriers themselves connect to each other. This process has gradually migrated to SIP too, using carrier versions of SIP trunking. This change is now accelerating, since the conversion is needed to enable the deployment of *Secure Telephone Identity Revisited* and *Signature-based Handling of Asserted information using toKENs* (STIR/SHAKEN), a SIP-based technology to combat robocalling^[5,6,7].

Without a doubt, this transformation of the telecommunications technology stack—that SIP enabled—has massively impacted the world, enabling lower costs, more bandwidth for data, better quality for voice, and added video.

Market Category Creation

This transformation of the telecommunications industry also created entirely new markets and market categories that didn't exist before SIP. To enumerate just a few of them:

- *IP PBX*: The *IP Private Branch Exchange* (PBX) provides phone services for businesses. This market was created as a direct replacement for the legacy hardware-based PBX products that preceded it. Cisco Systems led this market, which never had a product in the PBX market, along with incumbents like Avaya, Siemens, and Nortel, many of which had legacy products along with the newer IP-based ones. This market is now itself shrinking, being replaced by *Unified Communications as a Service* (UCaaS).
- *SIP Trunking*: This market is estimated to be around \$13B in 2021^[8] and is a replacement for legacy hardware phone network access technologies.
- *SIP Hardphones*: Before SIP, the PBX vendors made their own phones, and a given phone could only work with their own hardware. With SIP, it became possible for vendors to produce phones that could work with many different IP PBXs. These phones were often produced at low cost. Vendors include Yealink, Cisco, Grandstream, and Avaya.
- *Session Border Controller* (SBC): The usage of SIP trunking drove demand for a new category of product that could serve as a SIP firewall of sorts, managing the boundary between an enterprise and a carrier, or between carriers. Ribbon and Oracle are the market leaders, with a market size estimated at USD \$709M in 2022^[9].
- *Internet Multimedia Subsystem* (IMS): Market leaders include Ericsson, Siemens, and Nokia. The market size was USD \$1.8B in 2019^[10].
- *Communications Platform as a Service* (CPaaS): This market category is an entirely new one, enabled by the transformation of telecommunications to software. CPaaS vendors offer *Application Programming Interfaces* (APIs) that allow developers to build telecom applications easily. These APIs allow for sending of SMSs, placing and receiving of phone calls, and so on. Twilio created this market and is still the market leader. SIP enabled the CPaaS vendors to gain low-cost and global access to telephone services, and without SIP, the market could not have existed. The market is huge and growing—estimated at USD \$5.2B in 2021^[11], (though most of it is for sending *Short Message Service* (SMS), where SIP has been less impactful).
- *Unified Communications as a Service* (UCaaS) puts the IP PBX in the cloud so businesses can consume voice and video communications services from the cloud.

Market leaders include RingCentral, 8x8, Cisco Systems, Microsoft, and Zoom. All of these vendors depend on SIP-based interconnection to the telephone network. This market is really big—estimated to be USD \$28.9B in 2021!^[12]

- *Contact Center as a Service* (CCaaS) enables delivery of contact center software from the cloud, including voice response systems, agent desktop applications, and call distribution software. Vendors include Five9, Gensys, and NICE/InContact. Like UCaaS, these vendors depend on SIP to interconnect to the telephone network. This market was valued at USD \$4.8B in 2021.^[13]

When put together, SIP created or enabled these (no less than eight) distinct markets, representing approximately USD \$50B in market value!

Job Creation

For me, the greatest source of satisfaction from the success of SIP is when I hear from someone that they have built their careers and their livelihood around this technology. SIP is complex, and like any complex technology that many vendors use in many ways in many markets, expertise in it becomes a marketable skill.

Many LinkedIn profiles list “SIP” as a skill. Many are software developers, but many other jobs require SIP expertise. SIP network engineers and technicians build, deploy, and operate SIP networks. Sales and marketing engineers configure and demonstrate SIP-based products. IT workers who manage business communications for their companies need to understand SIP too. A search on LinkedIn for people matching “SIP” yields approximately 239,000 results.

Many companies now exist that provide SIP certifications and training—for example the SIP School.^[14] SIP is taught in many graduate classes that cover computer networking, and some even have dedicated courses just on VoIP.

It’s hard to know how many jobs SIP has created, but it would not be unreasonable to guess it is somewhere in the ballpark of 100,000 jobs. If you add the folks working in technical roles across the companies in the markets that SIP created, along with those working in telcos or in IT departments providing VOIP, it is easy to see how the number could be that large.

The Downside: Robocalling

Almost all technologies that have brought great benefits have come with some drawbacks. There is no better example than the automobile, which has brought countless benefits, but also caused 42,915 deaths in 2021 due to automobile accidents. The Internet too, has brought countless benefits, but has also brought with it problems that are becoming more apparent. SIP has had far less impact as other technologies, so its drawbacks are fewer, but they do exist.

Without a doubt, the biggest drawback has been the rise of robocalling and the fake caller IDs that come with it. Telemarketing calls predate SIP for sure. However, as SIP reduced the costs of placing calls and made it possible to make calls using off-the-shelf software, it caused a sharp increase in the volume of these unwanted calls.

The problem is exacerbated by a design flaw in SIP—the lack of an authenticated caller ID. Without that, it is easy for callers to insert any phone number they want. This design defect was inherited from email, as SIP copied this aspect of its design from how email worked. After many years of failed attempts to resolve the problem, there is finally “light at the end of the tunnel” using a SIP-based technology called STIR/SHAKEN^[5,6,7].

In Conclusion

It’s been the highlight of my career to have had the fortune to be the lead author for a technology that, 20 years later, has had a profound impact on the world. By enabling the transformation of telecommunications from hardware to software, SIP drove a re-engineering of both mobile and wired phone networks that resulted in lower cost communications services and more bandwidth available for data. It brought video to the enterprise, created entirely new markets and some new market categories, and created at least 100,000 jobs. I try and remind myself of that fact every time I get one of those annoying robocalls.

He’s the lead author of the Session Initiation Protocol (SIP) and related standards, such as ICE, STUN, TURN and SIMPLE. E-mail: jdrosen@jdrosen.net

IAB Comments on FCC Notice on Secure Internet Routing

The *Internet Architecture Board* (IAB), which provides oversight for the protocols and procedures used by the Internet and also handles the liaison management for the *Internet Engineering Task Force* (IETF), appreciates the opportunity to submit comments in response to the *Federal Communication Commission's* (FCC) Notice of Inquiry, "Secure Internet Routing"^[1]. The IETF is the main organization that works on standards relating to Internet technology. The mission of the IETF is to produce relevant technical documents that influence the way people design, use, and manage the Internet. The IETF is an open, diverse, global community of developers consisting of network operators, vendors, researchers and many other stakeholders.

The IETF originally developed the Internet protocol stack, including the routing system based on the *Border Gateway Protocol* (BGP), and continues to be responsible for maintaining and evolving the technical specifications that define the Internet and its protocols. The Internet's success has resulted from its flexible, modular architecture. BGP is the central protocol for providing global end-to-end connectivity across the world's heterogeneous network domains. It is fundamental to the operation of the Internet.

As in any protocol development, the adoption within the industry of new capabilities will vary. In recent decades, occurrences of BGP-related operational issues have increased. The existing BGP protocol stack is based on a design which can be extended, building on existing network investments. The IETF has two working groups dedicated to improving BGP interdomain routing, called *Inter-Domain Routing* (IDR) and *Global Routing Operations* (GROW). IDR is concerned with the correctness, robustness, and scalability of BGP. GROW is concerned with the operational problems associated with global routing systems, including measurement, policy, and security. The IETF will continue to evolve BGP to meet the needs of new network structures and applications, with a strong focus on security.

We believe in a continuous, modular, flexible evolution of the Internet and its protocols based on operational experience and requirements, where each service provider can determine their security needs based on their diverse requirements and in partnership with other providers. The success of future standardization efforts intended to increase routing security, will be highly dependent on educating BGP users about BGP operational issues and how well real-world deployment experience can be fed back into the multi-stakeholder standards development process, as opposed to a mandated top-down approach, which would fail to meet the diverse needs of the global community.

The FCC can support these efforts by supporting research and other work that help these communities to understand issues, develop solutions where needed, and deploy security technology more widely. The IAB believes that the IETF is an important partner in these efforts.

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

Thank You!	46

Although most of the core protocols of the Internet have remained unchanged for many decades, there is still active work in the *Internet Engineering Task Force* (IETF) and elsewhere to enhance, improve, and even replace some functions provided by the protocols with respect to design and with focus on operational best practice. In this issue we will explore two areas where such work is in progress, namely transport and the *Domain Name System* (DNS).

In our first article, Geoff Huston compares the *Transmission Control Protocol* (TCP) to QUIC. QUIC has seen rapid deployment in the Internet largely due to its improved performance and extensibility, as well as privacy and security. Geoff predicts that QUIC may some day replace TCP as the major transport protocol in the Internet. The IETF has a working group dedicated to QUIC.

Another very active work area in the IETF focuses on the DNS. One topic of interest in the *DNS Operations* (DNSOP) working group is *Minimized DNS Resolution*. In our second article, Burton Kaliski, Jr. describes four different approaches to minimization: *Qname Minimization*, *NXDOMAIN Cut Processing*, *Aggressive DNSSEC Caching*, and *Local Root*. All of these approaches have been documented in RFCs and are in various stages of deployment across the Internet.

Our final article, by Adiel Akplogan, is an overview of *Knowledge-Sharing and Instantiating Norms for Domain Name System and Naming Security* (KINDNS) [pronounced “kindness”], an initiative launched by the *Internet Corporation for Assigned Names and Numbers* (ICANN) to promote DNS security and best practices.

I was very pleased to learn that the 2022 *Jonathan B. Postel Service Award* was awarded to my friend and mentor George Sadowsky for his work on the Internet Society’s *Developing Countries Workshops* in the 1990s. The tradition of training network engineers on all aspects of Internet technology continues at numerous conferences around the world to this day, most notably at events hosted by various *Network Operator Groups* (NOGs) and regional events such as APRICOT. For more details on the award, visit: <https://tinyurl.com/Postel2022>

As always, we welcome your feedback and suggestions on anything you read in this journal. Letters to the Editor may be edited for clarity and length and can be sent to ipj@protocoljournal.org

Comparing TCP and QUIC

by Geoff Huston, APNIC

A common view out there is that the QUIC transport protocol^[0, 4] is just another refinement to the original *Transmission Control Protocol* (TCP) transport protocol^[1, 2]. I find it hard to agree with this sentiment, because for me QUIC represents a significant shift in the set of transport capabilities available to applications in terms of communication privacy, session-control integrity, and flexibility. QUIC embodies a different communications model that makes it intrinsically useful to many more forms of application behaviours. Oh, yes. It's also faster than TCP! In my opinion it's likely that over time QUIC will replace TCP in the public Internet. So, for me QUIC is a lot more than just a few tweaks to TCP. Here we will describe both TCP and QUIC and look at the changes that QUIC has brought to the transport table.

However, we should first do a brief recap of TCP.

What is TCP?

TCP is the embodiment of the end-to-end principle in the overall Internet architecture. All the functionality required to take a simple base of datagram delivery and impose upon this model an end-to-end signalling regime that implements reliability, sequencing, adaptive flow control, and streaming is embedded within the TCP protocol.

TCP is a *bilateral full-duplex* protocol. That means that TCP is a two-party communications protocol that supports both parties simultaneously, sending and receiving data within the context of a single TCP connection. Rather than impose a state within the network to support the connection, TCP uses synchronized state between the two end points, and much of the protocol design ensures that each local state transition is communicated to, and acknowledged by, the remote party without any mediation by the network whatsoever.

TCP is a *stream* protocol. The receiver sees the stream of data that the sender generates in precisely the same order as the sender generated. TCP is a true streaming protocol, and application-level network operations are not transparent. Other transport protocols have explicitly encapsulated each application transaction; for every sender's *write*, there must be a matching receiver's *read*. In this manner, the application-derived segmentation of the data stream into a logical record structure is preserved across the communication. TCP does not explicitly preserve such an implicit structure of the data, so there is no explicit pairing between *write* and *read* operations within the network protocol. For example, a TCP application may write three data blocks in sequence into the network connection, which the remote reader may collect in a single read operation. It is left to the application to mark the stream with its own record boundaries, if such boundaries exist in the data.

A rudimentary level of stream formatting is permitted within TCP through the concept of *urgent data* in which the sender can mark the end of a data segment that the application wants to bring to the attention of the receiver. The TCP data segment that carries the final byte of the urgent data segment can mark this data point, and the TCP receiving process has the responsibility to pass this mark to the receiving application.

The hosts at both ends identify the TCP connection by a 5-tuple of protocol identifier, source IP address, source port, destination IP address, and destination port.

The setup of a TCP connection requires a *three-way handshake*, ensuring that both sides of the connection have an unambiguous understanding of the byte-sequence values of the remote side. The operation of the connection setup is as follows: The local system sends an initial sequence number to the remote-end port using a SYN packet. The remote system responds with an *acknowledgement* (ACK) of the initial sequence number and the remote end's initial sequence number in a response SYN packet. The local end responds with an ACK of this remote sequence number. These handshake packets are conventionally TCP packets without any data payload. At this point, TCP shifts into a reliable data flow-control mode of operation. (Figure 1)

Figure 1: TCP 3-way Handshake

TCP is a *sliding window* protocol. The data stream is a sequence of numbered bytes. The sender retains a copy of all sent but as yet unacknowledged data in a local send buffer. When a receiver receives a data segment whose starting sequence number is the next expected data segment, it will send an ACK back to the sender with the sequence number of the end of the received data segment. This process allows the sender to discard all data whose sequence number is less than this received ACK sequence in the local send buffer and advance the send window.

When the received data is out of order, it will send an ACK back to the sender with the sequence number of the last in-order received data. In addition, the ACK message includes the size of the receiver's available buffer size (*receive window*). The volume of unacknowledged data must be no larger than this receiver window size. The overall constraint is that at all points in time the sender should ensure that the volume of unacknowledged data in flight in the network is the smaller of the advertised receive window size and the total capacity of the local send buffer.

TCP is an *ACK-clocked* flow-control protocol, in that within a static lossless mode of operation each received ACK packet indicates that a certain volume of data has been received at the receiver end (and hence has been removed from the network), and this clocking is accompanied by an advertised receive window that then permits the sender to inject the same volume of data into the network as the receiver has removed. Hence, the sending rate is governed by the received ACK rate.

However, TCP is not necessarily aware of the available path capacity of the network, and it must implement a control algorithm at the sending end that attempts to establish a dynamic equilibrium between the flow volume of the TCP session and all other concurrent TCP sessions that have path segments in common with this session. The mode of operation of this flow control is not fixed in the TCP specification, and numerous flow-control algorithms are in use. Many of these control algorithms use an induced instability in TCP through an approach of slow inflation of the sending window for each received ACK, and a rapid drop of the sending window in response to an indication of packet drop (3 duplicate ACKs). This process of sending rate inflation will stop when the send buffer is full, indicating that the sender cannot store any more sent data and must await ACKs before sending more data (send buffer rate limited). It will also stop sending rate inflation when the network cannot accept any further data in flight as the buffers of the network are already full, so further sent data will cause packet loss, which will be signalled back to the sender by duplicate ACKs.

This process has many outcomes relevant to service quality. First, TCP behaves adaptively rather than predictively. The flow-control algorithms are intended to increase the data-flow rate to fill all available network path capacity but also quickly back off if the available capacity changes because of network congestion or if a dynamic change occurs in the end-to-end network path that reduces this available capacity. Second, a single TCP flow across an otherwise idle network attempts to fill the network path with data, optimizing the flow rate (as long as the send buffer is larger than the network flow capacity). If a second TCP flow opens up across the same path, the two flow-control algorithms will interact so that both flows will stabilize to use approximately half of the available capacity per flow. More generally, TCP attempts to behave fairly, in that when multiple TCP flows are present the TCP algorithm is intended to share the network resource evenly across all active flows.

A design tension always exists between the efficiency of network use and enforcing predictable session performance. With TCP, you do not necessarily have predictable throughput but gain a highly utilized and efficient network.

TCP and TLS

Transport Layer Security (TLS)^[3] is handled as a further layer of indirection. When the TCP 3-way handshake is complete, the parties enter a TLS negotiation phase to allow authentication of the remote end of the connection, and to establish a session key that is used to manage the encryption of the session data.

TLS commences with an exchange of credentials. In version 1.3 of TLS (the latest version of this protocol), the client sends a *client hello* message that includes the TLS version the client supports, the cipher suites supported, the name of the service, and a string of random bytes known as the *client random*. The server responds with a *server hello* message that contains the public key certificate of the server, the *server random*, the chosen cipher suite, and a digital signature of the hello messages. Both ends now know each other's random values and the chosen cipher suite, so both can generate a master secret for session encryption. The client sends a *finished* message to indicate that the secure symmetric session key is ready for use (Figure 2).

Earlier versions of TLS used additional packets in the hello exchange that increased the time to complete the TLS handshake.

QUIC

We can now move on to QUIC. The QUIC transport protocol^[4] was apparently designed to address several issues with TCP and TLS, and in particular to improve the transport performance for encrypted traffic with faster session setup, and to allow for further evolution of transport mechanisms and explicitly avoid the emerging TCP ossification within the network.

It is a grossly inaccurate simplification, but at its simplest level QUIC is simply TCP encapsulated and encrypted in a *User Datagram Protocol* (UDP) payload. To the external network QUIC has the appearance of a bidirectional UDP packet sequence where the UDP payload is concealed. To the endpoints you can use QUIC as a reliable full-duplex data-flow protocol. Even at this level, QUIC has numerous advantages over TCP. The first lies in the deliberate concealing of the transport flow-control parameters from the network. The practice of deploying network middleware that rewrites TCP flow-control values to impair the behaviour of the application has not enjoyed widespread support from the application layer, and hiding these flow-control parameters from the network certainly prevents this practice. Second, it can allow the shift of responsibility for providing the transport protocol from the platform to the application. A tension between the application and the platform is longstanding.

Changes to kernel-level TCP are performed via updates to the platform software, and often applications have to wait for the platform to make changes before they can take advantage of the change. For example, if an application wanted to use the TCP *Bottleneck Bandwidth and Round-trip Propagation Time* (BBR) flow-control algorithm, then it would need to wait for a platform to integrate an implementation of the algorithm. By using a basic UDP interface to the transport services of the platform, you can lift the entire flow-control and encryption service into the application itself, if so desired. You may experience some performance penalty of shifting the transport code from the kernel to user space, but in return the application regains complete control of the transport service and allows it to operate in a mode that is not only independent of the platform, but also hidden from the platform. This shift gives the application environment greater levels of control and agility.

However, QUIC does a lot more than just wrapping up TCP in UDP, so let's look at the QUIC protocol in a little more detail.

QUIC Connections

A QUIC *connection* is a shared state between a single client and a single server. QUIC uses the combination of two numbers, one selected by each end, to form a pair of connection IDs. This pair of IDs acts as a persistent identity for the QUIC session, which is used to ensure that changes in addressing at lower protocol layers (addresses or ports) will not cause delivery of packets to a wrong recipient on the end host.

The primary function of a connection ID is to ensure that changes in addressing at lower protocol layers (IP source address and UDP source port numbers) do not cause packets for a QUIC connection to be dropped when the external IP address of an endpoint changes. Each endpoint selects a connection ID using an implementation-specific (and perhaps deployment-specific) method that allows identification of received packets with that connection ID by the endpoint upon receipt to the appropriate QUIC connection instance.

After an endpoint receives a packet with the same connection ID and a different IP address or UDP port, it will verify the peer's ownership of the new address by sending a *challenge frame* containing random data to this new address and waiting for an echoed response with the same data. This challenge and response exchange is performed within the established crypto state, so it is intentionally challenging for an eavesdropper to hijack a session in this way. The two endpoints can continue to exchange data after the verification of the new address.

This verification is particularly useful in terms of negotiating various forms of *Network Address Translation* (NAT) behaviour. NATs are intentionally transport-aware and for TCP, NATs will attempt to maintain a translation state until it observes the closing FIN protocol exchange. UDP offers no such externally visible clues as to the ending of a session, and NATs are prone to interpreting a silent period as a signal to tear down the NAT state.

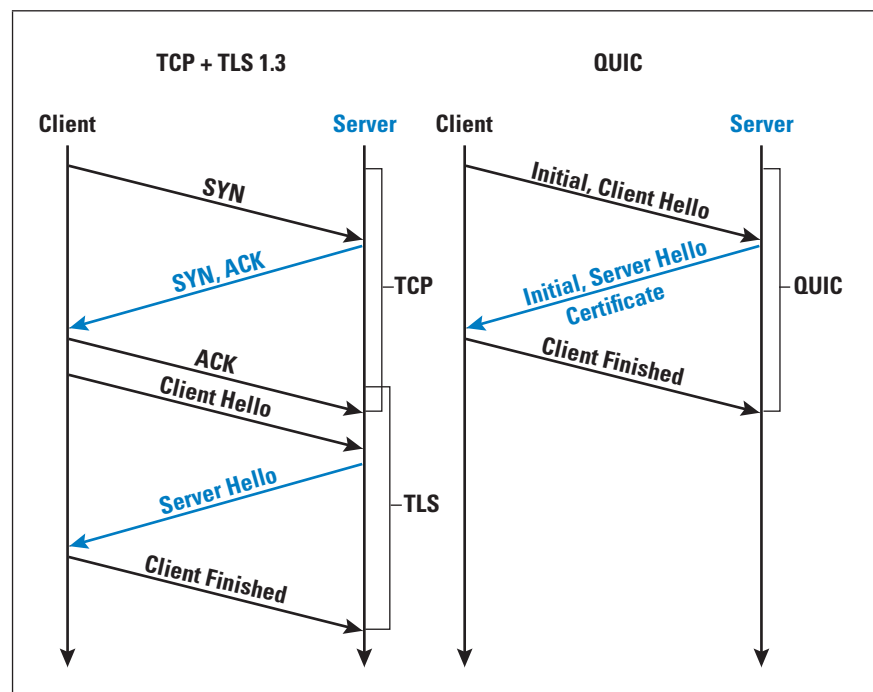

In such a case the next outbound packet might be assigned a new source address and/or UDP source port number by the NAT. It is also useful in terms of session resumption where the connection may have been idle for an extended period, and the NAT binding may have timed out. With TCP, any change in any of the four address and port fields of the connection 5-tuple will cause rejection of the packet as part of the TCP session. QUIC's use of a persistent connection ID permits the receiver to associate the new sender's address details with an existing connection.

You also can use this QUIC functionality of address agility in the context of network-level changes, such as a device switching between WiFi and cellular services while maintaining an active QUIC transport session.

QUIC Connection Handshake

A QUIC connection starts with a handshake that establishes a shared communications state and a shared secret using the QUIC-TLS protocol cryptographic handshake protocol in a single exchange. This protocol merges the TCP 3-way handshake and the TLS 1.3 3-way handshake into a single 3-packet exchange (Figure 2). This merge eliminates a full *Round Trip Time* (RTT) in the QUIC startup phase, which for short sessions is a very significant improvement in session performance.

Figure 2: TCP/TLS and QUIC Handshakes

QUIC also allows a client to send 0-RTT encrypted application data in its first packet to the server by reusing the negotiated parameters from a previous connection and a TLS 1.3 *Pre-Shared Key* (PSK) identity issued by the server, although these 0-RTT data exchanges are not protected against replay attack.

Packets and Frames

The QUIC protocol sends *packets* along the connection. Packets are individually numbered in a 62-bit number space. There is no allowance for retransmission of a numbered packet. If data is to be retransmitted, it is done in a new packet with the next packet number in sequence. That way there is a clear distinction between the reception of an original packet and a retransmission of the data payload.

You can load multiple QUIC packets into a single UDP datagram. QUIC UDP datagrams must not be fragmented, and unless the end performs *Path Maximum Transmission Unit* (PMTU) discovery, QUIC assumes that the path can support a 1,200-byte UDP payload.

A QUIC client expands the payload of all UDP datagrams carrying Initial packets to at least the smallest allowed maximum datagram size of 1,200 bytes by adding padding frames to the Initial packet or by coalescing a set of Initial packets. The payload of all UDP datagrams carrying ACK-eliciting Initial packets is padded to at least the smallest allowed maximum datagram size of 1,200 bytes. Sending UDP datagrams of this size ensures that the network path supports a reasonable PMTU in both directions. Additionally, a client that expands Initial packets helps reduce the order of amplitude gain of amplification attacks caused by server responses toward an unverified client address.

QUIC packets are encrypted individually so that the decryption process does not result in data decryption waiting for partially delivered packets. This encryption is not generally possible under TCP, where the encryption records are in a byte stream and the protocol stack is unaware of higher-layer boundaries within this stream. The additional inference from this per-packet encryption is that it's a requirement that QUIC IP packets are not fragmented. QUIC implementations typically use a conservative choice in the maximum packet size so that IP packet fragmentation does not occur.

A QUIC receiver ACKs the highest packet number received so far, together with a listing of all received contiguous packet number blocks of lower-numbered packets if there are gaps in the received packet sequence. Because QUIC uses purpose-defined ACK frames, QUIC can code up to 256 such number ranges in a single frame, whereas TCP *Selective Acknowledgment* (SACK) has a limit of 3 such sequence number ranges. This limit allows QUIC to provide a more detailed view of packet loss and reordering, leading to higher resiliency against packet losses and more efficient recovery. Lost packets are not retransmitted. Data recovery is performed in the context of each QUIC stream.

QUIC Streams

A QUIC connection is further broken into *streams*. Each QUIC stream provides an ordered byte-stream abstraction to an application similar in nature to a TCP byte stream. QUIC allows for an arbitrary number of concurrent streams to operate over a connection. Applications may indicate the relative priority of streams.

Because the connection has already performed the end-to-end association and established the encryption context, you can establish streams with minimal overhead. A single stream frame can open, pass data, and close down within a single packet, or it can exist for the entire lifetime of the connection.

By comparison, it is possible to multiplex a TCP session into streams, but all such multiplexed TCP streams share a single flow-control state. If the TCP receiver advertises a zero-sized window to the sender, then all multiplexed streams are blocked in a TCP scenario.

Each QUIC stream is identified by a unique *stream ID*, where its two least significant bits are used to identify which endpoint initiated the stream and whether the stream is bidirectional or unidirectional. The byte stream is segmented to data frames, and the stream frame offset is equivalent to the TCP sequence number, used for data-frame delivery ordering and loss detection and retransmission for reliable data delivery.

QUIC endpoints can decide how to allocate bandwidth between different streams, and how to prioritize transmission of different stream frames based on information from the application. This feature ensures effective loss recovery, congestion control, and flow-control operations, which can significantly impact application performance.

QUIC Datagrams

In addition to reliable streams, QUIC also supports an unreliable but secured data-delivery service with DATAGRAM frames, which will not be retransmitted upon loss detection^[5]. When an application sends a datagram over a QUIC connection, QUIC will generate a DATAGRAM frame and send it in the first available packet. When a QUIC endpoint receives a valid DATAGRAM frame, it is expected that it would deliver the data to the application immediately. These DATAGRAM frames are not associated with any stream.

If a received packet contains only DATAGRAM frames, then the ACK frame can be delayed, as the sender will not retransmit a frame when there is an ACK failure in any case. This service is not a reliable datagram service. If a sender detects that a packet containing a specific DATAGRAM frame might have been lost, the implementation may notify the application that it believes the datagram was lost. Similarly, if a packet containing a DATAGRAM frame is acknowledged, the implementation may notify the sender application that the datagram was successfully transmitted and received.

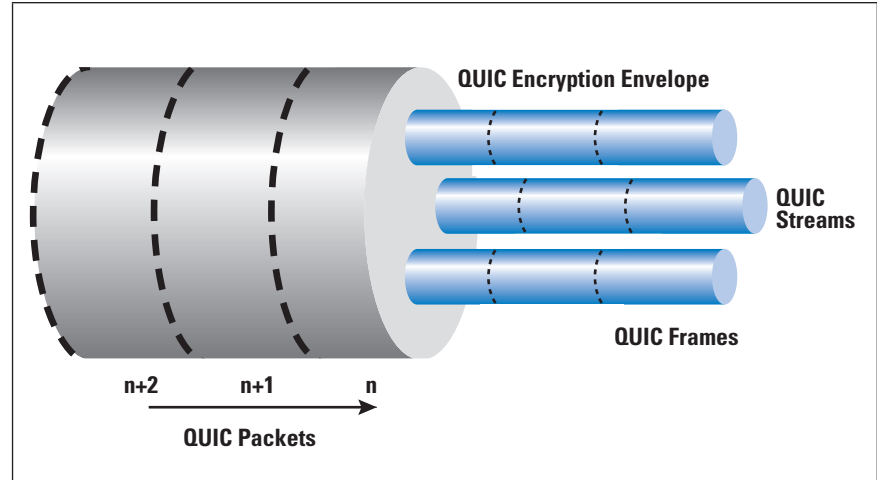

QUIC Frames

Each packet contains a sequence of *frames*. Frames have a frame-type field and type-dependant data. The QUIC standard^[4] defines 20 different frame types. They serve an analogous purpose to the TCP *flags*, carrying a control signal about the state of streams and the connection itself.

Frame types include padding, ping (or keepalive), ACK frames for received packet numbers, which themselves contain *Explicit Congestion Notification* (ECN) counts as well as ACK ranges, as well as stream data frames and datagram frames.

Figure 3 shows the larger organisation of QUIC connections, streams, and frames.

Figure 3: QUIC Logical Organisation

QUIC Recovery and Flow Control

QUIC packets contain one or more frames. QUIC performs loss detection based on these packets, not on individual frames. For each packet that the receiver acknowledges, all frames carried in that packet are considered received. The packet is considered lost if that packet is unacknowledged when a later sent packet has been acknowledged, and when a loss threshold is met.

QUIC uses two thresholds to determine loss. The first is a *Packet Reordering Threshold* t . When packet x is acknowledged, then all unacknowledged packets with a number less than $x - t$ are considered lost. The second is related to the QUIC-measured RTT interval, the *waiting time* w which is determined as a weight factor applied to the current estimated RTT interval. If the time of the most recent acknowledgement is t , then all unacknowledged packets sent before time $t - w$ will be considered lost.

For recovery, all frames in lost packets where the associated stream requires retransmission will be placed into new packets for retransmission. The lost packet itself is not retransmitted.

As with TCP's advertised receiver window, QUIC contains a mechanism to enable a QUIC receiver to control the maximum amount of data that a sender can send on an individual stream, and the maximum amount on all streams at any time. Also, as with TCP, QUIC does not specify the flow-control algorithm to be used by reliable streams, although one such sender-side congestion controller is defined in [6]. This algorithm is similar to TCP's *New Reno*^[7].

We now examine some problems with QUIC.

RPC Support

IP hosts commonly support just two transport services, UDP and TCP. UDP is a simple datagram-delivery service. Data encapsulated using UDP have no assured delivery. TCP, as we have seen, is a reliable streaming service. The TCP protocol repairs any packet loss or changes to the delivered packet sequence.

Another model, namely the *Remote Procedure Call* (RPC) model, emulates the functionality of procedure calls, and rather than the byte-stream model of TCP or the datagram model of UDP, the RPC model is a reliable request/reply model, where the reply is uniquely associated with the request. Perhaps the most well-known example today of an RPC framework is *gRPC*^[8]. *gRPC* is based on an HTTP/2 platform, implying that the framework is susceptible to head-of-line blocking as with any other TCP-based substrate.

The issue here is that a reliable byte stream is not the right abstraction for RPC, as the core of RPC is a request/reply paradigm, which is more aligned to a reliable messaging paradigm, with all that such a paradigm entails. A capable RPC framework needs to handle lost, mis-ordered, and duplicated messages, with an identifier space that can match requests and responses. The underlying message transport needs to handle messages of arbitrary size, which entails packetization adaptation within the transport.

The bidirectional stream framework is a reasonable match to the RPC communications model where each RPC can be matched against an individual stream. The stream is reliable and sequenced. The data framing is not contained in QUIC, and it is still an application task to add a record structure to an RPC stream, if that is what is required. The invocation overhead is low in that the encrypted end-to-end connection is already established.

It certainly appears that HTTPS behaves much more like RPC than a reliable byte stream. That can benefit applications that run over HTTP(S), such as *gRPC*, and a set of *Representational State Transfer* (REST)ful APIs.

Load-Balancing QUIC

In today's world of managing scale, it is very common to place a front-end load balancer across many servers. The load balancer in the TCP world typically categorizes packets as being in the same TCP session because of a common 5-tuple value of protocol, IP addresses, and port numbers, with the confident assurance that this value is stable for the life of the TCP session.

QUIC offers no such assurances. The 5-tuple load-balancing approach can work, but if the client is behind a NAT that performs what could be called "aggressive" rebinding, then any such load-balancing approach will be thrown. The reason why is that UDP does not provide session signalling to a NAT, so there is no a priori assurance that the NAT bindings (and the presented source address and port) will remain constant for the entire QUIC session.

Now in theory IPv6 could invoke the *Flow-ID* to provide a proxy persistent field that remains constant for a flow, but the Flow-ID is of limited size and has no assurances of uniqueness, as well as evidence of highly variable treatment by IPv6 network infrastructure and end hosts.

This topic touches upon a major assumption in today's high-capacity server infrastructure on the public Internet. Data streams use TCP and the DNS uses UDP. Using UDP to carry sustained high-volume streams may not match the internal optimisations used in server content-delivery networks.

DDoS Defence

The next issue here is exposure to *Distributed Denial-of-Service* (DDoS) attacks. An attacker can send a large volume of packets to the server and cause the server to perform work to attempt to decrypt the packet. For this capability to be successful in TLS over TCP the attacker must make a reasonable guess of the TCP sequence number and window size for the packet to be accepted and passed to the TLS decoder. QUIC has no lightweight packet filter before the decoder is invoked.

On the other hand, the session encryption uses symmetric crypto algorithms, which are less of a load on the receiver to decode than asymmetric encryption. Is this difference enough to allow large-scale QUIC platforms that are DDoS resistant to be constructed? I'm unsure if there are clear answers here, but it seems that it's part of the cost of having a more complete encryption framework, which in itself appears to be sorely needed on the public Internet.

Private QUIC

For private contexts, can QUIC negotiate a “null” TLS encryption algorithm? There is a bigger world out there beyond the public Internet, and in many private data centre environments the overheads of encrypting and decrypting packets may appear to be unnecessary. While QUIC can present some clear advantages in terms of suitability to complex application behaviours in the data centre that can leverage QUIC's multi-stream capability, the cost of encryption may be too high.

Of course, there is nothing stopping an implementation using a null encryption algorithm, but such an implementation could talk only to other implementations of itself. Strictly speaking, if you remove encryption, then it's no longer QUIC and it won't interoperate with anything else that is QUIC.

QUIC and OpenSSL

It is useful to ask that if QUIC has such clear advantages over TCP, then why hasn't the adoption of QUIC been rapid? Metrics of QUIC use tend to point to a use rate of some 30% of web sessions (such as Cloudflare's Radar report^[9]).

However, if you alter the measurement to measure the extent to which browsers on end systems are capable of supporting a QUIC session, then the measurement jumps to 60%^[10].

There are a couple of reasons why QUIC use is far lower than QUIC capability. The first is that the Chrome browser still relies on the content-level switch to QUIC, so the client has to visit the site for the first time using HTTP/2 (TCP/TLS) and thereby receive an indication if the server can support QUIC, and then on the second visit the client may use QUIC. It's not quite as simple as this, as HTTP/2 uses persistent connection, so if the second visit is sufficiently close in time to the first, then the HTTP/2 session will remain open and still be used. The Safari browser is capable of using QUIC on first use because it is triggered by the *Service Binding* (SVCB) record in the DNS, but the market share of Safari is relatively small in comparison to QUIC.

The second reason lies in the web server environment. Many servers rely on the *OpenSSL* TLS library^[11], and so far, (November 2022) *OpenSSL* does not include support for QUIC. QUIC is supported in *BoringSSL*^[12], but as the notes for *BoringSSL* state, *BoringSSL* is a fork of *OpenSSL* that is designed to meet Google's needs, and while it works for Google, it may not work for everyone else. Google does not recommend that third parties depend on *BoringSSL*. There is also *QuicTLS*, a fork of *OpenSSL* that Akamai and Google support^[13]. This fragmentation of *OpenSSL* is not exactly helpful, and the result is that many server environments are waiting for *OpenSSL* to incorporate a QUIC library. This effort was delayed by the work on *OpenSSL* release 3.0.0, and then the *OpenSSL* folks announced their intention to provide a fully functional QUIC implementation, and this development of a new QUIC protocol stack may further delay QUIC support in *OpenSSL* by months, if not years. This impediment may well be the major one behind the very large-scale deployment of QUIC in the guise of HTTP/3 across the Internet.

Conclusions

We can draw a few conclusions from this effort with QUIC:

Any useful public communications medium needs to safeguard the privacy and integrity of the communications that it carries. The time when open protocols represented an acceptable compromise between efficiency, speed, and privacy are over, and these days all network transactions in the public Internet need to be protected by adequate encryption. The QUIC model of wrapping a set of transactions between a client and a server in a single encryption state represents a sensible design decision.

Encryption is no longer an expensive luxury, but a required component for all transactions over the public Internet. The added imposition is that adding encryption into a network transaction should impose no additional performance penalty in terms of speed and responsiveness.

Network transactions come in many forms, and TCP and UDP tend to represent two ends of a relatively broad spectrum. UDP is just too susceptible to abuse, so we've heaped everything onto TCP. The problem is TCP was designed as an efficient single streaming protocol, and retro-fitting multiple sessions, short transactions, shared congestion state, and shared encryption state have proved to be extremely challenging.

Applications are now dominant in the Internet ecosystem, while platforms and networks are being commoditised. We are seeing users losing patience with platforms that provide common transport services for the application that they host, and a new model where the application comes with its own transport service. This model is not just the HTTP client/server model; it has been extended into application-specific *Domain Name System* (DNS) name resolution with DNS over HTTPS. It's highly likely that this trend will continue for the moment.

Taking an even broader perspective, the context of the Internet's success lies in shifting the responsibility for providing service from the network to the end system. This shift allowed us to make more efficient use of the common network substrate and push the cost of this packetization of network transactions over to end systems. It shifted the innovation role from the large and lumbering telco operators into the more nimble world of platform software. The success of Microsoft with its Windows product was not an accident by any means. QUIC takes this success one step further, and pushes the innovation role from platforms to applications, just at the time when platforms are declining in relative importance within the ecosystem. From such a perspective, the emergence of an application-centric transport model that provides faster services and a larger repertoire of transport models, the encompassing of comprehensive encryption was an inevitable development.

Minimized DNS Resolution: Into the Penumbra

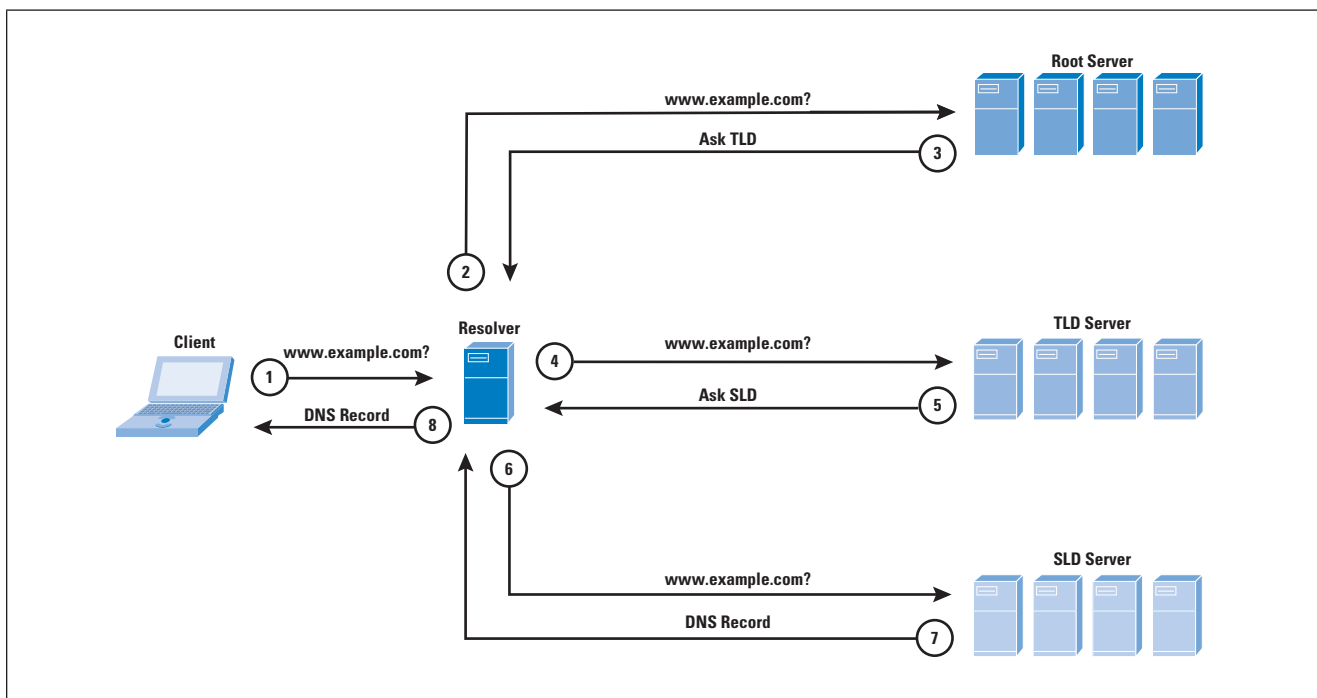

by Burton S. Kaliski Jr., Verisign

The *Domain Name System* (DNS) has long followed a traditional approach of answering queries, where resolvers send a query with the same fully qualified domain name to each name server in a chain of referrals, and, generally, apply the final answer they receive only to the domain name that was queried for. Motivated by interest in reducing both the quantity and sensitivity of information exchanged between DNS ecosystem components, DNS operators are now starting to deploy various minimization techniques that either put less information into queries or take more information out of answers, thereby reducing the need for additional queries. This article reviews four minimization techniques documented by the *Internet Engineering Task Force* (IETF), reports on their implementation status, and discusses the effects of their adoption on DNS measurement research.

DNS resolution begins with the usual occurrence that happens millions of times a second around the world: a client sends a DNS recursive resolver a query like “What is **www.example.com**’s *Internet Protocol* (IP) address?” The resolver answers, “**www.example.com**’s IP address is **93.184.216.34**.”

Many clients may use the same resolver, so the resolver may already have a response to the query in its cache. If the resolver has an empty cache, it will interact with the authoritative name-server system using a protocol flow such as shown in Figure 1.

Figure 1:Textbook DNS Resolution

1. The client asks the resolver, “What is **www.example.com**’s IP address?”
2. The resolver queries one of the DNS’s 13 root servers^[1] for an answer to question 1.
3. The root server responds with a referral-type response directing the resolver to the name server for the *Top-Level Domain* (TLD) in the query name, that is, the **.com** name server.
4. The resolver sends the query to the TLD server.
5. The TLD server refers the resolver to the name server for the *Second-Level Domain* (SLD), that is, the **example.com** name server.
6. The resolver sends the query to the SLD server.
7. The SLD server returns one or more DNS records that specify **www.example.com**’s IP address.
8. The resolver relays the DNS records to the client.

The referrals in steps 3 and 5 are a result of the delegation structure of DNS. The root zone has delegated the authority for responding to queries for domain names within existing TLDs to TLD servers. Many TLD zones have similarly delegated the authority for responding to queries within SLDs to SLD servers. In step 7, the SLD server has the authority to respond for the domain name **www.example.com**.

The DNS standard (based on RFC 1035^[2] and other documents)—as well as current practice—include many more details. For purposes of this article, the “textbook DNS” described here is an effective starting point, but two additional details may be helpful in framing the techniques that follow:

- If a name server knows that a domain name doesn’t exist, then it returns the negative response code (rcode 3), typically referred to as NXDOMAIN. (Otherwise, either the domain name exists and the name server is authoritative for it and returns a positive answer along with rcode 0; or the name server is not authoritative and returns a *referral*.)
- If a resolver and a name server implement the *Domain Name System Security Extensions* (DNSSEC)^[3], the resolver asks the name server to include DNSSEC information in its response, and if the domain name doesn’t exist, then the name server also returns an NSEC^[4] or NSEC3^[5] record that specifies two endpoints between which no other domain names exist, for some ordering of domain names. With NSEC, the ordering is based on the domain names themselves; with NSEC3, it’s based on their hash values. Either way, the resolver receives information demonstrating not only that the queried name doesn’t exist, but also that *other* domain names between the endpoints don’t exist.

(The records are formed this way so that they can be precomputed and signed when the name server is provisioned, based on domain names that do exist in a zone. The name server then already has the information it needs to respond to a query for a nonexistent domain name, without having to sign responses in real time, although some name servers do support dynamic signing.)

It's clear from a brief review of Figure 1 that textbook DNS resolution includes more information in DNS exchanges than necessary. This fact is particularly evident on the resolver-to-root exchange, where the resolver queries for a fully qualified domain name, yet the root server responds with a referral involving just the TLD. But the observation holds at other levels as well.

Forwarding fully qualified domain names may have historically simplified implementation, in that the resolver either gets the answer to a query from its cache, or it forwards the same query to a succession of name servers. This practice also minimizes the depth of the iterative resolution process, because the query includes enough information for each name server either to refer the resolver to another name server, or to answer the query itself (if the query wasn't fully qualified, then a name server might respond with a referral to itself in some cases, an unnecessary extra step). However, the textbook approach doesn't leverage all information available to the resolver, either from DNS or from other sources. Indeed, a fully qualified domain name, while convenient from an implementation perspective, may include more information than the name server needs to know.^[6]

Minimized DNS Resolution

Minimized DNS resolution encompasses an emerging set of techniques that bring the resolver-to-authoritative traffic closer to the need-to-know principle, while still facilitating DNS resolution. Four such techniques have received the most attention, each reducing the quantity and/or sensitivity of information exchanged between resolvers and authoritative name servers in a different way. Documented by the IETF's *DNS Operations* (DNSOP) working group, the techniques include:

- Query Name (or qname) Minimization, described in RFC 9156^[7];
- NXDOMAIN Cut Processing, described in RFC 8020^[8];
- Aggressive DNSSEC Caching, described in RFC 8198^[9]; and
- Local Root (sometimes called “hyperlocal”) and other locally served zones, described (in the case of the root zone) in RFC 8806^[10].

Important from an operational perspective, all four can generally be applied by a resolver on its own, without any coordinated changes by authoritative name servers, other than the participating name server conforming with previous DNS specifications. (The locally served zones technique requires that the zone data be made available.)

RFC 8932, produced by the IETF's *DNS Private Exchange* (DPRIVE) working group, encourages implementation of all four techniques to reduce both the quantity and sensitivity of “data sent onwards from the [recursive resolver] server”^[11]. (DPRIVE and other IETF working groups have also developed specifications for DNS encryption, but they are outside the scope of this article.)

The techniques can generally be adopted for interactions between resolvers and authoritative name servers for any zone. (They don't apply to the client-resolver exchange.) They are particularly beneficial for interactions with the root and TLD servers, for at least two reasons:

1. The primary purpose of the root and TLD servers is global navigational availability: referring requesters to other name servers that are actually authoritative for a response. A fully qualified domain name (or even a full set of queries) is therefore not generally needed at these servers, only enough information to make the referral, making minimization techniques appropriate options. But high-availability service is paramount, favoring techniques with low operational risk.
2. Because of the recursive, cached architecture of DNS, the sensitivity of the traffic on these exchanges is already relatively low compared to other parts of the DNS ecosystem, such as the client-to-resolver exchange. In particular, because the resolver is between the client and the authoritative name servers, its queries to the authoritative name server conceal the client's identity and instead represent aggregate interests of clients. (Moreover, although information about the client's IP address may be conveyed in a query via the “client subnet” option^[12], it is specifically recommended that this extension not be included in queries to the root and TLD servers.) Minimization techniques can therefore arguably lower the sensitivity of the information on the resolver-to-root and -TLD exchanges sufficiently that techniques with higher operational risk such as DNS encryption become questionable from a cost-benefit perspective, compared to disclosure risks on other exchanges such as client-to-resolver^[13].

Minimization techniques also can improve resolver performance, given that they enable a resolver to answer more queries on its own, and thereby respond more quickly. They can likewise improve performance for name servers, which will receive less unnecessary traffic—including attack traffic that might have leveraged a resolver as an intermediary. And as minimized traffic becomes the “new normal” on these exchanges, it may become easier for name servers to detect and deflect other types of attack traffic, which will become more “abnormal.”

Even if a resolver implements DNS encryption, it still makes sense for the resolver to implement minimization techniques to reduce the amount of information disclosed to name-server operators.

Minimization opens a new chapter in DNS resolution. With the new techniques, the traditional DNS resolution process is updated with a new approach optimized for the global DNS as it exists today, balancing confidentiality and availability objectives. The first minimization technique is perhaps the most fundamental, as it changes the most apparent nonminimized feature of textbook DNS: sending the fully qualified domain name to each name server in the chain of referrals. Note: In 2015, Verisign announced a royalty-free license to its qname minimization patents in connection with certain IETF standardization efforts. For more information, refer to IETF IPR disclosure 5197.

Query Name (Qname) Minimization

It is just a “tradition” that resolvers send the fully qualified domain name at each level of the DNS hierarchy, not a requirement of the DNS specifications. In the words of RFC 9156 (first reported by Stéphane Bortzmeyer in RFC 7816^[14]), the tradition is motivated by an early goal of minimizing the number of queries that might need to be made:

In a conversation with the author in January 2015, Paul Mockapetris explained that this tradition comes from a desire to optimise the number of requests, when the same name server is authoritative for many zones in a given name (something that was more common in the old days, where the same name servers served `.com` and the root) or when the same name server is both recursive and authoritative (something that is strongly discouraged now).

This practice, as discussed previously, can also optimize the number of requests when a name server is authoritative for only one zone.

The consequence of the tradition is that the resolver included more information than necessary in each query. Although the risk of disclosure of sensitive information on the resolver-to-root and -TLD exchanges is relatively low, as discussed previously, it would be better, per the principle of minimum disclosure, to send only as many labels as the name server needs to make a referral. Any labels beyond that point are extraneous information.

One way to reduce the amount of information disclosed is to remove one or more of the extraneous labels. In this “omitted-label” approach to reducing the amount of information included in a query to an authoritative name server, the query name `www.example.com` in the request to the root server could be replaced simply with the TLD, that is, with `.com`.

Another way is to replace one or more of the extraneous labels with random or other alternative labels. As examples of a “false-label” approach, we could replace `www.example.com` with `<r3>.<r2>.com` or with `<r2>.com`, where `<r2>` and `<r3>` are randomly generated labels. Another real-world qname minimization technique suggested replaces `www.example.com` with `_example.com`.^[7]

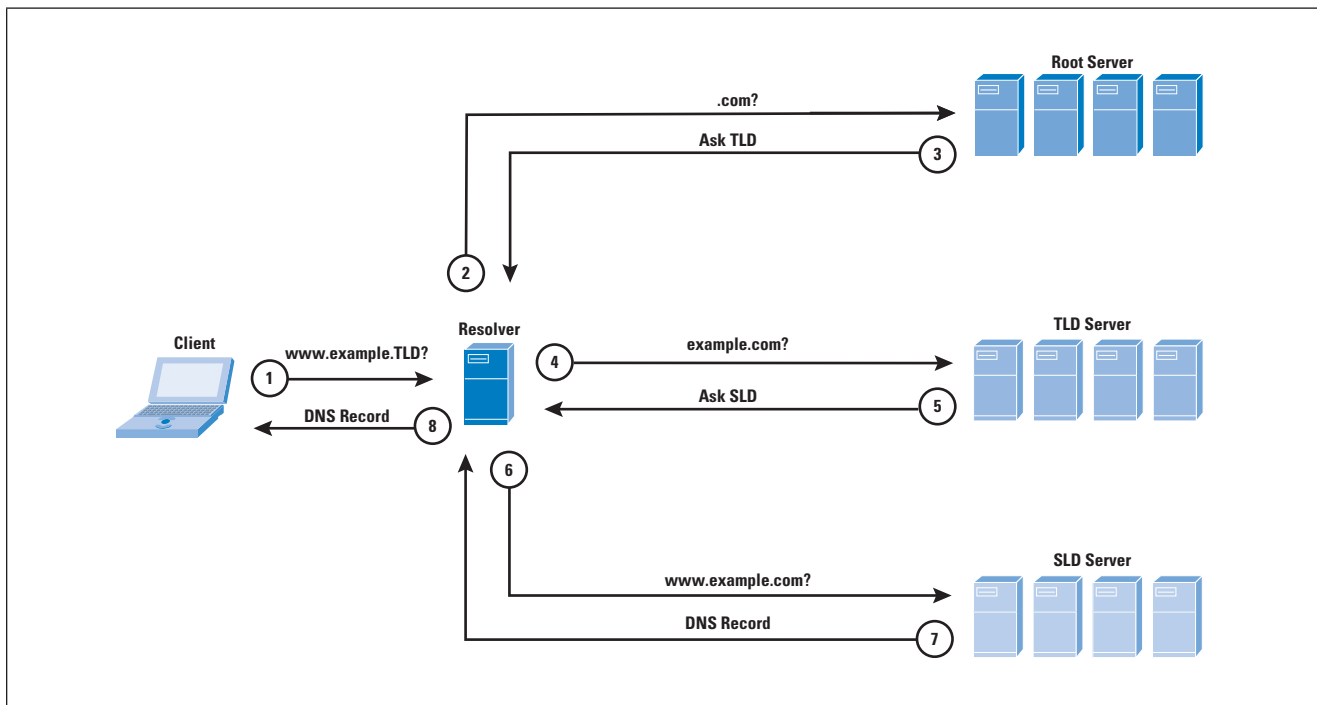

The RFC adopts the omitted-label approach for *query name* (or *qname*) minimization (or as it is spelled in the RFC, “minimisation”).

A resolver implementing *qname* minimization, as described in RFC 9156, takes advantage of information about how the DNS hierarchy is organized today at its higher, navigational levels, such as the root server delegating authority for existing TLDs to TLD servers, and typical TLD servers delegating authority for existing SLDs to SLD servers. As shown in Figure 2, when the resolver queries the root server as part of resolving a domain name, it sends only the TLD label to the root server. When it queries the TLD server, it sends only the SLD and TLD labels. It can also take advantage of the knowledge that some TLD servers delegate authority for some of their hierarchy at the third level rather than the second level, as discussed previously, thereby saving a step in those cases. The *Public Suffix List* (PSL)^[15] is a potential source for information about where these delegations or zone cuts may occur, as Geoff Huston has observed^[16].

In addition to replacing or removing labels, the resolver can also change the *Query Type* (QTYPE) from the one the client requested, to further reduce the amount of information disclosed. RFC 9156 recommends setting the QTYPE to “A” or “AAAA” regardless of the actual record type of interest, except for the final query with the full query name.

A resolver can apply *qname* minimization to its interactions with any authoritative name server at any level of the DNS hierarchy, and the name server won’t have to do anything differently. The name server will just receive queries with less information in them, except for the final name server in the chain.

Figure 2: DNS Resolution with *qname* Minimization

Qname minimization therefore provides a valuable information protection tool for both resolver operators and their users. Indeed, as Basileal Imana, Aleksandra Korolova, and John Heidemann state in their study of institutional privacy risks, “The currently available best way for institutions to reduce information leakage is to run their own resolver, and deploy query name minimization”.^[17]

Resolver operators have encountered one complication in deploying qname minimization: the *Empty Non-Terminal (ENT) Problem*, as described in RFC 7816^[14]. The problem can cause a resolver to continue to send queries during the minimized iterative resolution process, even after it should have become clear that the fully qualified domain name doesn’t exist. Retrying with the fully qualified domain name in the presence of ENTs wouldn’t disclose more information than the resolver would have been sent with traditional DNS resolution, but it would generate unnecessary additional queries. While it has become common practice simply to stop qname minimization after three labels, the underlying ENT problem remains. Resolving this complication is the focus of the next technique.

NXDOMAIN Cut Processing

NXDOMAIN, the negative answer in DNS, technically means that a domain name doesn’t exist—and therefore, by definition, that it has no subdomains.

However, because of the ENT ambiguity just mentioned, resolvers have traditionally limited their interpretation of NXDOMAIN to the domain name itself. This tradition has resulted in both additional workload for the resolver and extra traffic to the name-server system.

NXDOMAIN cut processing, described in RFC 8020^[8], expands the interpretation. As the title of the RFC states, a resolver implementing this technique interprets NXDOMAIN as “there really is nothing underneath;” the DNS tree is “cut.” In support, the RFC, authored by Stéphane Bortzmeyer and Shumon Huque, updates the DNS specifications to state that a name server must return NODATA in response to a query for an ENT, thereby resolving the ENT ambiguity.

Similar to qname minimization, a resolver can apply NXDOMAIN cut processing to its interactions with any authoritative name server. The name server doesn’t have to do anything differently as long as it handles ENT queries correctly. It will just receive less traffic.

With the root zone not having any ENTs, and with careful consideration given to the risks of ENTs in TLD zones^[18], it’s reasonable for resolvers to implement NXDOMAIN cut processing at the root and TLD levels of the DNS hierarchy, consistent with the deployment of qname minimization at those levels. Processing for additional zones can be enabled as resolver operators gain more confidence in the corresponding name servers’ handling of ENTs.

Or resolvers could simply adopt the technique unilaterally, regardless of the name server's behavior, a decision endorsed by RFC 8020:

“Such name servers are definitely wrong and have always been. Their behaviour is incompatible with DNSSEC. Given the advantages of ‘NXDOMAIN cut,’ there is little reason to support this behavior.”

NXDOMAIN cut processing helps qname minimization by enabling a resolver to stop the minimized iterative resolution process as soon as it receives an NXDOMAIN answer, meaning that the resolver will disclose less information in its traffic when a domain name doesn't exist, just as it discloses less when a domain name does exist. The combination of the two techniques can also be effective in defending against certain attacks, such as random subdomain attacks, where an adversary queries one or more resolvers for random subdomains of a common ancestor. With traditional processing, the resolvers will forward the subdomain queries to the ancestor's name server, generating a volumetric attack where the name server can't see the attack's original source. If the ancestor exists and is protected by DNSSEC, then aggressive DNSSEC caching can help a resolver reduce the number of additional subdomain queries that it forwards, as described by Petr Špaček.^[19] If the ancestor doesn't exist, then NXDOMAIN cut processing can keep the resolver from forwarding further subdomain queries after it knows that the ancestor doesn't exist.

With NXDOMAIN cut processing, a resolver broadens its interpretation of a negative answer to draw conclusions about subdomains of a domain name that it previously queried for. The next technique does something similar for negative answers in the DNSSEC case, drawing conclusions about other domain names in the zone as well.

Aggressive DNSSEC Caching

As discussed previously, negative answers in DNSSEC—in the form of NSEC and NSEC3 records—indicate that no domain names exist between two endpoints in some ordering of domain names. (One further detail: with the opt-out flag set in NSEC3, some domain names between the endpoints may actually exist, but not have DNSSEC-signed delegations. If a resolver is interested only in domain names that can be validated with DNSSEC, then the NSEC3 record is still useful information.)

Resolvers traditionally haven't taken advantage of the information these records provided about the nonexistence of other names, however.

Even though NSEC and NSEC3 records provide enough information for a resolver to conclude on its own that other domain names between the endpoints don't exist, resolvers have traditionally limited their interpretation to the domain name that was queried for.

Although authoritative name servers return NSEC or NSEC3 records in response to queries for both nonexistent domain names and ENTs, it's possible to tell the two classes apart, as detailed in Appendix B of RFC 8198^[9] for NSEC and in Sections 8.4–8.8 of RFC 5155^[5] for NSEC3.

The narrow interpretation is actually the correct one according to the original DNS specifications, not the result of an ambiguity as it was for the previous technique. RFC 4035^[3] describes the limitation as a “prudent” approach:

“In theory, a resolver could use wildcard or NSEC RRs to generate positive and negative responses (respectively) until the TTL or signatures on the records in question expire. However, it seems prudent for resolvers to avoid blocking new authoritative data or synthesizing new data on their own. Resolvers that follow this recommendation will have a more consistent view of the namespace.”

The limitation may once again result in the resolver doing more processing and sending more queries than it needs to, given the information it already has on hand.

Aggressive DNSSEC caching, described in RFC 8198^[9], takes a broader interpretation. The RFC, authored by Kazunori Fujiwara, Akira Kato, and Warren Kumari, updates the DNS specifications to state that a resolver may handle client queries for domain names that fall between the endpoints of previously received NSEC and NSEC3 records on its own. (It also allows the resolver to apply wildcard records to names between the endpoints when matching wildcard records exist.)

The technique offers an excellent illustration of the relative nature of the minimum disclosure principle, and it also improves the resolver's protection against random subdomain attacks as detailed in the previous section. Without DNSSEC, a resolver would need a name server's help for each new domain name it processes that's not a subdomain of a nonexistent domain. With DNSSEC, the resolver no longer needs as much help, so the threshold for minimum disclosure is reduced.

Similar to the two previous techniques, a resolver can apply aggressive DNSSEC caching to its interactions with any name server at any level. The name server again doesn't have a direct operational role and will just receive less traffic. The name server must handle NSEC or NSEC3 correctly, which is less of a concern than for NXDOMAIN and ENTs, given that the DNSSEC accounts for ENs.

The foregoing has three caveats:

First, as mentioned already, if an NSEC3 record has an opt-out flag, the resolver can't conclude that other domain names between the endpoints don't exist, only that they don't have secure delegations.

It therefore can't apply aggressive DNSSEC caching to such a record. Given that NSEC3 is the predominant choice for TLDs, and that the opt-out flag is commonly used^[20], aggressive DNSSEC caching will generally not help at the TLD level.

Second, the reduction in the number of queries sent assumes that the NSEC or NSEC3 endpoints actually span multiple domain names. Both techniques have variants, documented in RFC 4470^[20] and RFC 7129^[21], where the returned endpoints effectively span only the one domain name of interest, taking away the advantage of aggressive DNSSEC caching. Moreover, some implementations of these variants incorrectly report that some resource record types don't exist, possibly resulting in a resource record becoming unresolvable.^[22, 23] The "aggressive" interpretation of negative DNSSEC responses makes implementation errors more consequential as well.^[24]

Third, as Geoff Huston has observed,^[25] "the results [of aggressive DNSSEC caching] may not be that promising" for resolvers that load-balance their queries into servers with independent caches, for example, based on a hash of the query name.

These caveats aside, if the resolver were somehow to cache every NSEC or NSEC3 record in a pre-signed zone, and if there were no NSEC3 opt-outs, and if the ranges within the records collectively spanned the entire zone, then the resolver would be able to handle queries for every nonexistent domain name in the zone on its own, for as long as the records were valid.

If the resolver likewise were to cache every existing DNS record in the zone, then it could handle queries for existing domain names too.

A resolver might be able to bring all of these records into its cache if the set of queries it sends is directed, at least in part, by a carefully designed process. Using aggressive DNSSEC caching, the resolver will cache the NSEC record as evidence that domain names between the endpoints don't exist. In addition, it can cache the record as evidence that the two domain names at the endpoints do exist. Then the resolver can simply query for the DS and NS records for the two domain names at the endpoint, and it will have obtained the full DNS records for the two endpoints from this zone file. The resolver can repeat the process with other random long domain names until it has obtained a set of NSEC records that collectively span the zone. After sending queries for the zone's own DNSKEY, NS, and SOA records, the resolver will have obtained all the DNS records in the zone file. If the resolver implements NXDOMAIN cut processing and aggressive DNSSEC caching, it will then be able to answer client queries for every domain name without making further queries to the zone's authoritative name server. This process does not work well for NSEC3 and NSEC5.^[26, 27] By populating the resolver's cache in this way, the client would remove its own and other clients' interests in domain names from future resolver-to-authoritative queries.

But if the resolver just wants to avoid sending queries to a remote name server for a zone entirely, the next technique offers a more direct way to achieve the goal if the zone is appropriately configured.

Locally Served Zones

The DNS resolution processes shown in Figures 1 and 2 maintain a clear distinction between DNS ecosystem components: the client is separate from the resolver, which in turn is separate from the authoritative name servers. The separation implies a potentially global communications path between components, leading to the information disclosure concerns that have been the focus of this article.

But what if the communications path between two components was instead a local one? Such locality would not be unprecedented. Indeed, the resolver is often located within the same network as the client, which as discussed previously was one of the reasons for the relatively late standardization of an encrypted DNS protocol for the client-to-resolver exchange. An authoritative name-server instance can similarly be located within the same network as the resolver, as long as it can somehow be provisioned with a current copy of the zone file.

RFC 8806^[10], authored by Warren Kumari and Paul Hoffman, describes how to run a local instance of authoritative zone data with two constraints. First, the specification is limited to the root zone. Second, the local instance must indeed be run locally: that is, it must be accessible only to the resolver, and therefore not visible to other servers on the network. (Deploying the local instance at a loopback address, as proposed in the title to RFC 7706^[28], the predecessor to RFC 8806, is one way to ensure locality.)

ICANN's CTO organization describes the local root technique as "hyperlocal," and its OCTO-016 technical note^[29] proposes the technique as a way to "[improve] the decentralization of the root name service to mitigate risks that the [Root Server System] may face over time."

While OCTO-016 focuses on improving decentralization, and RFC 7706, per its title, on decreasing access time, it's also clear that the locally served zones technique also reduces the amount of information disclosed on the resolver-to-authoritative exchange. Indeed, RFC 8806 states that in addition to decreasing access time (particularly for negative responses), another goal of the technique is "to prevent queries and responses from being visible on the network."

A resolver can in principle get a copy of a zone file just like an authoritative name server might, via a zone-transfer protocol such as *Authoritative Transfer* (AXFR), described in RFC 5936^[30], and *Incremental Transfer* (IXFR), described in RFC 1995^[31]. These protocols give options for downloading a full zone file and for obtaining incremental updates respectively and may be enabled by a name server, depending on zone policy.

An encrypted version of these protocols, called *XFR-over-TLS* (XoT), is currently in development^[32]. Another alternative is for the zone data to be made available for download at a web address via the *Hypertext Transfer Protocol Secure* (HTTPS) protocol. For instance, ISI's *LocalRoot* project^[33] provides access to copies of the root zone, as well as the **.arpa**, **root-servers.net** and **dnssec-tools.org** zones.

In addition, the new ZONEMD record, described in RFC 8976^[34], provides a way to authenticate the integrity of a downloaded zone file (in contrast to DNSSEC, which authenticates individual sets of records).

Locally served zones and zone digests are more practical for small, slowly changing zones, such as the root zone, than for large, fast-changing ones. RFC 8976 states:

“ZONEMD is impractical for large, dynamic zones due to the time and resources required for digest calculation.”

The locally served zones technique, like others in this article, is another one that a resolver can apply to any zone at any level, in this case as long as zone data is made available for download. Its operational characteristics are similar to the other techniques: the name server doesn't need to do anything differently; the changes are all on the resolver's side (in terms of the resolution protocol); and the name server will receive less traffic (in this case, no traffic). The zone operator will need to provide a zone-transfer service, but this change is in provisioning, rather than resolution.

The technique does come with one significant caveat. The traditional DNS architecture with its resolver-to-authoritative exchanges has been optimized for the case where the operator for a zone is aware (or in the case of the root server, the multiple operators are collectively aware) of all of the name servers that are serving the zone. The operator(s) are therefore in a position where they can potentially check the consistency of the zone file information served by all these servers.

Until new mechanisms for synchronization are in place, locally served zone instances would fall outside a typical zone operator's awareness and ability to check consistency. OCTO-016 recognizes the need for additional work in stating:

“If hyperlocal were to see a significant uptake, a new system for root zone distribution would need to be devised to satisfy the reliability and scalability requirements associated with the widespread hyperlocal deployment in recursive resolvers.”

A system with these characteristics will be important if and when resolvers do adopt the locally served zones technique more broadly. But in the meantime, for resolvers that implement locally served zones, the technique will achieve the ultimate in minimum disclosure of information about client interests in domain names in the zone. The traditional resolver-to-authoritative exchange for these zones will have no conventional DNS queries at all.

Implementation Status

The minimization techniques described in the previous four sections are gradually being implemented and deployed in the DNS ecosystem. The following is a sampling of support by selected resolver operators and open source resolvers as of this writing.

A note on methodology: The distributed DNS ecosystem has tens of millions of resolvers^[35]. The ones referenced here are based on the list of “major Open DNS resolvers” in Huston’s qname minimization deployment study^[36], plus those in Mozilla’s *Trusted Recursive Resolver* (TRR) program^[37]. The determination of whether a resolver supports a technique is based primarily on public announcements. However, Huston’s study is also cited as likely evidence of qname minimization support. The open source resolver packages considered match the list included in Wouter de Vries et al.’s paper on qname minimization.^[38]

Qname Minimization

Qname minimization is included in the BIND^[39], *Knot Resolver*^[40], *PowerDNS*^[41], and *Unbound*^[42] open source resolver software packages. Cisco *Umbrella*^[43], Cloudflare’s 1.1.1.1^[44], Comcast’s *Xfinity Internet Service*^[45] (by virtue of its inclusion in Mozilla’s TRR program, which requires the capability), *Google Public DNS* (as related by Moura *et al.*^[46]), and *NextDNS*^[47] have all announced that they have implemented qname minimization. Google Public DNS has also reported that it uses a “nonce prefixes” technique where extraneous labels are replaced with a random label, an example of the “false-label” approach mentioned previously.^[48]

In addition, *dnswatch*, *dyn Recursive DNS*, *Quad9*, Neustar *Ultra-DNS Public*, and *Hurricane Electric* (HE) resolvers have been observed in Huston’s study as likely to be supporting qname minimization. The deployment of qname minimization has also been the subject of Internet measurement studies. De Vries observed that as early as April 2017, “0.9% (82 of 9,611) of RIPE Atlas probes had at least one [qname-minimizing] resolver,” and by October 2018, the percentage had grown to 11.7%.^[49] As of August 2021, NLnet Labs’ measurement dashboard showed that 47.8% of such probes interact with a qname-minimizing resolver.^[50]

Huston reported that as of mid-2020, “some 18% of users pass their queries through resolvers that actively work to minimize the extent of leakage of superfluous information in DNS queries,” adding that the percentage had increased from 3% since a year prior. Huston later clarified that the percentages likely underestimate actual adoption because the study’s active DNS measurement technique uses four-label client queries. Many resolver implementations of qname minimization revert to ordinary DNS resolution after three labels, potentially making the particular measurement technique undetectable by the study’s test servers.^[51]

In the same timeframe, according to research published by Matt Thomas,^[52] nearly half of all queries received by the **.com** and **.net** TLD servers consisted of only two labels.

The comparable percentage two years prior was 30%. The increase in two-label queries was accompanied by a similar decrease in three-label queries and thus can be taken as an indicator that qname minimization is being deployed at many resolvers. The upward trend has continued, reportedly reaching 55% as of February 2021.^[53] It should be noted, however, that many factors contribute to the composition of traffic to authoritative name servers, and the fraction of queries that have a certain number of labels may not be directly reflective of the fraction of resolvers that support qname minimization, nor with the fraction of users who interact with such resolvers.

NXDOMAIN Cut Processing

Knot Resolver,^[54] PowerDNS,^[55] and Unbound^[56] all support NXDOMAIN cut processing. BIND lists the technique as supported but made obsolete by Aggressive DNSSEC Caching.^[57] No announcements by recursive DNS operators have been found as of this writing. However, it is likely that many do support the technique, given that, as discussed previously, NXDOMAIN cut processing is not a new feature but rather the lack of accommodation for an old bug.

Aggressive DNSSEC Caching

Aggressive DNSSEC caching is included in BIND^[58], Knot Resolver^[59], PowerDNS^[60], and Unbound.^[61, 62] Cloudflare has reported that it has implemented aggressive DNSSEC caching,^[44] as well as Google.^[63]

Hyperlocal Zones

BIND^[64], Knot Resolver^[65] (following a “pre-filling” technique that RFC 8806 reports is consistent with the RFC’s requirements, but which diverges from the technique specified in RFC 7706), and Unbound^[56] all support hyperlocal zones. No announcements by recursive DNS operators were found.

Impact on DNS Measurement Research

The resolver-authoritative exchange has historically given authoritative name servers at all levels of the DNS hierarchy insights into the domain names being queried by a resolver’s clients. While the recursive, cached architecture of the DNS ecosystem conceals the identity of the specific client that originated a query, the receipt of a fully qualified domain name by an authoritative name server nevertheless reveals that *some* client is interested in the name. With the traditional DNS resolution process, that information potentially reaches all levels, starting with root and TLD.

One of the studies facilitated by this information was the DNS community’s research into name collisions related to the introduction of new *generic TLDs* (gTLDs) to the global DNS.

Root-server traffic already had shown significant evidence that resolvers (and therefore clients) were making many queries for domain names in TLDs that were not part of the global DNS^[66]. The root servers had historically, and correctly, responded that such domain names didn't exist, leading clients to query for different domain names (or to give up). But if a new TLD were added to the global DNS, the root servers (together with other servers) might begin to respond positively to client queries for domain names in the TLD. That change might then cause legacy clients to connect, inadvertently, to new, external servers—a name collision.

Because root servers had information about non-existent TLDs of interest to clients, as well as fully qualified domain names, researchers were able to determine not only which new gTLDs were already being queried for, but also which domain names within those new gTLDs were being queried. One of the sources for this information was the *Day in the Life* (DITL) exercise run annually by the *DNS Operations Analysis and Research Center* (DNS-OARC)^[67]. Researchers also performed additional analysis based on their own data sources and reported findings at a workshop on name collisions^[68].

The insights from root-server query data led to the identification of various network and client configurations that might be at risk if a new gTLD were delegated. For example, researchers identified vulnerabilities related to the *Web Proxy Auto-Discovery Protocol* (WPAD)^[69, 70, 71]. Researchers also found an operating-system vulnerability that did not involve new gTLDs based on their review of root-server query data^[72]. Verisign later conducted an outreach program that mitigated a broad range of name collision risks, again drawing from the query data^[73].

It is quite possible that if the minimization techniques described in this article had been broadly adopted a decade ago, researchers would not have been as able to study name collision risks as effectively, at least based on analyzing root-server data. One of the co-discoverers of independent vulnerability, *simMachines*—co-discoverer of the bug—is quoted in a blog post on qname minimization^[6] as stating that the “analysis would have been partially impacted” if fully qualified domain names had not been visible in root-server traffic.

The loss of visibility is exactly what should be expected, inasmuch as the goal of each of the minimization techniques is to reduce root and TLD servers' visibility into clients' interests in domain names. Adoption of the techniques will impact DNS measurement research at root and TLD servers in different ways.

- Qname minimization and NXDOMAIN cut processing, which amplify one another, reduce root and TLD servers' visibility into the lower-level domains that a resolver (and by implication, its clients) may be interested in. As more resolvers adopt qname minimization with an omitted-label approach, the overall query traffic to the root servers will trend toward single labels, while the traffic to the TLD servers will trend toward two or three labels depending on the delegation structure.

If these techniques had been in place at a given resolver when the name collisions research was performed, the root-server data associated with this resolver would only have indicated the TLDs the resolver was interested in, not the fully qualified domain names. Potential collisions between legacy systems and new gTLDs might have been highlighted, but some of the detail that helped determine the reason for the query and the impact of a positive response may have been obscured.

- Aggressive DNSSEC caching similarly reduces root and TLD servers' visibility into a resolver's interests in non-existent domain names that happen to be between the NSEC or NSEC3 endpoints obtained in response to another recently queried non-existent domain name. If aggressive DNSSEC caching had been in place at a resolver during the name collisions research, the root-server data associated with the resolver may have provided only partial information about the non-existent TLDs the resolver and its clients were interested in. This limitation on visibility may also have made it harder to assess the degree of risk associated with a given new gTLD.
- Finally, hyperlocal zones reduce the visibility of a name server into a participating resolver's interests entirely. ICANN's CTO organization, in its technical analysis of the hyperlocal root-zone technique^[74], aptly summarizes the impact on telemetry as follows: "...one likely consequence of significant hyperlocal root service deployment will be a general decrease in knowledge about how the global DNS operates."

We could make similar observations about other observations and actions motivated by root-server data. For instance, Matt Thomas' and Duane Wessels' study of DNS traffic to the root generated by Chromium-based browsers^[75] depends on statistics about queries to the root servers for non-existent TLDs. While qname minimization would not affect the statistics (the queries are already a single label), aggressive DNSSEC caching might. And the "mysterious root query data"^[76] reported by Duane Wessels and Christian Huitema, which includes many query names consisting of random 12- and 13-character SLDs followed by existing TLDs, would not have been seen if the resolver(s) that sent the queries had implemented qname minimization with an omitted-label approach. (To be fair, initial community feedback^[77] attributes the data to a different approach to reducing the amount of information in queries to the root server: the "nonce prefixes" technique previously mentioned in connection with Google Public DNS^[48].)

As minimization techniques are applied to the resolver-to-root and -TLD exchanges, researchers will need to expand their use of data sets from other parts of the DNS ecosystem—appropriately anonymized and summarized for sharing—if they want to maintain a larger view of the types of queries that clients are making. There are already numerous approaches for sharing data outside the resolver-to-root and -TLD exchanges.

DNS-OARC already collects research data from other “busy and interesting DNS servers,” not just root servers. Passive DNS tools^[78] offer an alternative approach for analyzing DNS query traffic patterns at an ecosystem level. And query data specific to security vulnerabilities can be shared with general threat-indicator tools.

The resolver-to-root and -TLD exchanges themselves will likely still have interesting data for researchers as well. Indeed, studies of these exchanges will provide important insights into the deployment of minimization techniques, which will be a gradual process over many years. Such studies may give even more information about the configuration of individual resolvers than was previously available when resolver behavior was more uniform.

Researchers may also be able to infer statistical information about the resolver selections of certain client environments, by measuring how known changes in these environments are filtered through the resolvers of different configurations. One potentially fruitful area for such research: the new HTTPS resource record^[79]. The record is gradually being introduced with early support by Apple’s iOS 14 and macOS 11 operating-system betas^[80]. Clients that support the HTTPS record will typically make three queries to their resolver, for the A, AAAA, and HTTPS record types. Traditional resolvers will then forward queries of all three types to the root and TLD servers. But resolvers that implement qname minimization may send only minimized A type queries to get a referral to the server that is actually authoritative for all three. The presence of HTTPS queries on the resolver-to-root and -TLD exchanges for a given resolver will therefore be an indicator not only that the resolver likely isn’t yet applying qname minimization, but also that a portion of the clients that query for the HTTPS record type are using the resolver.

Just as minimization techniques represent a new chapter in DNS protocol evolution, they also will bring a new era in DNS measurement research. DNS resolution will still be taking place, although in different ways, and data analysis will still be possible, but with alternate arrangements. Such alternatives will likely depend more on active measurement techniques where clients send queries that are designed to be detectable even if minimized resolution is taking place. Both the practice and the study of DNS will go on.

Conclusion: Into the Penumbra

For the past few decades, as DNS resolution has followed the textbook DNS approach shown in Figure 1, DNS operators have had significant visibility into aggregate client interests in domain names. While the visibility, as noted earlier, has not included information about specific client identities, it has included fully qualified domain names, forwarded to each authoritative name server in the chain of referrals.

As minimization techniques are deployed, less information will be sent on the resolver-to-authoritative exchange, especially at the root and TLD levels, both because individual queries will include less information (for example, because of qname minimization), and because fewer queries will be sent (because of the other techniques). That's a gain for the need-to-know principle, which is the primary motivation for the change. But it's also a loss for DNS measurement research—at least for the passive measurement research based on assumptions that textbook DNS is deployed.

Because DNS resolvers are gradually deploying minimization techniques, rather than adopting all at once, they are like an eclipse: a slow and steady occlusion of the information content of the resolver-to-authoritative DNS exchange. The minimization eclipse likely will never be a total one, as many legacy DNS resolvers will continue doing what they've been doing all along. But its effects will be noticeable, and, inasmuch as the change in visibility will be novel—minimization techniques haven't been broadly deployed before—the effects will also be a motivation for new research.

Astronomical eclipses, too, have been a source of inspiration to researchers, perhaps most notably the famous Eddington experiment of 1919 (ironically, for the time of this present writing, in the midst of another global pandemic). Eclipses had long been studied, but the change in visibility of stars, or more precisely, of the observed location of starlight passing the Sun, had not been measured. Arthur Stanley Eddington and Frank Watson Dyson organized expeditions to Principe and Sobral to record the location of the Hyades, a group of stars, during a solar eclipse^[81]. The starlight's degree of deflection by the Sun's gravity confirmed Einstein's theory of General Relativity.

Whereas Eddington's team understandably focused on a single group of stars, the DNS community will have millions of resolvers to watch. Eventually, perhaps, minimization will reach a practical maximum. But in the meantime, each resolver will be impacted in its own ways by minimization techniques. Each will also provide unique insights about the global DNS, given the aggregate characteristics of its clients and how they use DNS. Each step along the way is therefore well worth studying. For DNS and Internet protocol researchers, the minimization eclipse is just starting, and the shadows are still partial. DNS resolution is entering the *penumbra*^[0].

Acknowledgements

- The idea for this article emerged from multiple conversations with my Verisign colleagues about the history and future of qname minimization. Special thanks to Danny McPherson for his foundational work and strategic direction in this area, and to Duane Wessels and Matt Thomas for their expert technical guidance on both details and data of the techniques.
- Geoff Huston, Chief Scientist of APNIC, Vladimír Čunát and Ladislav Lhotka of CZ.NIC, Puneet Sood of Google, Victoria Risk and her colleagues at ISC, and Benno Overeinder of NLnet Labs all gave generously of their time to review drafts and respond to questions.
- The article would not have reached final form without Zaid Albanna's leadership in arranging multiple rounds of internal and external reviews, and in coordinating the revisions based on reviewers' helpful feedback. A thank you also to Kim Kelly for her careful technical editing.
- Finally, a thank you to Ole Jacobsen for persevering with IPJ and to IPJ's anonymous reviewers for their important work in reviewing this and many other contributions.

BURTON S. KALISKI JR. (bkaliski@verisign.com) is senior vice president and chief technology officer of Verisign. He leads Verisign’s long-term research program and is responsible for the company’s industry standards engagements, university collaborations, and technical community programs. He previously served as the founding director of the EMC Innovation Network, as vice president of research at RSA Security, and as the founding scientist of RSA Laboratories, where his contributions included the development of the *Public-Key Cryptography Standards* (PKCS). He received a doctorate, master’s degree, and bachelor’s degree in computer science from the Massachusetts Institute of Technology.

KINDNS

by Adiel Akplogan, ICANN

In September 2022, the *Internet Corporation for Assigned Names and Numbers* (ICANN) launched <https://kindns.org> to support its *Knowledge-Sharing and Instantiating Norms for Domain Name System and Naming Security* (KINDNS) initiative. KINDNS was developed to improve DNS operations by promoting voluntary adherence to a clear set of security best practices tailored to authoritative and recursive DNS operators.

This initiative aligns with ICANN’s strategic goal to “Strengthen DNS coordination in partnership with the DNS stakeholders to improve the shared responsibility for upholding the security and stability of the DNS.” In other words, ICANN plans to actively promote DNS ecosystem security and relevant best practices. The KINDNS initiative is one of many programs and projects ICANN supports to help make the DNS safer.

The Domain Name System plays a crucial role in connecting users to services on the Internet. Like the Internet itself, the underlying protocols or rules that govern DNS operation are open. This is one of the greatest strengths of the DNS and the Internet: These open protocols are responsible for connecting billions of devices instantaneously all over the world.

This strength can also be a weakness. The DNS was not designed for security. Actors may snoop on DNS traffic, forge DNS traffic, and engage in denial-of-service attacks on DNS operations, among other activities. Similarly, the security systems and best practices of the DNS, which support the Internet’s operation, are characteristically open and voluntary. A clear example of this is the uneven global deployment of the *Domain Name System Security Extensions* (DNSSEC), a security enhancement specification developed by the *Internet Engineering Task Force* (IETF) more than 20 years ago.

DNS security challenges, however, are not unique. Key to Internet security, or security issues in general, is the necessity to coordinate behaviors across systems. Security challenges call for collective action and the voluntary adherence to a set of ever-evolving behaviors and technologies.

ICANN is uniquely positioned, in close collaboration with its many partners and peers, to help in collectively mitigating specific forms of DNS security threats, that fall within its mission (see below for more details). The organization’s greatest strength, in many ways, is its partnerships, active community participation, and global engagement activities. This network of technical organizations and experts from various backgrounds can provide a formidable tool in helping make the global DNS safer.

What is KINDNS?

KINDNS is an ICANN initiative tailored to authoritative and recursive DNS operators to promote voluntary adherence to a clear set of security best practices. A challenge facing DNS security is implementing and maintaining security at the same level for all authoritative and recursive operators in the DNS ecosystem. Smaller operators struggle to keep abreast of the latest security measure improvements, while large operators may implement only measures which help them achieve their professional business goals. As a result, a patchwork of varying security practices among DNS operators has led to weaknesses that malicious actors may find and use.

Currently, KINDNS has three areas of focus:

- Promoting the adoption of DNS security practices through the operator community. This includes maintaining a dynamic information portal that promotes KINDNS practices, helps operators to self-assess their practices and offers guidelines on how to implement them.
- Soliciting and gathering feedback on the KINDNS guidelines to refine and identify areas of improvement and emerging best practices that may be candidates for future additions to the framework.
- Developing advanced tools for operators to conduct self-assessments and an observatory platform around key DNS security indicators that can help measure and assess the impact of KINDNS.

KINDNS Portal

ICANN has worked with its community to develop a baseline level of security operations, a relatively small set of mutually agreed practices that operators of any size can easily implement. ICANN published the initial version of KINDNS in September 2022 with its own dedicated website: <https://kindns.org>

Voluntary Self-Assessment Form

To learn more about the initiative, KINDNS offers operators a simple self-assessment tool to check their current security practices and offers suggestions where they could improve. The current version of the self-assessment tool does not run any code on an operator's server or make any real-time measurements. KINDNS only asks questions and generates a compliance report upon completion of the survey. The form is found here: <https://kindns.org/assessments-tools>

KINDNS Guidelines and Practices

The guidelines and practices promoted by KINDNS were designed to help operators identify and implement critical security best practices. ICANN, however, does not view the KINDNS initiative as the only source of information on DNS security. On the contrary, it encourages operators to also check and work in accordance with the security dictated by the construct of their own infrastructure.

Currently, the KINDNS Framework covers the following categories:

Guidelines for Authoritative Server Operations

TLD and Critical Zones and Other Second-Level Domains (SLD) Zones: There are two types of best practices for operators of authoritative servers: DNS security and DNS availability and resilience. To learn more about these guidelines see:

<https://kindns.org/critical-zones>

and

<https://kindns.org/other-sld-zones>

Guidelines for Recursive Server Operators

These guidelines are tailored for three specific categories of recursive server operators. Depending on a company's policy or business practice, it may be operating one or more of these types of resolvers. These three categories include:

- *Private Resolvers*: these are not publicly accessible and cannot be reached over the open Internet. They are typically found in corporate networks or other restricted-access networks. Private resolvers in some cases are part of a trusted computing domain (for example, *Active Directory*).
- *Shared Private Resolver Operators*: these are typically *Internet Service Providers* (ISPs) or similar hosting service providers. They offer DNS resolution services to their customers (including for mobile, cable, DSL, fiber residential and commercial users, and hosted servers and applications).
- *Public resolvers*: this category includes both open and closed public resolvers. Closed public resolvers are typically commercial DNS filtering or scrubbing services. These service providers are typically not ISPs and the clients sending queries to them are located on remote networks. Note, some operators of closed public resolvers may also offer a free tier service, which also makes them open public resolvers.

To learn more about these guidelines visit:

<https://kindns.org/recursive-server-operators>

Guidelines for Platform Hardening

KINDNS recommends that all operators pay careful attention to practices for hardening the platforms their DNS services use. There are three types of hardening practices:

- *Network Security*: these best practices are aimed at preventing unauthorized network access to DNS servers and ensuring internal traffic does not leak onto other networks.
- *Host and Service Security*: these best practices are aimed at improving the security of hosts running DNS services to reduce the likelihood of a host compromise, denial-of-service attack or other attack.
- *Customer-Facing Portal and Service Security*: these practices are aimed at supporting the security needs of customers.

To learn more about these guidelines, visit:

<https://kindns.org/platform-hardening>

Conclusion

The website launch marks the completion of this initial phase of the KINDNS initiative, where ICANN's Technical Engagement team worked closely with the operator community and DNS experts to identify and document DNS security threats and their mitigation measures, which are the basis for the current guidelines. We hope and expect to evolve them as the DNS and the Internet continue to evolve. We invite anyone interested in participating in this initiative to join the KINDNS mailing list at:

<https://mm.icann.org/mailman/listinfo/kindns-discuss>

If you have any questions, please contact the KINDNS team at:

kindns-info@icann.org

ADIEL AKPLOGAN is Vice President, Technical Engagement at ICANN. With more than 25 years' experience in the ICT industry (20 specifically in the Internet Technology Industry), Adiel previously served as CEO for AFRINIC (The African Network Information Centre), IT Director for Symbol Technology in France (2001–2003) and Director of New Technology at CAFÉ Informatique in Togo (1994–2000). He earned a graduate degree in Electrical Engineering and holds a Master's degree in E-Business and New Technology Management from Paris Graduate School of Management. Recognized as one of the Internet technology pioneers in Africa, he has contributed to technical capacity building and deployment of some of the first private Internet Service Providers in Africa from 1996 to 1999. He can be reached at: **adiel.akplogan@icann.org**

Twenty-Five Years Later	23
Supporters and Sponsors	49
Thank You!	50

Twenty-five years ago, we published the first issue of *The Internet Protocol Journal* (IPJ). Since then, 87 issues for a total of 3,316 pages have been produced. Today, IPJ has about 20,000 subscribers all around the world. In the early days of IPJ, most of our readers preferred the paper edition, but over time preferences have shifted steadily to a situation where only some 1,200 print subscribers remain. The rest are downloading the PDF version. This shift in reading habits is likely related to the changes in technology that have taken place in the last 25 years. Lower costs and higher-resolution displays and printers, as well as improvements in Internet access technologies, have made the online “experience” a lot better than it was in 1998.

In this issue, we will first look at two areas of work taking place in the *Internet Engineering Task Force* (IETF). The *Application-Layer Traffic Optimization* (ALTO) protocol aims to make network state such as topology, link availability, routing policies, and path cost metrics information available to applications in a standardized manner. The next article concerns the thorny topic of *tracking* of users and their devices on the Internet. This area is complex, with many potential solutions, including the use of randomized *Media Access Control* (MAC) addresses as described by members of the *MAC Address Device Identification for Network and Application Services* (MADINAS) Working Group in the IETF.

Our final article is a look back at the last 25 years of Internet technology development. As we did with our 10th anniversary issue in 2008, we asked Geoff Huston to provide an overview of the many changes that have taken place in this period. At the end of his article, you will find a list of previously published articles from IPJ on numerous aspects of Internet technologies. All back issues are, of course, available from our website.

Let me take this opportunity to thank all the people who make IPJ possible. We are grateful to all our sponsors and donors, without whose generous support this publication would not exist. Our authors deserve a round of applause for carefully explaining both established and emerging technologies. They are assisted by an equally insightful set of reviewers and advisors who provide feedback and suggestions on every aspect of our publications process. The process itself relies heavily on two individuals: Bonnie Hupton, our copy editor, and Diane Andrada, our designer. Thanks go also to our printers and mailing and shipping providers. Last, but not least, our readers provide encouragement, suggestions, and feedback. This journal would not be what it is without them.

The IETF ALTO Protocol

Optimizing Application Performance by Increasing Network Awareness

by Qin Wu, Mohamed Boucadair, and Jordi Ros-Giralt

In today's Internet, network-related information (for example, topology, link availability, routing policies, and path cost metrics) are usually hidden from the application layer. As a result, endpoints make network-unaware decisions that may lead to suboptimal service placement and selection decisions, sometimes resulting in poor user experience and unnecessary inter-*Internet Service Provider* (ISP) traffic. Previous approaches to this problem space have considered snooping on the lower layers to determine the state and capabilities of the network, but such techniques require applications to be aware of lower-layer components (for example, routing protocols) and, furthermore, if left unspecified, can potentially overload key network resources.

To overcome this challenge, it is necessary to gather and expose network state information (for example, the bandwidth and latency properties between two network endpoints) to applications that do not interact directly with their underlying network protocols, without increasing the risk of network service disruption. For instance, empowered with such information, service providers can safely optimize the placement of their applications in locations of the network that provide higher capacity and lower latency to the clients they intend to serve. Similarly, with such information, client applications can also optimize the selection of the server instances they decide to attach to, while relying upon a variety of cost metrics.

This article provides an overview of how the *Internet Engineering Task Force* (IETF) *Application-Layer Traffic Optimization* (ALTO) protocol enables applications with improved network awareness to overcome these challenges, and reports on some of the implementations and deployments of the ALTO protocol.

The ALTO Approach and Architecture

The IETF ALTO protocol defines a client/server network service that applications can use to gain insightful information about the current state of the network. As defined in the base protocol^[1], each ALTO server maintains a “my-Internet” view of the network it represents. In its simplest form, this view consists of a set of endpoints and costs between pairs of endpoints for each possible cost type (for example, hop count, latency, or bandwidth). An application seeking to gain this information to make optimized decisions can use an ALTO client to connect to an ALTO server using the *Hypertext Transfer Protocol* (HTTP)-based protocol defined in the ALTO base specification.

The ALTO protocol uses a *Representational State Transfer* (RESTful) design and encodes its requests and responses using *JavaScript Object Notation* (JSON) objects.

An ALTO request carries a set of source-destination endpoints and a cost type. The triggered ALTO response provides the cost value for each given source-destination endpoint. To improve scalability (for example, to reduce the load of an ALTO server) and privacy (for example, to avoid revealing sensitive topology information), ALTO introduces the concept of *groups*, which specify sets of endpoints that are close to each other from a network connectivity standpoint. In larger-scale networks, this aggregation leads to greater scalability without losing critical information. A group may be represented as an IP prefix, a *Point of Presence* (PoP), a type of access connectivity (wireless, fiber, etc.), an *Autonomous System* (AS), or a set of ASes. The entity that operates an ALTO server, called the *ALTO Service Provider*, is responsible for assigning a unique *Provider-defined Identifier* (PID) to each group.

Another generalization of the endpoint object is enabled using the concept of *Abstract Network Element* (ANE). This concept provides an abstract representation of a component in a network that handles data packets and whose properties can potentially affect the end-to-end performance of an application^[14]. ANEs can include not only endpoints, but also switches and routers that connect them.

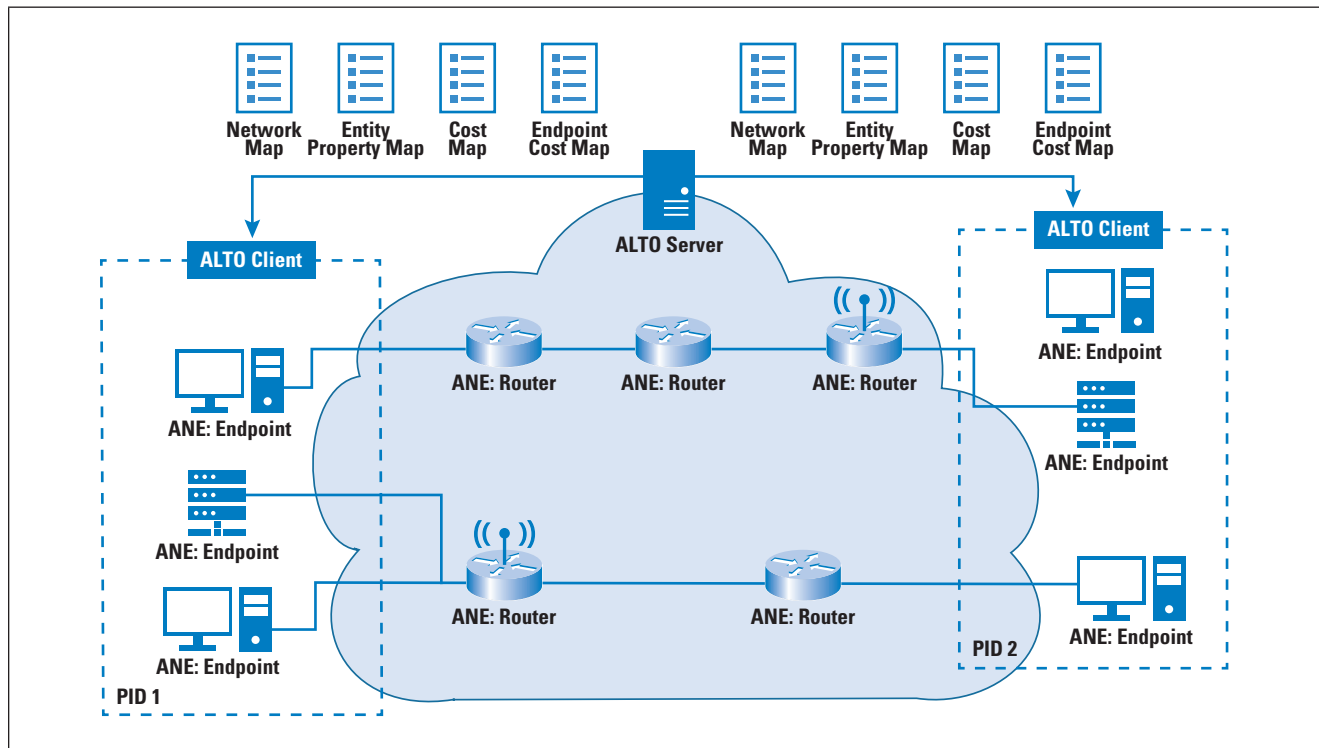

Figure 1, on the next page, depicts the main ALTO abstract objects involved in a network. In this figure, application endpoints are represented as ANEs clustered in two groups with provider-defined identifiers “PID1” and “PID2.” An endpoint can select to communicate with another endpoint based on the network properties that the ALTO server exposes. For instance, in a *Content Delivery Network* (CDN), ANEs correspond to client and server hosts, and a specific content (for example, a movie) is in general replicated in more than one server instance. A client host can decide to retrieve the content by selecting the server instance that provides the higher communication bandwidth according to the exposed ALTO information. Each of the abstract objects that are illustrated in Figure 1 is further elaborated in the following sections.

ALTO Maps

An ALTO server organizes the network information using the concept of *maps*. Maps can be constructed from physical information, logical information, or a combination thereof. ALTO supports four types of maps, as shown in Figure 1:

- The *Network Map* lists all the endpoint groups that the ALTO server tracks. This map includes PIDs that uniquely identify each group.
- The *Entity Property Map* describes the properties of each ANE in the network, including the geolocation or the connectivity type (for example, fiber or wireless) of an ANE.
- The *Cost Map* provides the cost information (for example, hop count, latency, or bandwidth) between each pair of PIDs enclosed in the network map, where a PID identifies a group of endpoints.
- The *Endpoint Cost Map* provides finer-grained cost information between specific endpoints.

Figure 1: Base ALTO Abstract Objects

ALTO Extensions

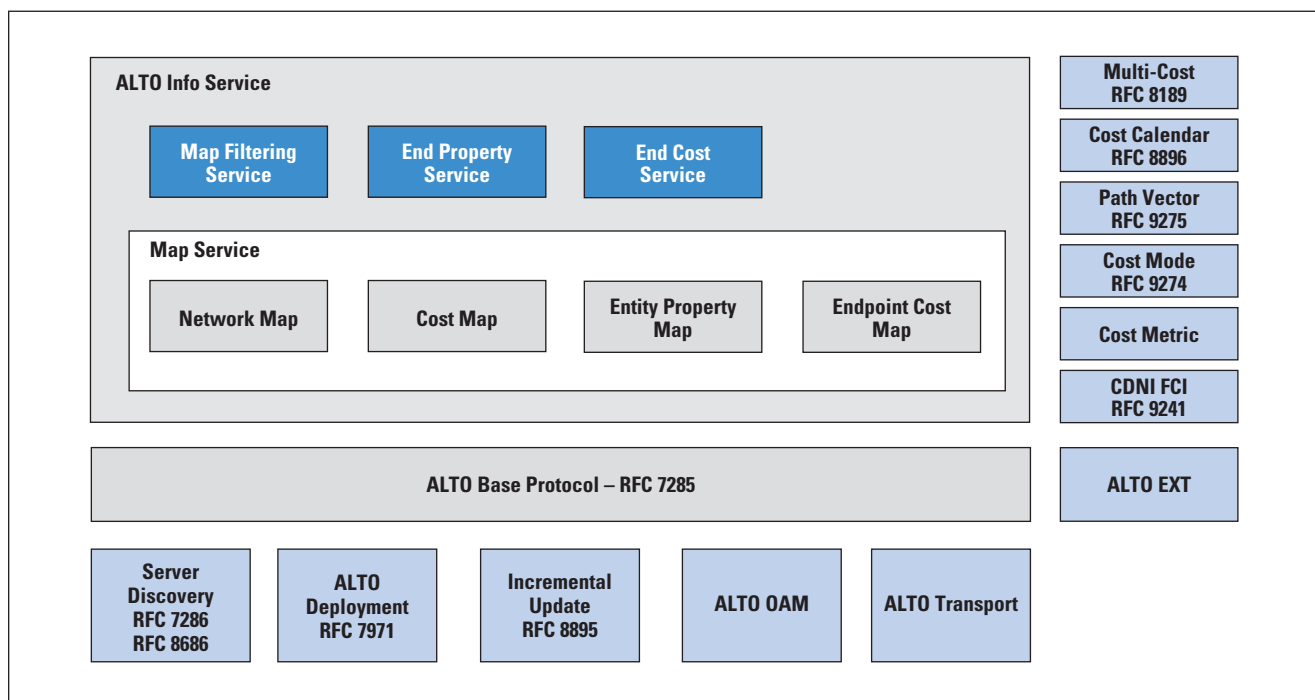

In addition to its base abstractions and maps, the ALTO protocol supports the following extensions to enable a richer network-aware application experience:

- The *Information Resource Directory* (IRD) lists the services an ALTO server provides and the locations from where you can access these services.
- The *Cost Calendar* provides a set of cost values as a function of time, allowing applications to know not only where to connect to, but also when.
- Incremental Updates using *Server-Sent Events* (SSEs) allow an ALTO server to expose cost values as delta updates, reducing the amount of server-client data exchanged.
- The CDNI Advertisement exposes a *CDNI Footprint and Capability Advertisement Interface* (FCI)^[26].
- The *Path Vector extension* exposes the set of ANEs along the path between two endpoints and the performance properties of these ANEs.
- The *Extended Performance Cost Metrics* enrich ALTO with advanced metrics such as network one-way delay, one-way delay variation, one-way packet-loss rate, hop count, and bandwidth.
- The *Entity Properties* generalize the concept of ALTO endpoint properties by presenting them as entity property maps.

Figure 2 shows the ALTO protocol core services as they are documented by the IETF as well as some of the related ALTO documents. The previously mentioned ALTO extensions are marked with a light-blue shading. The core services are organized as part of the *ALTO Information Service* consisting of the *Map Filtering*, *End Property*, and *End Cost* services, along with the *Map Service*, which is itself broken into separate map services as previously described. All of the services are dependent on the base protocol, which is documented in [1]. The ALTO protocol is enhanced through *Server Discovery*^[5, 25], and extensions for *Incremental Updates*^[9], *Operations and Management (OAM)*^[23], and support for carrying the ALTO protocol over more modern transport protocols^[22]. The practical understanding of how you can use the ALTO protocol together with a set of deployment recommendations is documented in [13].

Additional ALTO features, for example, cost manipulation^[7, 8], are shown on the right side of Figure 2.

Figure 2: Overview of ALTO Core and Extensions

History of ALTO

The ALTO Working Group was established in 2008 with an initial charter to develop a request/response protocol that would allow hosts to extract enough state information from a network to make optimized server selection decisions. The working group's first charter focused on the optimization of *Peer-to-Peer* (P2P) applications, with the first four RFCs introducing the problem statement^[11] and requirements^[4], the base protocol^[1], and support for server discovery^[5].

The working group was then rechartered in 2014 to support a broader set of applications that included CDNs and data centers.

That stage led to the development of five RFCs: Deployment recommendations^[13], protocol extensions for reducing the volume of on-the-wire data exchange^[7, 9], server discovery for multi-domain environments^[25], and a cost calendar capability to allow applications to identify the optimal times to connect to a service^[8].

The current ALTO Working Group charter was approved in 2021 with the goal to focus on three operational areas: (1) support for modern transport protocols such as HTTP/2 and HTTP/3^[22]; (2) development of OAM mechanisms^[23], and (3) collection of deployment experiences^[24]. These three areas constitute the current highest priorities of the ALTO Working Group.

Four additional RFCs that had originated from the second charter have also been published since then: (1) support of property maps for generalized entities^[10], (2) a new *Footprint and Capabilities Advertisement Interface* (FCI) protocol for CDNI^[12], (3) a new *Internet Assigned Numbers Authority* (IANA) registry for tracking cost modes supported by ALTO^[3], and (4) extensions to the cost map and ALTO property map services to allow the application to identify optimized paths^[14].

ALTO Deployments and Implementations

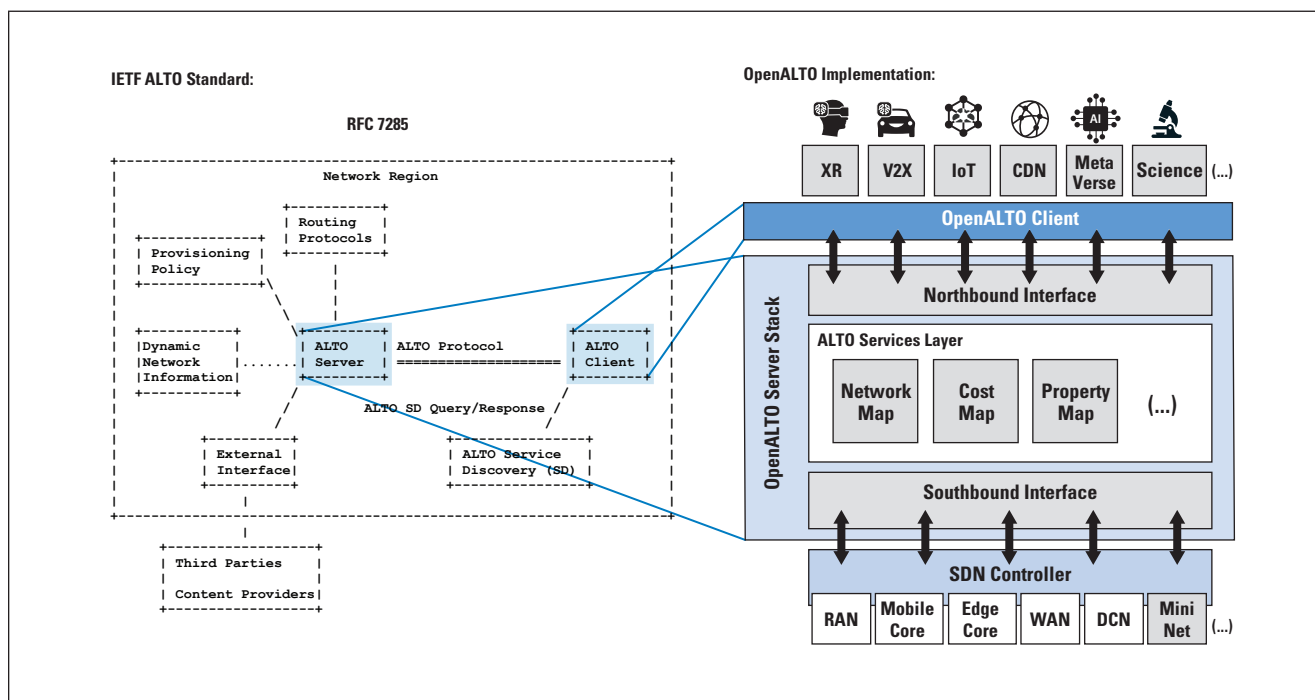

The ALTO base protocol was first implemented by Korea Telecom^[16], NEC^[17], Benocs^[18], Alcatel-Lucent Bell Labs^[19], and Nokia. An open-source implementation of the ALTO stack was also made available via the *OpenDaylight* (ODL) Project^[6]. Starting in 2020, China Mobile, Tencent^[20], and Telefonica^[21] have been actively involved in ALTO and initiated trials in their mobile networks and CDNs. Qualcomm Technologies, Inc. also joined the ALTO effort in 2021 with a focus on evaluating the fit of ALTO for exposing network state information in the context of edge computing. At the time of this writing (2023), two new deployments of ALTO are being initiated to support the networks from CERN (LHCONE) in Europe and the Network Research Platform in the United States^[27].

A further open-source initiative, the *OpenALTO* Project^[2], was initiated in 2021 to provide a standalone implementation of the ALTO stack independently of the ODL Project. The OpenALTO Project is an initiative spawning from the IETF ALTO Working Group, which focuses on developing an open-source implementation of the ALTO specifications, including the latest Internet Drafts that have been moved to Working Group Last Call to support modern transport protocols^[22] and OAM^[23]. As shown in Figure 3, the architecture maps the IETF ALTO server and ALTO client onto the OpenALTO software stack as follows:

- The OpenALTO Server stack includes three core building blocks: The Application-facing Interface, the Network-facing Interface, and the ALTO Services Layer.
- The Application-facing Interface provides an *Application Programming Interface* (API) that applications can query to retrieve the state of the network.

- The Network-facing Interface implements a variety of network plugins to support the retrieval of network state information; each plugin supports a different type of network. To facilitate the development of OpenALTO, this interface also includes plugins for simulation and emulation environments such as *Mininet*.
- The ALTO Services Layer provides the core ALTO functions by implementing [1]. This layer currently includes the Network Map, the Cost Map, and the Property Map services.
- The OpenALTO client is a thin layer that implements the HTTP-based client-side protocol described in [1] and [9]. The ALTO client is installed as a library in the same device in which the application is being run, and the application uses it to retrieve the network state from the ALTO server.

Figure 3: Mapping of RFC 7285 Entities onto the OpenALTO Software Architecture

Future Perspectives

The ALTO protocol initially started with the goal of supporting the optimization of P2P applications in 2008, then evolved to incorporate extensions for the support of CDNs in 2014, and today it is well-positioned to support the requirements of new advanced edge computing applications such as augmented reality, vehicle networks, and the metaverse, among others. Because this new class of applications requires stringent *Quality of Experience* (QoE) performance, the ALTO protocol becomes a key component to enable collaborative application/network schemes.

Specifically, ALTO contributes to the optimization of service placement and selection decisions based on the communication properties of the network. In this regard, and as its current charter is being finalized, proposals are being made to extend the protocol towards supporting edge computing applications in three possible areas: (1) extending ALTO metrics to include information about the compute resources (for example, *Central Processing Unit* [CPU], *Graphics Processing Unit* [GPU], memory, and storage) found in the distributed edge computing network, (2) incorporating protocol semantics for the sharing of state between ALTO servers in multi-domain networking environments, helping applications gain a global end-to-end view of the network, and (3) potentially incorporating information about the level of trust offered by each ANE along a communication path to improve the security of new advanced applications such as the metaverse.

Beyond the IETF, several other *Standards Development Organizations* (SDOs) such as the *3rd Generation Partnership Project* (3GPP) are also investigating solutions for exposing network capabilities to enable the optimization of new advanced applications. These solutions can naturally take advantage of ALTO, and there is the potential for IETF technology to become an important enabler of Internet capabilities demanded by developments arising in other SDOs. To enable these cross-SDO synergies, the ALTO protocol needs to be further socialized inside and outside the IETF with a focus on illustrating how it can provide the intended exposure features.

Future directions of the ALTO protocol are currently being discussed in the WG mailing list (<https://mailarchive.ietf.org/arch/browse/alto/>). The WG welcomes your participation to help identify the key priorities towards supporting the newly arising edge computing applications.

The Impact of Randomized Layer-2 Addresses on Privacy and Applications

by Carlos J. Bernardos, Juan-Carlos Zuñiga, Jerome Henry, and, Alain Mourad

Wi-Fi technology has revolutionized communication and become the preferred technology and sometimes the only networking technology used by devices such as smartphones, tablets, and *Internet-of Thing* (IoT) devices.

On the other hand, Internet privacy is becoming a huge concern, as more and more mobile devices are connecting to the Internet. This ubiquitous connectivity, together with not-very-secure protocol stacks and the lack of proper education about privacy, make it very easy to track/monitor the location of users and/or eavesdrop on their physical and online activities. The cause of this situation has many factors, such as the vast digital footprint that users leave on the Internet; for example: information sharing on social networks, the cookies that browsers and servers use to provide a better navigation experience, connectivity logs that allow tracking of a user's Layer 2 *Media Access Control* (L2 MAC) or Layer 3 (L3) address, web trackers, etc., and/or the weak (or even null in some cases) authentication and encryption mechanisms used to secure communications.

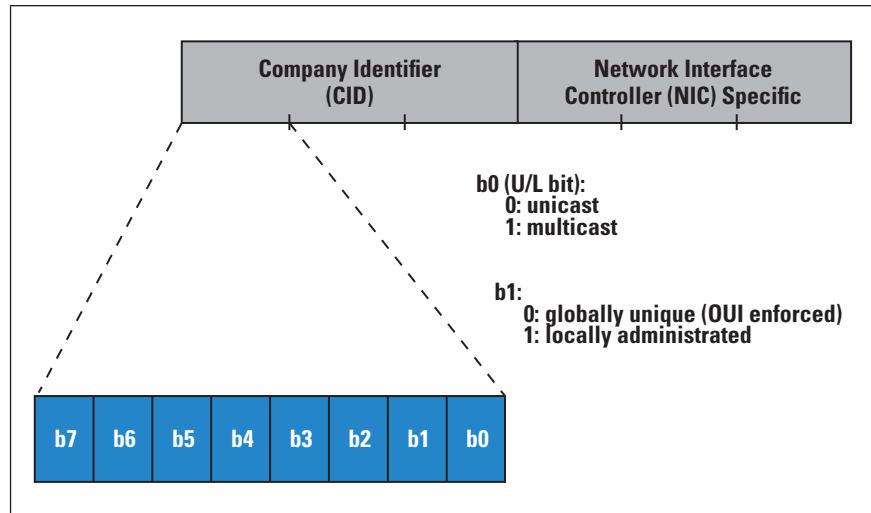

This privacy concern affects all layers of the protocol stack, from the lower layers involved in the actual access to the network (for example, you can use the L2 and L3 addresses to obtain a user's location) to higher-layer protocol identifiers and user applications^[1]. In particular, IEEE 802 MAC addresses have historically been an easy target for tracking users^[2]. Attackers who are equipped with surveillance equipment can “monitor” Wi-Fi packets and track the activity of Wi-Fi devices. After the association between a device and its user is made, identifying the device and its activity is sufficient to deduce information about what the user is doing, without the user's consent.

IEEE 802.11 (Wi-Fi) interfaces, as any other kind of IEEE 802-based network interface, like Ethernet (that is, IEEE 802.3), have a Layer 2 address, also referred to as the MAC address, which anybody who can receive the signal transmitted by the network interface can see. Figure 1 shows the format of these addresses.

A third party, such as a passive device listening to communications in the same network, can easily observe MAC addresses. In an 802.11 network, a station exposes its MAC address in two different situations:

- While unassociated and actively scanning for available networks, the MAC address is used in the *Probe Request* frames that the device sends (aka IEEE 802.11 STA).
- After it is associated to a given *Access Point* (AP), the MAC address is used in frame transmission and reception, as one of the addresses used in the address fields of an IEEE 802.11 frame.

Figure 1: IEEE 802 MAC Address Format

MAC addresses can be either universally or locally administered. A MAC address is identified as being locally administered when the second-last significant bit of the most significant octet of the address (the U/L bit) is set. The MAC address is identified as globally unique when the U/L bit is unset.

A universally administered address is uniquely assigned to a device by its manufacturer (and is called the *burned-in address*). Most physical devices are provided with a universally administered address, which is composed of two parts: (i) the *Company Identifier* (CID), which is the first three octets in transmission order, identified by the organization that issued it, and (ii) the *Network Interface Controller* (NIC)-specific address, which is the following three octets, assigned by the organization that manufactured the controller, in such a way that the resulting MAC address is globally unique. Since universally administered MAC addresses are by definition globally unique, when a device uses this MAC address to transmit data—especially over the air—it is relatively easy to track this device by simple medium observation. This possibility poses a privacy concern^[3] when the device is directly associated to a single user (for example, smartphones, etc.).

Locally administered addresses can override the burned-in address, and they can be set up by either the network administrator or the *Operating System* (OS) of the device to which the address pertains. This feature allows you to generate local addresses without the need for any global coordination mechanism to ensure that the generated address is still unique within the local network. You can use this feature to generate random addresses, which decouple the globally unique identifier from the device and thereby make it more difficult to track a user device from its MAC/L2 address^[4]. There are initiatives at the IEEE 802 and other organizations to specify ways in which these locally administered addresses should be assigned, depending on the use case.

To reduce the risks of correlation between a device activity and its owner, multiple vendors have started to implement *Randomized and Changing* MAC (RCM) addresses. With this scheme, an end device implements a different RCM over time when exchanging traffic over a wireless network. By randomizing the MAC address, the persistent association between a given traffic flow and a single device is made more difficult, assuming no other visible unique identifiers are in use.

However, such address changes may affect the user experience and the efficiency of legitimate network operations. For a long time, network designers and implementers relied on the assumption that a given machine in a network implementing IEEE 802 technologies would be represented by a unique network MAC address that would not change over time, despite the existence of tools to flush out the MAC address to bypass some network policies. When this assumption is broken, elements of network communication may also break.

For example, sessions established between the end device and network services may be lost and packets in translation may suddenly be without a clear source or destination. If multiple clients implement fast-paced RCM rotations, network services may be over-solicited by a small number of stations that appear as many clients.

At the same time, some network services rely on the client station providing an identifier, which can be the MAC address or another value. If the client implements MAC rotation but continues sending the same static identifier, then the association between a stable identifier and the station continues despite the RCM scheme. There may be environments where such continued association is desirable, but others where the user privacy has more value than any continuity of network service state.

Application and Network Scenarios That RCM Can Affect

Device identity is important in scenarios where the network needs to know the device or user identity in order to offer, operate, and maintain certain valid services. Currently, many use cases and applications make an implicit assumption that a device is represented by an IEEE 802 L2 permanent and unique MAC address. This assumption is being used in both control- and data-plane functions and protocols. RCM breaks this assumption. This paradigm shift requires updating applications to function across MAC address changes.

When a device changes its MAC address, other devices on the same LAN may fail to recognize that the same machine is attempting to communicate with them. Additionally, multiple layers implemented at upper layers have been designed with the assumption that each node on the LAN, using these services, would have a MAC address that would stay the same over time (a *persistent* MAC address).

This assumption sometimes adds to the *Personally Identifiable Information* (PII) confusion, for example in the case of *Authentication, Association, and Accounting* (AAA) services authenticating the user of a machine and associating the authenticated user to the device MAC address. Other services focus solely on the machine, for example, the *Dynamic Host Configuration Protocol* (DHCP), but still expect each machine to use a persistent MAC address, for example to re-assign the same IP address to a returning device. Changing the MAC address may disrupt these services and the user experience.

The impact of using a persistent or a randomized and changing MAC address very much depends on the environment where the device operates (that is, the use case), on the presence and nature of other devices in the environment, and on the type of network the device is communicating through. Therefore, a device can use a MAC address that can persist over time if trust with the environment is established, or that can be temporal if that address is going to be used as an identity for a service in an environment where trust has not been established. Note that this trust is not binary, and it ranges from: (i) full trust: environments where a personal device establishes a trust relationship and can share a persistent device identity with the access network devices, without the fear of that identity being shared beyond the L2 broadcast domain; (ii) selective trust: environments where the device may not be willing to share a persistent identity with some elements of the Layer 2 broadcast domain but may be willing to do it with other elements; and (iii) zero trust: environments where the device may not be willing to share any persistent identity with any local entity reachable through the AP and may express a temporal identity to each of them.

This trust relationship naturally depends on the relationship between the user of the personal device and the operator of the service. Thus, it is useful to enumerate some scenarios (which can be easily translated into use cases) where the use of RCM might have an impact:

- *Residential settings under the control of the user*: this case is typical of a home network with Wi-Fi in the LAN and an Internet connection. In this environment, traffic over the Internet does not expose the MAC address if it is not copied to another field before routing happens. The user controls the wire segment within the broadcast domain, and this segment, therefore, is usually not at risk of hosting an eavesdropper. Full trust is typically established at this level among users and with the network elements. The device trusts the AP and all Layer 2 domain entities beyond the AP. However, unless the user has full access control over the physical space where the Wi-Fi transmissions can be detected, there is no guarantee that an eavesdropper would not be observing the communications. As such, it is common to assume that, even in this environment, full trust cannot be achieved.

- *Managed residential settings*: examples of this type of environment include shared living facilities and other collective environments where an operator manages the network for the residents. The over-the-air exposure is similar to that of a home. A number of devices larger than in a standard home may be present, and the operator may be requested to provide IT support to the residents. Therefore, the operator may need to identify the activity of a device in real time, but may also need to analyze logs so as to understand a past reported issue. For both activities, a device identification associated with the session is needed. Full trust is often established in this environment, at the scale of a series of a few sessions, not because it is assumed that no eavesdropper would observe the network activity, but because it is a common condition for the managed operations.
- *Public guest networks*: public hotspots, such as in shopping malls, hotels, stores, train stations, and airports, are typical of this environment. The guest network operator may be legally mandated to identify devices or users or may have the option to leave all devices and users untracked. In this environment, trust is commonly not established with any element of the Layer 2 broadcast domain (zero trust model by default).
- *Enterprises (with Bring Your Own Device [BYOD])*: users may be provided with corporate devices or may bring their own. The devices are not directly under the control of a corporate IT team. Trust may be established as the device joins the network. Some enterprise models mandate full trust; others, considering the BYOD nature of the device, allow selective trust.
- *Managed enterprises*: in this environment, users are typically provided with corporate devices, and all connected devices are managed, for example through a *Mobile Device Management* (MDM) profile installed on the device. Full trust is created as the MDM profile is installed.

Ongoing Efforts/Approaches Regarding RCM

Practical experiences of RCM in live devices helped researchers fine-tune their understanding of attacks against randomization mechanisms^[5]. At IEEE 802.11 these research experiences eventually formed the basis for a specified mechanism introduced in the IEEE 802.11aq in 2018, which recommends mechanisms to avoid pitfalls when using randomized MAC addresses^[6].

More recent developments include turning on MAC randomization in mobile operating systems by default, which affects the ability of network operators to personalize or customize services^[7]. Therefore, follow-on work in the IEEE 802.11 mapped effects of a potentially large uptake of randomized MAC identifiers on many commonly offered operator services in 2019^[8].

In the summer of 2020, this work resulted in two new standards projects with the purpose of developing mechanisms that do not decrease user privacy and enable an optimal user experience when the MAC address of a device in an *Extended Service Set* is randomized or changes^[9] and user privacy solutions applicable to IEEE Std 802.11^[10].

The IEEE 802.1 Working Group has also published a specification that defines a local MAC address space structure, known as the *Structured Local Address Plan* (SLAP). This structure designates a range of local MAC addresses for protocols using a CID assigned by the IEEE Registration Authority. Another range of local MAC addresses is designated for assignment by administrators. The specification recommends a range of local MAC addresses for use by IEEE 802 protocols^[11].

Work within the IEEE 802.1 Security Task Group on privacy recommendations for all IEEE 802 network technologies has also looked into general recommendations on identifiers, reaching the conclusion that temporary and transient identifiers are preferable in network technology designs if there are no compelling reasons of service quality for a newly introduced identifier to be permanent. This work has been specified in the recently published IEEE P802E: “Recommended Practice for Privacy Considerations for IEEE 802 Technologies”^[12]. The IEEE P802E specification will form part of the basis for the review of user privacy solutions applicable to IEEE Std 802.11 (aka Wi-Fi) devices as part of the RCM^[7] efforts.

Currently, two task groups in IEEE 802.11 are addressing issues related to RCM:

- The IEEE 802.11bh Task Group, looking at mitigating the repercussions that RCM creates on 802.11 networks and related services, and
- The IEEE 802.11bi Task Group, which will define modifications to the IEEE Std 802.11 MAC specification to specify new mechanisms that address and improve user privacy.

At the *Wireless Broadband Alliance* (WBA), the *Testing and Interoperability Working Group* has been looking at the issues related to MAC address randomization and has identified a list of potential impacts of these changes to existing systems and solutions, mainly related to Wi-Fi identification. As part of this work, WBA has documented a set of use cases that a Wi-Fi Identification Standard should address in order to scale and achieve longer-term sustainability of deployed services. A first version of this document has been liaised with the IETF as part of the *MAC Address Device Identification for Network and Application Services* (MADINAS) activities through the “Wi-Fi Identification in a post MAC Randomization Era v1.0” paper^[13].

Several IP address assignment mechanisms such as the IPv6 *Stateless Address Auto-Configuration* (SLAAC) techniques^[14] generate the *Interface Identifier* (IID) of the address from its MAC address (via EUI64), which then becomes visible to all IPv6 communication peers. This feature potentially allows for global tracking of a device at L3 from any point on the Internet. Besides, the prefix part of the address provides meaningful insights into the physical location of the device in general, which together with the MAC address-based IID, makes it easier to perform global device tracking.

Some solutions might mitigate this privacy threat, such as the use of temporary addresses^[15] and opaque IIDs^[16,17]. Additionally, [18] proposes an extension to DHCPv6 that allows a scalable approach to link-layer address assignments where preassigned link-layer address assignments (such as by a manufacturer) are not possible or unnecessary. [19] proposes extensions to DHCPv6 protocols to enable a DHCPv6 client or relay to indicate a preferred SLAP quadrant to the server, so that the server may allocate MAC addresses in the quadrant requested by the client or relay.

Not only can you use MAC and IP addresses for tracking purposes, but some DHCP options allow you to also carry unique identifiers. These identifiers can enable device tracking even if the device administrator takes care of randomizing other potential identifications such as link-layer addresses or IPv6 addresses. [20] introduces anonymity profiles, designed for clients that wish to remain anonymous to the visited network. The profiles provide guidelines on the composition of DHCP or DHCPv6 messages, designed to minimize disclosure of identifying information.

Existing Solutions

One possible solution is to use 802.1X with *Wi-Fi Protected Access* 2/3 (WPA2/WPA3). At the time of association to a Wi-Fi access point, 802.1X authentication coupled with WPA2 or WPA3 encryption schemes allows for the mutual identification of the client device or of the user of the device and an authentication authority. The authentication exchange is protected from eavesdropping. In this scenario, you can obfuscate the identity of the user or the device from external observers. However, the authentication authority is in most cases under the control of the same entity as the network access provider, thus making the identity of the user or device visible to the network owner. This scheme is therefore well-adapted to enterprise environments, where a level of trust is established between the user and the enterprise network operator.

A different approach is the Wireless Broadband Alliance *OpenRoaming* standard, which introduces an intermediate trusted relay between local venues and sources of identity. The federation structure also extends the type of authorities that can be used as identity sources (compared to the traditional enterprise-based 802.1X scheme for Wi-Fi), and facilitates the establishment of trust between a local venue and an identity provider.

Such a procedure dramatically increases the likelihood that one or more identity profiles for the user or the device will be accepted by a local venue. At the same time, authentication does not occur to the local venue, thus offering the possibility for the user or device to keep their identity obfuscated from the local network operator, unless that operator specifically expresses the requirement to disclose such identity (in which case the user has the option to accept or decline the connection and associated identity exposure). The OpenRoaming scheme therefore seems well-adapted to public Wi-Fi and hospitality environments, allowing for the obfuscation of the identity from unauthorized entities, while also permitting mutual authentication between the device or the user and a trusted identity provider.

It is also worth mentioning that most evolved client device OSes already offer RCM schemes, enabled by default (or easy to enable) on client devices. With these schemes, the device can change its MAC address, when not associated, after using a given MAC address for a semi-random duration window. These schemes also allow for the device to manifest a different MAC address in different *Service Set Identifiers* (SSIDs). Different OSes follow slightly different approaches, which are also evolving with the new releases. Such a randomization scheme enables the device to limit the duration of exposure of a single MAC address to observers. In the IEEE 802.11-2020 specification, MAC address rotation is not allowed during a given association session, and thus rotation of MAC address can occur only through disconnection and reconnection.

Ongoing Work in the IETF

The MADINAS Working Group in the IETF is addressing documentation of the services that may be affected by RCM and evaluation of possible solutions to maintain the quality of user experience and network efficiency in the presence of RCM, while user privacy is reinforced.

The group will generate documents regarding the state of affairs of RCM, and a *Best Current Practices* (BCP) document recommending a means to reduce the impact of RCM on the documented use cases while ensuring that the privacy achieved with RCM is not compromised. For scenarios where device identity stability is desirable, the BCP document will recommend existing protocols that you can use to protect the request and exchange of identifiers between the client and the service provider.

The MADINAS Working Group is focused on coordination with other IETF Working Groups (for example, DHC and IntArea). In addition, it actively liaises with other relevant organizations, such as IEEE 802 and the Wireless Broadband Alliance. The objective is to coordinate on the different recommendations, as well as planning potential follow-up activities within or outside the IETF.

It is expected that the outcome from the coordinated efforts among these standards organizations will enable the use of RCM in the different scenarios previously analyzed, providing both privacy and the operational characteristics about the quality of user experience and network efficiency that each one of the scenarios requires.

JUAN CARLOS ZÚÑIGA is a technology and business development trilingual leader with more than 20 years of international experience. He currently leads wireless standardisation and IP efforts within the Global Technical Standards team at Cisco Systems. He has extensive experience with heterogeneous Radio Access Networks and 4G/5G Core network cloud technologies. Juan is an active thought leader and contributor in different standards and industrial fora, such as IETF, IEEE 802, ISOC, ETSI, 3GPP SA/CT/RAN, ITU, W3C, and GS1. He has strong experience developing, managing, analyzing, and developing international intellectual property (IPR) patent portfolios. He has been granted patents for more than 70 USPTO/EPO inventions and over 100 published applications. Juan holds several recognitions and awards. E-mail: juzuniga@cisco.com

JEROME HENRY is a Principal Engineer in the Enterprise Infrastructure and Solutions Group at Cisco Systems. Jerome joined Cisco in 2012. Before that time, he consulted and taught about heterogeneous networks and wireless integration with the European Airespace team, which Cisco later acquired to become its main wireless solution. Jerome holds more than 150 patents, is a member of the IEEE, where he was elevated to Senior Member in 2013, and also represents Cisco in multiple Wi-Fi Alliance working groups. With more than 10,000 hours in the classroom, Jerome was awarded the IT Training Award Best Instructor silver medal. He is based in Research Triangle Park, North Carolina. E-mail: jerhenry@cisco.com

ALAIN MOURAD is an award-winning innovator with over 20 years of experience in the Research and Development of wireless technologies spanning four generations of cellular systems (3G/4G/5G and heading towards 6G). He currently heads the Future Wireless Europe Research and Innovation Lab at InterDigital in London (UK). Prior to InterDigital, Alain was a Principal Engineer at Samsung Electronics Research and Development and a Senior Engineer at Mitsubishi Electric R&D Centre Europe, where he was active in the specification of wireless standards (3GPP, IEEE802, DVB, and ATSC). E-mail: Alain.Mourad@interdigital.com

Twenty-Five Years Later

by Geoff Huston, APNIC

The Internet is not quite as young and spritely as you might have thought. Apple's iPhone, released in 2007, is now 16 years old, and YouTube is an ageing teenager at 18 after its initial release in 2005, and these two examples are relatively recent additions to the Internet. The first web browser, Mosaic, was released some 30 years ago in 1993. Going back further, the Internet emerged from its early *Advanced Research Projects Agency* (ARPA) roots in the form of the *National Science Foundation Network* (NSFNET) in 1986. At the start of 1983, the *ARPA Network* (ARPANET) had a flag day and switched over to use the *Transmission Control Protocol* (TCP). Going back further, in 1974 Vint Cerf and Bob Kahn published the first academic paper describing the protocol and the underlying architectural framework of a packet-switched network that became the Internet. This achievement was built upon earlier foundations, where numerous efforts in the late 1960s showed the viability of a *packet-switched* approach to computer networking. These packet-switched networking efforts included a program led by Donald Davies at the UK National Physics Laboratory, an effort in the US in the form of an ARPA project led by Larry Roberts, and Louis Pouzin's work in France with the CYCLADES network. This work, in turn, has some of its antecedents in work by Paul Baran at the RAND Corporation on distributed communications and packet-switched networks, published between 1960 and 1964. The Internet has managed to accumulate a relatively lengthy pedigree.

And it has been a wild ride. The Internet has undergone numerous cycles of economic boom and bust, each of which is right up there with history's finest episodes of exuberant irrational mania. It has managed to trigger a comprehensive restructuring of the entire global communications enterprise and generated a set of changes that have already altered the way in which we now work and play. That's quite a set of achievements in just 25 years!

We should start this exploration of our past some 25 years ago in 1998 at the time of publication of the first edition of the *Internet Protocol Journal*. At that time, any lingering doubts about the ultimate success of the Internet as a global communications medium had been thoroughly dispelled. The Internet was no longer just a research experiment, or an intermediate way stop on the road to adoption of the *Open Systems Interconnection* (OSI) framework. By 1998 there was nothing else left standing in the data communications landscape that could serve our emerging needs for data communications. The *Internet Protocol* (IP) was now the communications technology for the day, if not for the coming century, and the industry message at the time was a clear one that said: "adopt the Internet into every product and service or imperil your entire future in this business."

No longer did the traditional telecommunications enterprises view the Internet with some polite amusement or even overt derision. It was now time for a desperate scramble to be part of this revolution in one of the world's major activity sectors. The largest enterprises in this sector, the old-world ex-monopoly telcos, had been caught wrong-footed in one of the biggest changes of the industry for many decades, and this time the concurrent wave of deregulation and competition meant that the future of the communications industry was being handed over to a small clique of Internet players.

By the early 2000s, the Internet had finally made it into the big time. The job was apparently done, and the Internet had prevailed. But then came a new revolution, this time in mobility services, where after numerous clumsy initial efforts by others, the iPhone entered the market with a seamless blend of sleek design and astounding capability. The mobile carriage sector struggled to keep up with the new levels of rapacious demand for Internet-based mobile data. The Internet then took on the television networks, replacing the incumbent broadcast and cable systems with streaming video. But the story is not over by any means. Communications continues to drive our world, and the Internet continues to evolve and change.

The evolutionary path of any technology can often take strange and unanticipated turns and twists. At some points simplicity and minimalism can be replaced by complexity and ornamentation, while at other times a dramatic cut-through exposes the core concepts of the technology and removes layers of superfluous additions. The technical evolution of the Internet appears to be no exception, and this story contains these same forms of unanticipated turns and twists.

Rather than offer a set of unordered observations about the various changes and developments over the past 25 years, I will use the traditional protocol stack model as a template, starting with the underlying transmission media, then looking at IP, the transport layer, then applications and services, and closing with a look at the business of the Internet.

Transmission

It seems like a totally alien concept these days, but the *Internet Service Provider* (ISP) business of 1998 was still based around the technology of dial-up modems. The state-of-the-art of modem speed had been continually refined, from 9600 bps to 14.4 kbps, to 28 kbps, to finally 56 kbps, squeezing every last bit out of the phase amplitude space contained in an analogue voice circuit. Analogue modems were capricious, constantly being superseded by the next technical refinement, unreliable, difficult for customers to use, and on top of that, they were slow! Almost everything else on the Internet had to be tailored to download reasonably quickly over a modem connection. Web pages were carefully composed with compressed images to ensure a rapid download, and plain text was the dominant medium as a consequence. It could only get better.

The evolution of access networks was initially one that exposed the inner digital core of the network out to the edges. The first approach was *Integrated Services Digital Network* (ISDN), where the underlying digitised voice circuit was drawn out to the network edge. At 64 kbps, this level of improvement was inadequate, and the next major step was to use *Digital Subscriber Line* (DSL) technology. DSL used the last mile of the network for an analogue channel, but instead of running a single low-speed bearer signal, DSL layered a large collection of individual bearer signals into the single circuit, performing a form of frequency division multiplexing on the basic analogue circuit in a trellis framework. DSL relied on the combination of the telephone company's efforts to operate the copper access circuits within a base level of signal quality and noise suppression, and the modem industry's continual incremental improvements in digital-signal-processing capability. Surprisingly, DSL achieved speeds of tens of megabits per second through these legacy copper access networks. However, DSL was largely an interim holding position while the search for a viable business model that could underwrite the costs of deployment and use of an open fibre-based access networks was underway.

The transition into fixed-wire access networks based on fibre-optic cable continues. The challenge is not in finding a suitable technology for fibre, but one of finding a suitable business model than can sustain the necessary capital investment in replacing the existing copper-based infrastructure. Some national communities used a model of a public-sector program, such as the *National Broadband Network* program in Australia, while others have remained as dedicated private-sector activities, and others have taken a hybrid approach with some level of local public-sector incentives being added into a private-sector program. The issue here is that fixed wire residential access networks do not offer compelling investment opportunities in most cases, with the high initial capital costs and the generally inadequate levels of take-up across the dwellings passed by the access infrastructure acting as disinhibitory factors. It is often the case that a residential community cannot support multiple access network deployments, bringing up the related issue of local access monopolies and the challenge of permitting some level of competitive access across a single physical access network. Nevertheless, fibre access rollouts continue across many parts of the world, and the transition of the wired copper network into a fibre access network capable of sustaining hundreds of megabits per connection is still progressing, seemingly in spite of the financial barriers that exist in many scenarios.

Mobile

The mobile network has experienced a completely different evolution, and for many years now the mobile sector has been demand-driven. The first mobile data service networks, introduced in the 1980s, were little more than low-speed digital encoders working across a single voiceband circuit. These 1G networks typically delivered a 2.4-kbps data download capacity.

The next generation of mobile services, 2G, was used in the 1990s. It was still predominately a voice service, and while it could theoretically support data access at speeds of 100 kbps, this data-transfer rate was largely aspirational, and the mobile network was predominantly used by the *Short Message Service* (SMS) as an adjunct to voice. The intersection of the Internet and mobile services occurred with the introduction of 3G mobile services. The 3G architecture could push IP connectivity directly out to the handset, supporting data-transfer speeds of 1–2 Mbps. This network capability, coupled with a new generation of handsets, first with the BlackBerry in 2002 and then the iPhone in 2007, transformed the mobile service into a mass-market consumer service. The high margins available from the service captured the attention of the traditional voice industry, and the result was a large-scale opening up of radio spectrum to create an Internet access environment that quickly rivalled the wire-line access market in size, but totally outpaced it in terms of revenue margins. This massive escalation of demand created further pressures on the capacity of the mobile system, and in 2009 the mobile sector introduced 4G services, opening up more spectrum bands, and also adding *Multiple-Input Multiple Output* (MIMO) to the mobile device to achieve greater deliverable capacity to each connected device. Over time these services were to deliver peak download speeds of 50 to 100 Mbps. The industry was also selling hundreds of millions of mobile devices per year. 4G dispensed with circuit-switched services, and it exclusively used packet switching. In 2018 5G was introduced. 5G can be supported over more spectrum bands, including a high-band millimetre spectrum at 24–47Ghz. These higher carrier frequencies permit multi-gigabit data services, but they come at a cost of higher density of base-station towers to compensate for the lower propagation distances.

Wi-Fi and Bluetooth

A second radio technology that has also transformed the Internet emerged in 1998, and it could be argued that it has become so fundamental that it has weaved itself so naturally into our environment that it all but disappeared. The combination of low-power radio systems and unlicensed radio spectrum allocation, or *Wi-Fi*, and subsequently *Bluetooth*, has been transformational. The combination of efficient battery technology, computer chips that operate with low power consumption, and the unwiring of the last few meters in the home and office completely changed our collective of technology, and it is only because of our desire to use products that are portable, unobtrusively wearable, and powerful enough to be useful that the component technologies such as batteries and processors have been pushed in this direction over this period. While large bands of radio spectrum space have been allocated to cellular mobile service operators, the intensity of use and the utility of use of radio spectrum peaks in the unlicensed spectrum space used by Wi-Fi and Bluetooth. It could be argued that the economic value of these unlicensed spectrum bands exceeds the exclusively licensed cellular radio systems by orders of magnitude. It could also be argued that the untethering of the last meter of the Internet transformed the Internet, and digital technologies in general, from a specialist pursuit into the consumer product space.

In the 1990s we described the effort to simplify the use of technology through the term “plug and play.” Wi-Fi was the critical technical development that made that term irrelevant by removing any need for the plug, or the socket for that matter!

Satellite

Mobile data services, Wi-Fi, and Bluetooth really revolutionised the Internet, taking it from a “destination you visit” to an “always-on utility in your pocket.” The Internet was now a set of applications on a device that went with you everywhere. Always available, always connected, no matter where you might be or what you might be doing. But that was not exactly the full truth. Head out into remote country far enough, or head onto the world’s oceans, and your connection options quickly disappeared, leaving only somewhat expensive satellite-based services.

These satellite services have been in operation since the early 1960s, but the high launch costs, limited capacity, and competing interests of terrestrial providers have meant that these services were often operated at the margins of viability. The best example is Motorola’s *Iridium* project of the late 1990s, where even before the entire service constellation of satellites was launched, the \$5B Iridium project was declared bankrupt. *Starlink*, a recent entrant in the satellite service area, is using a constellation of some 4,000 low-earth-orbiting spacecraft and appears so far to have been able to break through this financial barrier. Using reusable launch vehicles, smaller (and lighter) satellites, transponder arrays on board, and a new generation of digital-signal-processing capabilities, Starlink is in a position to offer retail access services of 100 Mbps or more to individual customers. The low altitude of the spacecraft means that the Starlink service competes directly with terrestrial access services in terms of performance. The introduction of inter-spacecraft laser links means that the system can provide a service in any location, and the limiting factor, as with the Iridium effort decades ago, is obtaining the necessary clearances and licenses to have customers located in the respective national geographies. Starlink is certainly revolutionary in terms of capacity, coverage, and cost. The questions are whether it is sufficiently revolutionary and whether it can scale up to provide a high-capacity service to hundreds of millions of users. At this point in time these questions are not easy to answer, but the limitations inherent in *Low Earth Orbit* (LEO)-based services point to a potential advantage in terrestrial-based access networks. Nevertheless, Starlink is redefining the Internet access market space in many countries, and setting price/performance benchmarks that their terrestrial competitors now have to match.

If we move away from access networks to look at the changes in the “core” of the Internet over the past 25 years, then once more we can see a dramatic change. In 1998, the Internet was constructed using the margins of oversupply in the telephone networks. In 1998, the core infrastructure of most ISPs was still being built by leasing telephone trunk supergroups (E-1 and T-1 circuits, and then E-3 and T-3 as capacity needs escalated, and then OC-1 circuits).

While it was not going to stop here, squeezing even more capacity from the network was now proving to be a challenge; 622-Mbps IP circuits were being deployed, although many of them were constructed using 155-Mbps *Asynchronous Transfer Mode* (ATM) circuits using router-based load balancing to share the IP load over four of these circuits in parallel. Gigabit circuits were just around the corner, and the initial exercises of running IP over 2.5-Gbps *Synchronous Digital Hierarchy* (SDH) circuits were being undertaken in 1998.

In some ways 1998 was a pivotal year for IP transmission. Until this time, IP was still just one more data application that was positioned as just another customer of the telco's switched-circuit infrastructure. This telco infrastructure was designed and constructed primarily to support telephony. From the analogue voice circuits to the 64K digital circuit through to the higher-speed trunk bearers, IP had been running on top of the voice network infrastructure. Communications infrastructure connected population centres where there was call volume. The Internet had different demands. Internet traffic patterns did not mirror voice traffic, and IP performance is sensitive to every additional millisecond of delay. Constraining the Internet to the role of an overlay placed on top of a voice network was showing signs of stress, and by 1998 things were changing. The Internet had started to make ever larger demands on transmission capacity, and the driver for further growth in the network infrastructure was now not voice, but data. It made little sense to provision an ever-larger voice-based switching infrastructure just to repackage it as IP infrastructure, and by 1998 the industry was starting to consider just what an all-IP high-speed network would look like, building an IP network all the way from the photon in a fibre-optic cable all the way through to the design of the Internet application.

Fibre Optics

At the same time, the fibre-optic systems were changing with the introduction of *Wave Division Multiplexing* (WDM). Older fibre equipment with electro-optical repeaters and *Plesiochronous Digital Hierarchy* (PDH) multiplexors allowed a single fibre pair to carry around 560 Mbps of data. WDM allowed a fibre pair to carry multiple channels of data using different wavelengths, with each channel supporting a data rate of up to 10 Gbps. Channel capacity in a fibre strand was between 40 and 160 channels using *Dense WDM* (DWDM). Combined with the use of all-optical amplifiers, the most remarkable part of this entire evolution in fibre systems is that a cable system capable of an aggregate capacity of a terabit can be constructed today for much the same cost as a 560-Mbps cable system of the mid-1990s. That's a cost-efficiency improvement of a factor of one million in a decade. The drive to deploy these high-capacity DWDM fibre systems was never based on expansion of telephony. The explosive growth of the industry was all about supporting the demand for IP. So, it came as no surprise that at the same time as the demand for IP transmission was increasing there was a shift in the transmission model where instead of plugging routers into telco switching gear and using virtual point-to-point circuits for IP, we started to plug routers into wavelengths of the DWDM equipment and operate all-IP networks in the core of the Internet.

DWDM is not the only technology that has fundamentally changed these core transmission systems in the past 25 years. Two further technologies have been transformational in the fibre-optic area. The first is the use of optical amplifiers. *Erbium Doped Fibre Amplifiers* provide a highly efficient means of signal amplification without the need to convert the signal back into a digital form and then passing it back through a digital/analogue converter to modulate the next-stage laser driver. This technology has allowed fibre systems to support terabit-per-second capacity without necessarily having to integrate terabit-per-second digital systems. The second fundamental change was a switch in signal modulation from a basic on/off signal into a signal modulation technique that uses signal-phase amplitude and polarity to increase the total capacity of a wavelength within a fibre strand. *Digital Signal Processors* (DSPs) offered the key technology here, and as we improve on the track width of conductor tracks in these processors we can increase the gate count on a single chip, thereby allowing support for more complex signal manipulation algorithms. These algorithms can be used to increase the sensitivity of the DSP function. In 2010, we were using 40-nm track silicon chips in DSPs, supporting *Polarization Mode Quadrature Phase Shift Keying* (PM-QPSK), which allowed a cable to operate with 100-Gbps data rates in a single wavelength, or an aggregation of 8 Tbps in a fibre strand. In 2023, DSPs now use 5-nm tracks, which can support PCS-144QAM modulation of a base 190-Gbaud signal, which can support 2.2-Tbps data rates per wavelength, or 105-Tbps total capacity per fibre strand. A 12-strand cable would have a total capacity of 1.2 Pbs.

Such very-high-performance fibre cable systems are generally used in submarine cable systems to link data centres between continents. In data-centre contexts and other terrestrial scenarios, we are now using 200- and 400-G per wavelength fibre system as the common technology base. The major outcome is that, in general, transmission is no longer a scarce resource. It is in every sense of the term an abundant commodity. There is no sense in rationing access to communications capacity, be it short or long haul. This change is a major one not only in the economic framework of the communications industry, but also in phrasing the way in which we use communications. In a scarce system, we tend to use “just-in-time” delivery mechanisms, passing content across the communications system only when it is needed, while an abundant system allows us to use “just-in-case” delivery mechanisms, causing a dramatic impact on the architecture of the Internet. Indeed, this extraordinary increase in the underlying capacity of our communications infrastructure through the past 25 years is perhaps the most significant change in the entire landscape of the Internet, as we will see when we look at content networking.

Network Management

In network operations, we are seeing some stirrings of change, but it appears to be a rather conservative area, and adoption of new network management tools and practices takes time.

The Internet converged on using the *Simple Network Management Protocol* (SNMP) more than a quarter of a century ago, and despite its security weaknesses, its inefficiency, its incredibly irritating use of *Abstract Syntax Notation One* (ASN.1), and its application in sustaining some forms of *Distributed Denial-of-Service* (DDoS) attacks, it still enjoys widespread use. But SNMP is only a network monitoring protocol, not a network configuration protocol, as anyone who has attempted to use SNMP write operations can attest. The more recent *Network Configuration Protocol* (NETCONF) and *Yet Another Next Generation* (YANG) data modelling languages are attempting to pull this area of configuration management into something a little more usable than *Command-Line Interface* (CLI) scripts driving interfaces on switches.

At the same time, we are seeing orchestration tools such as *Ansible*, *Chef*, *Network Automation and Programmability Abstraction Layer with Multivendor* (NAPALM), and *Salt* enter the network operations space, permitting the orchestration of management tasks over thousands of individual components. These network operations-management tools are welcome steps forward to improve the state of automated network management, but it's still far short of a desirable endpoint. The desired endpoint of a fully automated network-management framework is still far from our reach. Surely it must be feasible to feed an adaptive autonomous control system with the network infrastructure and available resources, and allow the control system to monitor the network and modify the operating parameters of network components to continuously meet the service-level objectives of the network? Where is the driverless car for driving networks? Maybe the next 10 years will get us there.

The Internet Layer

If our transmission systems have been subject to dramatic changes in the past quarter century, then what has happened at the IP layer over the same period?

First, we need to consider the “elephant” in the Internet layer room. One fundamental change at the Internet level of the protocol stack was meant to have all happened some 20 years ago, and that's the transition to IP version 6. Twenty-five years ago, in 1998, we were forecasting that we would have consumed all the remaining unallocated IPv4 addresses by around 2025. That estimate gave us slightly more than 25 years, so there was no particular sense of urgency. We didn't need to ring the emergency bell or raise any alarms. The overall aim was to proceed in an orderly manner. Things took a different course because we failed to appreciate the true impact of the shift of the Internet to mobile devices. All of a sudden, we were dealing with an Internet with billions of users, using billions of new mobile devices, and our comfortable predictions of a stately and steady run-down of the IPv4 address pools were discarded about as quickly as you could say the word “iPhone.” From “all the time in the world” we reached “no time left to do anything” within a year.

In the 5-year period between 2005 and 2010, when mobile services exploded in volume, the total count of allocated IP addresses rose from 1.5B addresses to 3.1B, from a total address pool of 3.7B addresses. The network had doubled in size, and the time left to complete the transition had shrunk from more than 20 years to a little over 1!

At that point, all the plans for an orderly transition were discarded, and many network administrators scrambled to obtain IPv4 addresses, further depleting the IPv4 pools. The central pool of IPv4 addresses, operated by the *Internet Assigned Numbers Authority* (IANA), was exhausted in February 2011. The *Asia Pacific Network Information Centre* (APNIC) depleted its IPv4 pool in April of that year, the *Réseaux IP Européens Network Coordination Centre* (RIPE NCC) 18 months later, the *Latin America and Caribbean Network Information Centre* (LACNIC) in 2014, and the *American Registry for Internet Numbers* (ARIN) in 2015. We had expected that this situation would motivate network operators to hasten their plans for IPv6 deployment, yet, perversely, that did not happen. Less than 1% of the Internet user base was using IPv6 in 2011. Five years later, as each of the *Regional Internet Registries* (RIRs) ran down their remaining pools of IPv4 addresses, this Internet-wide IPv6 user count had increased to just 5%. In 2023, the process is still underway, and some 35% of the Internet user base has IPv6 capability. I'm not sure anyone is willing to predict how long this anomalous situation of running the IPv4 Internet "on an empty tank" will persist.

NATs

How has the Internet managed to continue to operate, and even grow, without a supply of new IPv4 addresses? In a word, the answer is "NATs." While the *Network Address Translator* (NAT) concept received little fanfare when it was first published, it has enjoyed massive deployment over the past 25 years, and today NATs are ubiquitous. The application architecture of the Internet has changed, and we are now operating a client/server framework. Servers have permanent IP addresses, while clients "borrow" a public IPv4 address to complete a transaction and return it back to a common pool when they are done. Time-sharing IP addresses, and also using the 16-bit source port field in TCP and the *User Datagram Protocol* (UDP), has managed to extend the IPv4 address space by some 20 bits, making the IPv4+NAT address space up to a million times larger than the original 32-bit IPv4 address space. In practice, the story is a little more complicated than that, and some very large service providers have reached logistical limits in using NATs to compensate for the exhaustion of IPv4 addresses. This situation has motivated these providers to transition to a dual-stack mode of operation, and they are relying on a dual-stack host behaviour that prefers to use IPv6 when possible, thus relieving the pressure on the IPv4 NAT functions

NATs have prompted a significant change at the IP level in changing the default assumption about the semantics of an IP address. An IP address is no longer synonymous with the persistent identity of the remote party, but it has assumed the role of an ephemeral session token.

The leisurely pace of the IPv6 transition is partly due to this altered role of addresses, as we no longer require every connected device to have a persistently assigned globally unique IP address.

IPv6 and NATs are not the only areas of activity in the Internet layer in the past 25 years. We have tried to change many parts of the Internet layer, but interestingly, few, if any, of the proposed changes have managed to gain any significant traction out there in the network. The functions performed at the Internet layer of the protocol stack are no different from those of 25 years ago. IP Mobility, Multicast, and *IP Security* (IPSec) are largely Internet layer technologies that have failed to gain significant levels of traction in the marketplace of the public Internet.

QoS *Quality of Service* (QoS) was a “hot topic” in 1998, and it involved the search for a reasonable way for some packets to take some form of expedited path across the network, while other packets took an undifferentiated path. We experimented with various forms of signalling, packet classifiers, queue-management algorithms, and interpretations of the *Type of Service* bits in the IPv4 packet header, and we explored the QoS architectures of *Integrated and Differentiated Services* in great detail. However, QoS never managed to get established in mainstream Internet service environments. In this case, the Internet took a simpler direction, and in response to not enough network capacity we just augmented the network to meet demand.

Again, this is an aspect of the altered mindset when the communication system shifts from scarcity and rationing to one of abundance. We have given up installing additional intricate mechanisms in the network, in host protocol stacks, and even in applications to negotiate how to share insufficient network capacity. So far, the simple approach of just adding more capacity to the network has prevailed, and QoS remains largely unused.

MPLS The switch from circuit switching to packet switching has never managed to achieve universal acceptance. We have experimented with putting circuits back into the IP datagram architecture in various ways, most notably with the *Multi-Protocol Label Switching* (MPLS) technology. This technology used the label-swapping approach that was previously used in X.25, *Frame Relay* and ATM virtual circuit-switching systems, and it created a collection of virtual paths from each network ingress to each network egress across the IP network. The original idea was that in the interior of the network you no longer needed to load up a complete routing table into each switching element, and instead of performing destination-address lookup you could perform a much smaller, and hopefully faster, label lookup. This performance differentiator did not eventuate and switching packets using the 32-bit destination address in a fully populated forwarding table continued to present much the same level of cost efficiency at the hardware level as virtual circuit label switching.

However, one aspect of MPLS and similar approaches has proved to be invaluable for many network operators. A general-purpose network utility has many disparate client networks, and a single packet-switched environment does not allow the network operator to control the way in which the common network resource is allocated to each client network. It also does not readily support segmentation of reachability. Virtual circuit overlays, such as MPLS, provide mechanisms to control resource allocation and constrain cross-network leakage, and for many network operators these reasons are adequate to head down an MPLS-like path for their network platform.

Routing

Moving sideways at this level of the protocol stack, we probably should look at the evolution of routing technologies. The early 1990s saw a flurry of activity in the routing space, and various routing protocols were quickly developed and deployed. By 1998 the conventional approach to routing was to use either *Intermediate System-to-Intermediate System* (IS-IS) or *Open Shortest Path First* (OSPF) as the interior routing protocol, and the *Border Gateway Protocol* (BGP) as the inter-domain routing protocol. This picture has remained constant right up to today. In some ways, it is reassuring to see a basic technology that can sustain a quite dramatic growth rate through many years of scaling, but in other ways it is less reassuring to see that the unresolved issues we had with the routing system in 1998 are largely still with us today.

The largest of these unresolved issues lies in the trust we place in the inter-domain routing system of the Internet. There is no overall orchestration of the routing system. Each network advertises reachability information to its adjacent networks and selects what it regards as the “best” reachability information from the set received from these same network peers. This mutual trust that each network places in all other networks can, and has, been abused in various ways. The effort to allow each routing entity to distinguish between what is a “correct” item of routing information and what is a “false” route has a rich history of initiatives that have faltered for one reason or another. The most recent effort in this space is built upon the foundations of the number system, and it uses the association of a public/private key pair with the current holders of addresses and autonomous system numbers, allowing these holders to issue signed authorities about the use of these number resources in the context of routing, and by coupling these authorities with the information being propagated in the routing system, the intention being that unauthorized use cases will be detected.

RPKI

This effort, the *Resource Public Key Infrastructure* (RPKI), has achieved some level of acceptance in the networking space, and in 2023 around one-third of all route objects have associated RPKI credentials. The work is still “in progress” because the more challenging aspect of this work is to associate verifiable credentials with the propagation route through a network that does not impose onerous burdens on the routing system and is not overly fragile in its operation.

The extended period where the routing system has operated in a state that essentially cannot be trusted has prompted the application layer to generate its own mechanisms of trust. These days it is largely left to *Transport Layer Security* (TLS) to determine whether a client has reached its intended server. Given that we have been unable to construct a secured routing system for many decades, the question arises whether there is still the same level of need for such a system that we had some 25 years ago, given that the application space sees this problem as largely solved through the close-to-ubiquitous use of TLS.

This tension between the Internet layer and the upper layers of the protocol stack is also evident in the way in which we have addressed the perennial issue of location and identity. One of the original simplifications in the IP architecture was to bundle the semantics of identity, location, and forwarding into an IP address. While that has proved phenomenally effective in terms of simplicity of applications and simplicity of IP networks, it has posed some serious challenges when considering mobility, routing, protocol transition, and network scaling. Each of these aspects of the Internet would benefit considerably if the Internet architecture allowed identity to be distinct from location. Numerous efforts have been directed at this problem over the past decade, particularly in IPv6, but so far, we really haven't arrived at an approach that feels truly comfortable in the context of IP. The problem we appear to have been stuck on for the past decade is that if we create a framework of applications that use identity as a rendezvous mechanism and use an IP layer that requires location, then how is the mapping between identity and location distributed in an efficient and suitably robust manner? The transport layer of the protocol stack has also looked at the same space and developed some interesting approaches, as we will see in the next section.

Transport

Back in 1998 the transport layer of the IP architecture consisted of UDP and TCP, and the network use pattern was around 95% TCP and 5% UDP. It has taken all of the intervening 25 years, but this picture has finally changed.

We have developed some new transport protocols in this period, such as the *Datagram Congestion Control Protocol* (DCCP) and the *Stream Control Transmission Protocol* (SCTP), which can be regarded as refinements of TCP to extend a flow-control mechanism to apply to datagram streams in the case of DCCP and a shared flow-control state over multiple reliable streams in the case of SCTP. However, in a world of transport-aware middleware that has been a constant factor over this period, the level of capability to actually deploy these new protocols in the public Internet is marginal at best. Firewalls do not recognize these more recent transport protocols, NATs and similar, and as a result, the prospects of wide-scale deployment of such protocols in the public Internet are not very good. We seem to be firmly stuck in a world of TCP and UDP.

TCP has proved to be remarkably resilient over the years, but as the network increases in capacity the ability of TCP to continue to deliver ever-faster data rates over distances that span the globe is becoming a significant issue. Much work has been done to revise the TCP flow-control algorithms so that they still share the network fairly with other concurrent TCP sessions yet can ramp up to multi-gigabit-per-second data-transfer rates and sustain those rates over extended periods of time. The mainstream TCP flow-control protocol has been shifting from the conventional Reno-styled protocol to CUBIC, which attempts to find a stable sending rate and then slowly add flow pressure to the network path to see if the network can support greater sending rates. The response to packet drop remains a dramatic rate drop, but not quite as dramatic as the rate halving of Reno, but nevertheless it is still a drop-sensitive ack-paced flow-control protocol.

However, the picture has changed with the introduction of the *Bottleneck Bandwidth and Round-Trip* (BBR) protocol. Driving the network into the point not only of network queue formation, but right to the point of queue overflow and packet loss, is a crude approach. The problem here is that packet loss represents a loss of feedback, and in a feedback-based flow-control protocol, this loss of feedback pushes the protocol into a space where it has to pull back its sending rate to re-establish a signal flow. BBR represents a different way of looking at flow control, and it attempts to drive the flow to the point of the onset of queue formation in the network rather than aiming at the point of queue collapse. This process reduces the latency of the flow and the cost of network switching equipment by reducing the very-high-speed fast memory buffer requirements.

This area is not the only one of new experimentation in changing the TCP congestion-control, paradigm. Another approach is being explored in the *Low Latency Low Loss Scalable* throughput initiative (L4S), which is looking at incorporating network signals into the flow-control algorithm. Here the packet switches use the *Explicit Congestion Notification* (ECN) signal in the IP header when standing queues start to form. The receiver of this signal is expected to back off its sending rate in a manner similar to packet loss. The advantage of this approach is that there is no loss of feedback signalling, and the flow reacts to the formation of congestion conditions rather than the end point of queue collapse. However, ECN requires the deployment of ECN-marking equipment, and the effort of synchronising network equipment and transport-protocol behaviours is far greater when compared to protocol-only approaches such as BBR.

Other initiatives in the transport space that are also worthy of note include Multipath TCP and QUIC.

The first of these initiatives is *Multipath TCP*. The observation here is based around the increasing ubiquity of both Wi-Fi and cellular radio services, and the configuration of most mobile devices to include the ability to access both of these networks.

In general, the choice of which network interface to use is a single decision made by the mobile platform for all active applications. When a usable Wi-Fi network is detected, the device will prefer to use that connection for all new connections because it is assumed that the Wi-Fi service will be cheaper for the user and will operate at a higher performance level. But if performance and resilience are issues, then can we allow a TCP session to use *all* the available networks at once, and optimise its use of these multiple network paths to the destination such that the total data throughput is optimised? This is the objective of Multipath TCP, where a single TCP session is broken into numerous sub-sessions, where each sub-session uses a different network path by using a different local network interface.

Multipath TCP allows separate TCP states to control the flows passing across each network path to optimise throughput. It also can permit flow migration, allowing a logical TCP flow to switch from one network path to another while preserving integrity. The interesting aspect of this behaviour is that the control of the multipath behaviours is, in the first instance, under the control of the application rather than the host platform. This response was an early one to recognize the increasing capacity and diversity in edge networks, and how we could respond to this situation at the transport session level.

QUIC

The second initiative, which for me is a fundamental change in transport capabilities and functions, is the introduction of the QUIC protocol. At its simplest level, you could say QUIC is a packaging of the combination of TCP and TLS into a UDP wrapping. However, I would suggest that such a description is well short of the mark. QUIC is in many ways a far more ambitious transport protocol, bringing transport to the point where it is better suited to the current application behaviour. QUIC is intended to improve the transport performance for encrypted traffic with faster session setup. QUIC allows for further evolution of transport mechanisms with support for *Remote Procedure Calls* (RPC). QUIC also has integral support for concurrent session multiplexing that avoids TCP head-of-line blocking. QUIC encrypts the payload data, but unlike TLS, QUIC also encrypts the control data (the equivalent of the TCP header) and explicitly avoids the emerging TCP ossification within the network by occluding the entirety of the control exchange from the network of the session. QUIC is address agile, in that it can react to network-level address renumbering in an active QUIC session, as can occur with the presence of NATs on the network path. You can implement QUIC in user space, so applications can control their own transport functions. There is no longer a dependence on the platform in terms of the quality of the implementation of the transport service. With QUIC the application exercises a comprehensive level of control of the way the application interacts with the network.

Numerous lessons can be drawn from the QUIC experience. Any useful public communications medium needs to safeguard the privacy and integrity of the communications that it carries.

The time when open protocols represented an acceptable compromise between efficiency, speed, and privacy are over, and these days all network transactions in the public Internet need to be protected by adequate encryption. The QUIC model of wrapping a set of transactions, including both data and control transactions between a client and a server, into an end-to-end encryption state represents a minimum level of functionality in today's networking environment.

Secondly, QUIC provides needed additional transport functionality. TCP and UDP represent just two points of transport functions within a broader spectrum of possible transport models. UDP is just too susceptible to abuse, so we have heaped everything onto TCP. The issue is that TCP was designed as an efficient single streaming protocol, and retrofitting multiple sessions, short transactions, remote procedure calls, reliable single-packet transactions, and shared congestion states have proved to be impossible to implement in TCP.

Applications are now dominant in the Internet ecosystem, while platforms and networks are being commoditised. We are seeing loss of patience with platforms that provide common transport services for the application that they host, and a new model where the application comes with its own transport service. Taking an even broader perspective, the context of the success of the Internet lies in shifting the responsibility for providing service from the network to the end system. This shifting allowed us to make more efficient use of the common network substrate and push the cost of this packetization of network transactions over to end systems.

It shifted the innovation role from the large and lumbering telco operators into the nimbler world of software. QUIC takes it one step further, and pushes the innovation role from platforms to applications, just at the time when platforms are declining in relative importance within the ecosystem. From such a perspective, the emergence of an application-centric transport model that provides faster services, a larger repertoire of transport models, and encompassing comprehensive encryption were inevitable developments.

We have pushed the responsibility for end-to-end authentication into the transport layer with the close-to-ubiquitous TLS. TLS layers themselves above TCP (or merges with the TCP-like function in the case of QUIC), and the client passes the name of the service it intends to connect with to the remote server. The server passes its public key to the client, and the client authenticates this key using its own trust anchors. The server and client then negotiate a session key and proceed with an encrypted session. TLS is robust in almost every respect. Its major weakness lies in the highly distributed trust model, where there are hundreds of different operators of trusted credentials (certification authorities) and thousands of various registration agents. These entities are placed in a highly trusted role, and they can never lie.

The problem is that they have proved to be corruptible occasionally. They typically operate using online services, and a successful attack against such platforms can be abused to allow the issuance of trusted public certificates. We have invested considerable time and effort in shoring up this trust framework, but at the same time we have been working to make these public key certificates a commodity rather than an expensive luxury. The introduction of free certification authorities has succeeded in making these certificates available to all, but at the same time the totally automated certificate issuance process is liable to various forms of abuse. Despite these considerations, we have placed the entirety of the burden of service authenticity and session encryption onto TLS, to the point that other related efforts, such as IPsec, BGP routing security, and *Domain Name System Security Extensions* (DNSSEC) in the DNS, are generally perceived as optional extras rather than basic essentials to be included the security toolkit.

Applications and Services

This layer has also seen quite profound changes over the past quarter century, tracking the progress of increasing technical capability as well as consumer demands. In the late 1990s, the Internet was on the cusp of portal mania, where *LookSmart* was the darling of the Internet boom and everyone was trying to promote their own favourite “one stop shop” for all your Internet needs.

By 1998 the *AltaVista* search engine had made its debut, and these content-collation portals were already becoming passé. This change, from compiling directories and lists to active search, completely changed the Internet. These days we simply assume that we can type any query we want to into a search engine and the search machinery will deliver a set of pointers to relevant documents. And every time it occurs our expectations about the quality and utility of search engines are reinforced. Content is also changing as a result, as users no longer remain on a *site* and navigate around the site. Instead, users are driving the search engines, and pulling the relevant pages without reference to any other material. But it has not stopped there. Search engines are morphing into “instant answer machines,” where instead of providing a set of pointers to sources where there is a high level of correlation between the source and the question, the search engine attempts to extract material from the source and show what it believes is the answer to the implicit question in the search term. Even this process is just a way point in a longer journey, and today we are seeing *Artificial Intelligence* (AI) chat bots appearing, where the underlying data set that has been indexed by the search machinery is now being used as a corpus of data to drive an AI chat engine. The interaction is based on a natural language model.

If you thought of the Internet as an information resource, then the use of AI in this manner is a disturbing step. In this AI model the responding system generates plausible, but very definitely not necessarily factual, natural language responses to the implicit question in the query.

It's challenging to see this path from indexing data sources and matching query terms to the terms that primary sources use to one of a natural language generator that produces textual responses that are not grounded in facts, nor necessarily derived from primary sources, as being progress! Despite such misgivings about the deliberate abasement of the quality of the Internet as an information resource, this shift does fit into a larger picture of the transformation of the Internet to a mass entertainment vehicle, which is much of the driving force in today's content world.

Social Media

A related area of profound change has been the rise of social media. The television, radio, film, and print industries had evolved to use content mediators, compilers, and editors to curate their content, and the widespread deployment of highly capable user devices allowed end users to directly perform content production without the need to engage with mediators or producers. This situation has transformed many societies, and the social media platforms, including YouTube, Flickr, Facebook, Instagram, and TikTok, have been rocketed into societal prominence, prompting major debates about the role of these platforms and levels of societal influence that such platforms can generate.

Underlying these changes is another significant development, namely the change in the content economy. In 1998 content providers and ISPs were eyeing each other in an effort to gain user revenue. Content providers were unable to make pay-per-view and other forms of direct financial relationships with users work in their favour and argued that ISPs should fund content. After all, they pointed out, the only reason users paid for Internet access was the perceived value of the content they found there. ISPs, on the other hand, insisted that content providers were enjoying a "free ride" across the ISP-funded infrastructure, and content providers should contribute to network costs. The model that has gained ascendancy as a result of this unresolved tension is that of advertisement-funded content services, and this model has been able to sustain a vastly richer, larger, and more compelling content environment.

However, using this model comes at a price, and in this case the price lies in the motivations of the platforms that perform ad delivery. The critical objective now is to engage the user for longer periods, so that they can present more ads and glean more information about the user's profile. Merely informing a user is largely a transactional interaction, whereas entertaining a user can be far more lucrative in terms of generating advertising revenue because of the longer attention span. This model has been highly successful for some content players, particularly the current giants of streaming content, and it's therefore unsurprising that the largest entities in the content world, such as Alphabet, Microsoft, Amazon, and Apple, are more valuable in terms of market capitalization than their counterparts in the carriage world. We are now seeing the next round of the friction between content and carriage, where the access network operators are arguing that the content players should contribute to the costs of access carriage.

The *Domain Name System* (DNS) also merits a mention in this section. From one perspective, little has changed in this space, and the DNS name-resolution protocol hasn't changed to any appreciable extent. In some sense that's true, but at the same time there have been some significant changes.

DNS

The first of these changes is adoption of *Domain Name System Security Extensions* (DNSSEC), a framework that allows DNS clients to validate the answers that they receive from the DNS. The DNS has always been a point of security vulnerability in the Internet in that it has always been prone to various forms of attack where false answers are substituted in place of the genuine answer. DNSSEC provides a digital signature record to each normal record, and also implements an interlocked chain of signatures to link to the key associated with the root zone. A client may request the signature record to be provided with the normal response, and then make further requests to construct the validation chain all the way to the root zone. Successful validation assures a client that the data provided in the original response is authentic and current. The root zone of the DNS was first signed in 2010, but adoption of DNSSEC has been slow. While the addition of such a validation mechanism is undoubtedly a step forward in protecting users against various forms of name-based interference, the cost is increased fragility of the DNS and increased resolution times. One underlying problem is that the addition of digital signatures to a DNS response is highly likely to push the DNS into sending large responses, and large responses over a UDP-based transport is prone to fragmentation-based unreliability, and the switch to use TCP also takes time. What this problem has implied is that the path to adoption of DNSSEC has been slow, despite the obvious protections it can provide regarding potential tampering with the DNS.

The second major theme of change in the DNS concerns the larger issue of pervasive monitoring in the DNS, highlighted by the Snowden revelations of 2013. Most Internet transactions start with a call to the DNS, and the meta-data contained in DNS queries and responses provides a rich real-time profile of user activity, both in general and potentially on a user-by-user basis. This situation has prompted a concerted effort to improve the privacy aspects of the DNS as a protocol. One approach has been to take the existing use of DNS across a TCP session and add TLS to the TCP session, so the contents of the interaction between the client and the DNS server are impervious to third-party inspection or manipulation. This approach can be taken a step further with DNS over *Hypertext Transfer Protocol Secure* (HTTPS)/2, where the DNS payload has a lightweight HTTP wrapper in addition to TLS. This approach allows DNS traffic to be melded in with all other HTTP traffic as a further step of obscuring DNS transactions. More recently we have seen DNS over QUIC, using QUIC faster session start times and fast open capabilities to improve the performance of the arrangement, and DNS over HTTPS/3, which combines QUIC with HTTP object semantics.

The primary focus of this work has been the part of the DNS where the client's stub resolver interacts with a recursive resolver, because this scenario identifies the client. The useful property of this part of the DNS is that the same client/server setup is used repeatedly, so either a long-held secure transport session or a fast-reopen session can amortise the high setup cost of a reliable secure session over many subsequent queries, making the overall cost of such a secure transport arrangement more palatable.

Such measures still have some security problems, as the recursive resolver is privy to both the client's identity and the DNS queries that they make. Recent work has begun on an "oblivious" model of DNS operation, where the recursive resolver function is split in two and two layers of encryption are used. The client talks to the first party, a DNS relay over an encrypted session, and passes it a query that has been encrypted using the public key of the second party, the recursive resolver. The relay resends the encrypted DNS query to the recursive resolver to resolve. The first party knows the identity of the client, but not the DNS query that is being made. The second party knows the DNS query, but not the identity of the client.

This work on DNS privacy has extended into the scenarios of the recursive resolver talking with authoritative name servers, although it's unclear as to the extent of the security benefits (because the end user is not identified directly in such queries), nor is session reuse as feasible in this scenario.

Cloud

In many ways applications and services have been the high frontier of innovation in the Internet in this period. An entire revolution in open interconnection of content elements has taken place, and content is now a very malleable concept. It is no longer the case of "my computer, my applications, my workspace" or "your server, your content" but an emerging model where not only the workspace for each user is held in the network, but where the applications and services themselves are part of the network, and all are accessed through a generic mechanism based around permutations of the HTTPS access model. This world is one of the so-called *Cloud Services*. The world of cloud services takes advantage of abundance in computation, storage, and communications resources, and rather than a network facilitating users to connect to service delivery points, the cloud model inverts the model and attempts to bring replicant copies of content and services closer to the user. If distance equates to cost and performance in the networking world, then the cloud model dramatically shortens the distance between consumer and content, with obvious implications in terms of cost and performance reductions. The clouded Internet can achieve extremely challenging performance and cost objectives by changing the provisioning model of the content and service from "just-in-time" on-demand service to "just-in-case" pre-provisioning of local caches so that the local cache is ready if a local client accesses the service.

Cyber Hostility

We still are under relentless attack at all levels. We are beset by data leaks, surveillance, profiling, disruption, and extortion.

Attacks are now commonplace. Many of them are brutally simple, relying on a tragically large pool of potential zombie devices that are readily subverted and co-opted to assist in attacks. The attacks are often simple, such as UDP reflection attacks where a single UDP query generates a large response. The source address of the query is forged to be the address of the intended attack victim, and not much more needs to be done. A small query stream can result in a massive attack. UDP protocols such as SNMP, the *Network Time Protocol* (NTP), the DNS, and *memcached* have been used in the past and doubtless will be used again.

Why can't we fix this problem? We've been trying for decades, and we just can't seem to get ahead of the attacks. Advice to network operators to prevent the leakage of packets with forged source addresses was published more than two decades ago, in 2000. Yet massive UDP-based attacks with forged source addresses still persist today. Aged computer systems with known vulnerabilities continue to be connected to the Internet and are readily transformed into attack bots.

The picture of attacks is also becoming more ominous. Although we previously attributed these hostile attacks to "hackers," we quickly realised that a significant component of them had criminal motivations. The progression from criminal actors to state-based actors is also entirely predictable, and we are seeing an escalation of this cyber warfare arena with the investment in various forms of vulnerability exploitation that are considered desirable national capabilities.

It appears that a major problem here is that collectively we are unwilling to make any substantial investment in effective defence or deterrence. The systems that we use on the Internet are overly trusting to the point of irrational credulity. For example, the public key certification system used to secure web-based transactions is repeatedly demonstrated to be entirely untrustworthy, yet that's all we trust. Personal data is continually breached and leaked, yet all we seem to want to do is increase the number and complexity of regulations rather than actually use better tools that would effectively protect users.

The larger picture of hostile attacks is not getting any better. Indeed, it's getting much worse. If any enterprise has a business need to maintain a service that is always available for use, then any form of in-house provisioning is just not enough to withstand attack. These days only a handful of platforms can offer resilient services, and even then, it's unclear whether they could withstand the most extreme of attacks.

A constant background level of scanning and probing goes on in the network, and any form of visible vulnerability is ruthlessly exploited. One could describe today's Internet as a toxic wasteland, punctuated with the occasional heavily defended citadel.

Those who can afford to locate their services within these citadels enjoy some level of respite from this constant profile of hostile attack, while all others are forced to try to conceal themselves from the worst of this toxic environment, while at the same time aware that they will be completely overwhelmed by any large-scale attack. It is a sobering thought that about one-half of the world's population are now part of this digital environment. A more sobering thought is that many of today's control systems, such as power generation and distribution, water distribution, and road-traffic-control systems are exposed to the Internet.

IoT What makes this scenario even more depressing is the portent of the so-called *Internet of Things* (IoT). In those circles where Internet prognostications abound and policy makers flock to hear grand visions of the future, we often hear about the boundless future represented by this Internet of Things. This phrase encompasses some decades of the computing industry's transition from computers as esoteric pieces of engineering affordable only by nations to mainframes, desktops, laptops, handheld devices, and now wrist computers.

Where next? In the vision of the IoT, we are going to expand the Internet beyond people and press on using billions of these chattering devices in every aspect of our world. What do we know about the "things" that are already connected to the Internet? Some of them are not very good. In fact, some of them are just plain stupid. And this stupidity is toxic, in that their sometime-inadequate models of operation and security affect others in potentially malicious ways.

If such devices were constantly inspected and managed, we might see evidence of aberrant behaviour and correct it. But these devices are unmanaged and all but invisible. Examples include the controller for a web camera, the so-called "smart" thing in a smart television, or the controls for anything from a washing machine to a goods locomotive. Nobody is looking after these devices. When we think of an IoT we think of a world of weather stations, webcams, "smart" cars, personal fitness monitors, and similar things.

But what we tend to forget is that all of these devices are built on layers of other people's software that is assembled into a product at the cheapest possible price point. It may be disconcerting to realise that the web camera you just installed has a security model that can be summarised with the phrase: "no security at all," and it's actually offering a view of your house to the entire Internet. It may be slightly more disconcerting to realise that your electronic wallet is on a device that is using a massive compilation of open-source software of largely unknown origin, with a security model that is not completely understood, but appears to be susceptible to be coerced into being a "yes, take-all-you-want" device. It would be nice to think that we have stopped making mistakes in code, and from now on our software in our things will be perfect. But that's hopelessly idealistic. It's just not going to happen. Software will not be perfect. It will continue to have vulnerabilities.

It would be nice to think that this Internet of Things is shaping up as a market where quality matters, and consumers will select a more expensive product even though its functional behaviour is identical to a cheaper product that has not been robustly tested for basic security flaws. But that too is hopelessly naive.

The IoT will continue to be a marketplace where the compromises between price and quality will continue to push us on to the side of cheap rather than secure. What is going to stop us from further polluting our environment with a huge and diverse collection of programmed unmanaged devices with inbuilt vulnerabilities that will be all too readily exploited? What can we do to make this world of these stupid cheap toxic things less stupid and less toxic? So far, we have not found workable answers to this question.

Our ability to effectively defend the network and its connected hosts continues to be, on the whole, ineffectual. Anyone who still has trust in the integrity of the systems that make up the digital world is just hopelessly naive. This space is toxic and hostile, and we still have no idea how we can shift it to a different state that can resist such erosive and insidious attacks. But somehow, we are evidently not deterred by all this information. Somehow each of us has found a way to make the Internet work for us.

The Business of the Internet

As much as the application environment of the Internet has been on a wild ride over the past 25 years, the business environment has also had its tickets on the same roller coaster ride, and the list of business winners and losers includes some of the historical giants of the telephone world as well as the Internet-bred new wave of entrants.

In 1998, despite the growing momentum of public awareness, the Internet was still largely a curiosity. Its environment was inhabited by geeks, game players, and academics, whose rites of initiation were quite arcane. As a part of the data networking sector, the Internet was just one further activity among many, and the level of attention from the mainstream telco sector was still relatively low. Most Internet users were customers of independent ISPs, and the business relationship between the ISP sector and the telco was tense and acrimonious. The ISPs were seen as opportunistic leeches on the telco industry; they ordered large banks of phone lines, but never made any calls; their customers did not hang up after 3 minutes, but kept their calls open for hours or even days at a time, and they kept on ordering ever-larger inventories of transmission capacity, yet had business plans that made scribbles on the back of an envelope look professional by comparison.

The telco was unwilling to make large long-term capital investments in additional communications infrastructure to pander to the extravagant demands of a wildcat set of Internet speculators and their fellow travellers.

The telco, on the other hand, was slow, expensive, inconsistent, ill-informed, and hostile to the ISP business. The telco wanted financial settlements and bit-level accounting while the ISP industry appeared to manage quite well with a far simpler system of peering and tiering that avoided putting a value on individual packets or flows.

This relationship was never going to last, and it resolved itself in ways that in retrospect were quite predictable. From the telco perspective, it quickly became apparent that the only reasons the telco was being pushed to install additional network capacity at ever-increasing rates were demands from the ISP sector. From the ISP perspective, the only way to grow at a rate that matched customer demand was to become one's own carrier and take over infrastructure investment. And, in various ways, both outcomes occurred. Telcos bought up ISPs, and ISPs became infrastructure carriers.

All this activity generated considerable investor interest, and the rapid value escalation of the ISP industry and then the entire Internet sector generated the levels of wild-eyed optimism that are associated only with an exceptional boom. By 2000 almost anything associated with the Internet, whether it was a simple portal, a new browser development, a search engine, or an ISP, attracted investor attention, and the valuations of Internet start-ups achieved dizzying heights. Of course, one of the basic lessons of economic history is that every boom has an ensuing bust, and in 2001 the Internet collapse happened. The bust was as inevitable and as brutal as the preceding boom was euphoric. But, like the railway boom and bust of the 1840s, after the wreckage was cleared away what remained was a viable, and indeed a valuable, industry.

By 2003 the era of the independent retail ISP was effectively over. But it reshaped itself dramatically with the introduction of mobile services. It was the old telco sector that had secured spectrum allocations in the bidding wars in the early 2000s, and while they had thought that mobile voice would be the reason why these investments would make sense, it was mobile Internet services that proved to be the lasting service model. In this period, the Internet was the amalgam of the largest of the original ISP, the transformed cable television operators, and the mobile providers. Each national regime was populated with some three to five major service providers, and the business started to stabilise around this model.

Into this world came the content world of the Internet, using cloud-based models of service delivery to circumvent communications bottlenecks in the long-haul transit sector. They embarked on service models that included advertiser-funded models of content generation and delivery and direct subscription models, and the result has been so effective that the value of this sector is far greater than the traditional ISP and carriage sector. The content world is now the major funder of subsea cable systems, and the carriage world has been very reluctantly pushed into an undistinguished commodity role as a result.

This situation is reflective of a broader process of technology permeation. The telephone world used the network as the major focus of technology and investment. The edge devices, telephone handsets, were simple, cheap devices, whereas network switches and transmission elements were built to exacting and expensive standards. As we attached computers to the edges of the network, these devices were able to tolerate a broader spectrum of network behaviours, and had a lower base-level expectation of behaviour. Consequently, value has moved out from the core of the network to its edges.

But this process has also been reflected within these edge devices. We started with a model of a highly capable and complicated operating system platform, and relatively simple applications that used platform services. Some 25 years ago the release of Windows 98 was a Big Thing, and rightly so. As these edge devices become more capable and have higher processing capability, more local storage applications have elected to take on more of the responsibility in terms of the user's experience. In doing so they no longer rely on the release schedules of the platform provider, and they are no longer as concerned about the level of control being exercised by this platform provider and gaining an essential level of self-control. Modern browsers (Chrome and a few far smaller fellow travellers) are far more complex than most operating systems, and they continue to subsume functions and roles that the platform previously carried out. With DNS over HTTPS, the task of DNS name resolution can be transformed to an application function, rather than a common platform function. With QUIC, the transport protocol itself has been subsumed into the application space.

Not only have we seen the commoditisation of the network over the past 25 years, we have also seen similar commoditisation pressures on the end-device platforms and on the operating systems used on these devices. Even the browser space has been commoditised. The brunt of competitive differentiation in this industry has been pushed up the protocol stack into the content and service economy, and there is the distinct feeling that even in that space competitive differentiation is perhaps a misnomer, and what we have is a synthetic form of competition between a select small group of digital service-delivery behemoths that in any other time and context would probably be called a cartel.

What Now?

It's been a revolutionary quarter-century for us all, and the Internet has directly or indirectly touched the lives of almost every person on this planet. Current estimates put the number of regular Internet users at one half of the world's population.

Over this period, some of our expectations were achieved and then surpassed with apparent ease, while others remained elusive. And some things occurred that were entirely unanticipated. At the same time, very little of the Internet we have today was confidently predicted in 1998, while many of the problems we saw in 1998 remain problems today.

This work-in-progress means the next quarter-century will probably see the same level of intensity of yet more structural changes to the global communications sector. And that is a somewhat scary prospect, given the collection of other challenges that we will all confront in the coming decades. At the same time, I think it would be good to believe that the debut of the Internet in our world has completely rewritten what it means to communicate, the way in which we can share our experience and knowledge, and, hopefully, the ways in which we can work together on these challenges.

GEOFF HUSTON AM, B.Sc., M.Sc., is the Chief Scientist at APNIC, the Regional Internet Registry serving the Asia Pacific region. He has been closely involved with the development of the Internet for many years, particularly within Australia, where he was responsible for building the Internet within the Australian academic and research sector in the early 1990s. He is author of numerous Internet-related books, and was a member of the Internet Architecture Board from 1999 until 2005. He served on the Board of Trustees of the Internet Society from 1992 until 2001. At various times Geoff has worked as an Internet researcher, an ISP systems architect, and a network operator. Technologies used for accessing the Internet have evolved a great deal since my very first encounter with the ARPANET in 1976. Using a 110-baud Teletype machine, I accessed a computer at SRI International in Menlo Park, California, from my laboratory at the *Norwegian Defence Research Establishment* (NDRE) at Kjeller, Norway. Today, my Internet service is delivered by fiber-optic cable at 1 Gbps. Numerous other technologies for Internet access have emerged, and in this issue we look at two of them, namely 5G mobile systems and *Low Earth Orbit* (LEO) satellites.

In simple terms 5G can be described as a new set of cellular radio frequencies to allow for much faster data connections for mobile devices. Beyond this simplified explanation lies numerous details that are described in a two-part article by William Stallings. Part One introduces the standards and specifications that define 5G and describes the usage scenarios that 5G supports. Part Two, to be published in a future issue, will provide an overview of the structure and function of 5G networks. A third article on *Network Slicing*, which is closely related to 5G, will also be published in a future edition of this journal.

The world's first communication satellite, *Telstar 1*, which was launched in July 1962, provided proof-of-concept for both live television transmission and telephone service. Since that time, satellites have been deployed for many services, ranging from weather observations, navigation systems, and more recently Internet access. LEO satellites are particularly well-suited for Internet access because they offer coverage to remote areas without introducing substantial propagation delays as compared to other alternatives. Our second article, by Dan York and Geoff Huston, provides an overview of LEO systems for Internet access.

This journal now has around 1,000 print subscribers and just over 18,000 online subscribers who download their copy from our website. Given this shift in subscriber demographics, we will no longer be printing those long and cumbersome URLs in the references section at the end of each article. Instead, you can simply click on the references themselves using the PDF copy.

As always, we welcome your feedback and suggestions on anything you read in this journal. Letters to the Editor may be edited for clarity and length and can be sent to ipj@protocoljournal.org

Introduction to 5G

Part One: Standards, Specifications, and Usage Scenarios

by William Stallings

5G is the fifth-generation technology for wireless cellular networks. A significant technological leap beyond the capabilities of the 4G networks that currently dominate available cellular network services, 5G delivers a substantial increase in peak and average speeds and capacity. A significant increase in download and upload speeds will enhance many existing use cases, including cloud-based storage, augmented reality, and artificial intelligence. It also will enable cell sites to communicate with a greater number of devices. Reduced latency enables edge computing and will transform *Internet of Things* (IoT) capabilities and application breadth.

This two-part article provides an introduction to 5G. Part One introduces the standards and specifications that define 5G and describes the usage scenarios that 5G supports. Part Two, to be published in a future issue, will provide an overview of the structure and function of 5G networks.

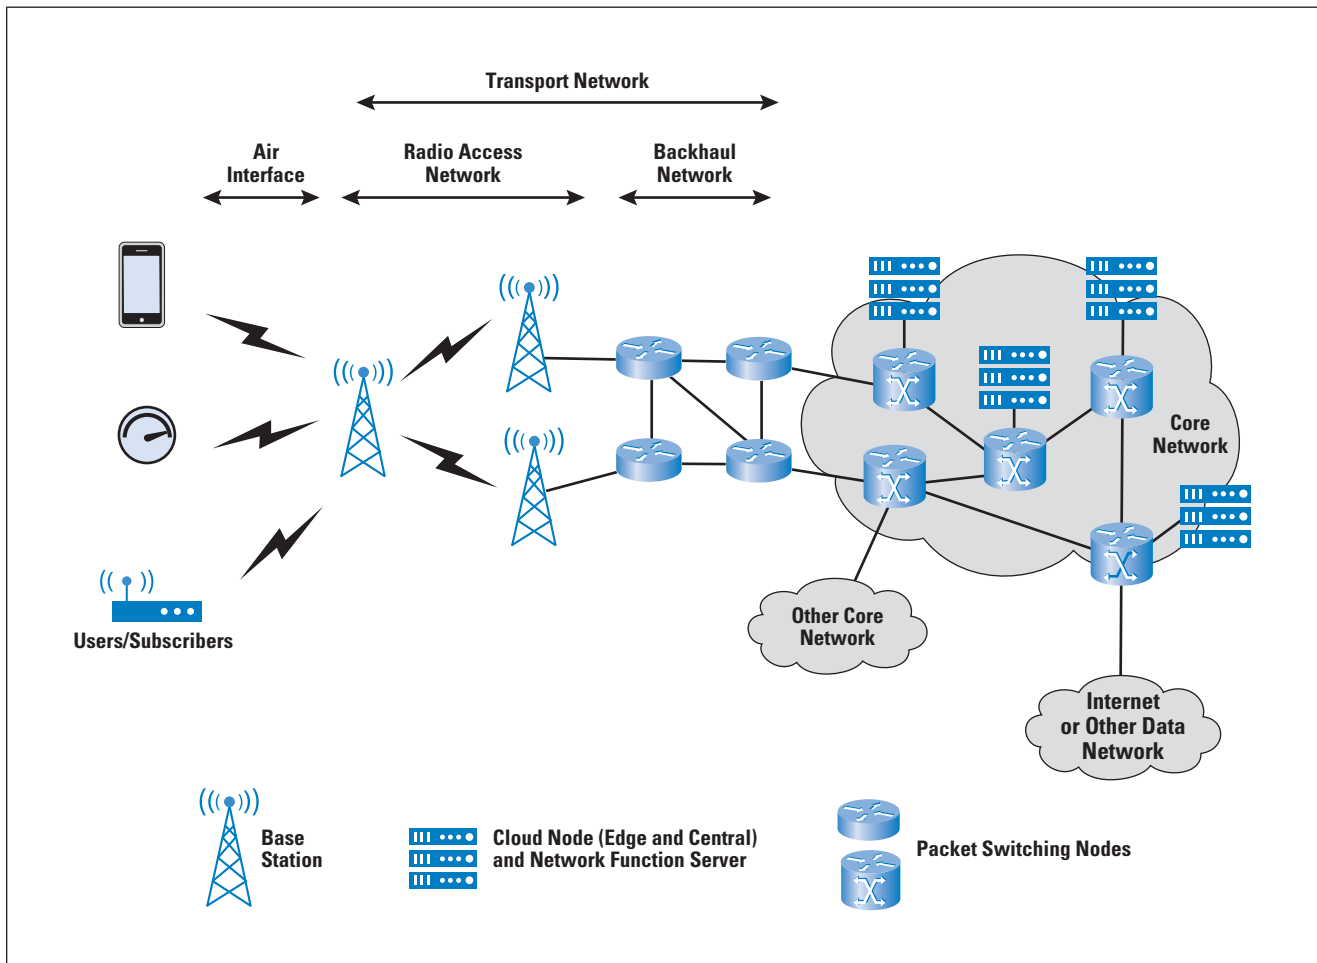

Simplified View of a 5G Network

Figure 1 shows a very simplified view of a 5G cellular network; it provides a useful framework for discussing standards and specifications for the technology. Users, or subscribers, to the network are fixed or mobile wireless devices, referred to in 5G documents as *User Equipment* (UE). Examples of fixed wireless UE include a modem that serves as an access point from a home or office Wi-Fi or Ethernet network to the 5G network, and IoT devices such as sensors or surveillance cameras. Mobile UE includes cell phones, laptops, and other mobile or portable devices equipped with 5G capability.

The *Air Interface*, also called a *Radio Interface*, is the wireless link between UE and the nearest cellular base station. The air interface specifies the method for transmitting information over the air between base stations and mobile units, including protocols, frequency range, channel bandwidth, channel coding, and the modulation scheme.

The *Radio Access Network* (RAN) consists of a collection of base stations that provide service to the UE in a geographic region. The base station provides radio transmission and reception in one or more cells to or from the user equipment. A base station can have an integrated antenna or can be connected to an antenna by feeder cables. Each base station communicates with nearby base stations, generally wirelessly, to enable handoff of UE from one base station to another as the UE moves. The RAN also includes other management and transmission elements.

Figure 1: Simplified View of 5G Network

The *Core Network* is a backbone network that provides interconnection service between RANs in different regions; it provides access for UE to the Internet or other data networks and UE on other RANs. In addition, the core network implements numerous network functions that support user- and control-plane traffic and provides for *Quality of Service* (QoS) and management and orchestration. Core networks also generally provide both edge and central cloud services for 5G users.

The *Transport Network* is the collection of communication links that interconnect nodes of the RAN, as well as communication links connecting RAN elements to the 5G core network. Links between RAN elements and UE are generally not considered part of the transport network.

Standards and Specifications for 5G

Many of the important developments in information and technology and communications, such as the Internet, IoT, Cloud Computing, and Virtualization, have been driven in part by international standards.

However, in all of these cases, much of the technology was developed and deployed in advance of universally agreed-upon standards. The case of 5G is quite different. Although a reasonably complete set of standards based on fixed specification is only just coming to fruition, the implementations and deployments that preceded these standards and specifications anticipated their final form. Throughout the 5G ecosystem, which includes device and component manufacturers, cellular network providers, network software providers, and application developers, the work done prior to the introduction of the first set of standards in 2020 closely follows what has ultimately been standardized. Going forward, there is universal agreement that 5G-related implementations will follow the standards.

Because an understanding of 5G depends on an understanding of the process by which the standards are developed and the content of those standards, the first part of this article provides an overview. It covers the two organizations that are responsible for the development of 5G: the *International Telecommunication Union* (ITU) and the *3rd Generation Partnership Project* (3GPP). In essence, the process of standards development for 5G follows this sequence:

1. The ITU has issued—and continues to issue—standards, called *Recommendations*, and other documents, called *Reports*, that define the overall concept for 5G, as well as the technical, performance, and service requirements for 5G.
2. Based on the ITU requirements, as well as requirements generated by national and regional standards organizations and market-based organizations, 3GPP has developed—and continues to develop—a detailed set of technical specifications for the implementation of 5G.
3. The ITU has translated these specifications into international standards (Recommendations) that dictate how 5G is being implemented.

This process is ongoing as further refinements and capabilities are added to the requirements and the technical specifications.

With respect to 5G, the two relevant components of ITU are the *ITU Radiocommunication* (ITU-R) Sector and the *ITU Telecommunication Standardization* (ITU-T) Sector. In general terms, ITU-R issues standards related to user requirements and the air interface. ITU-T issues standards related to the RAN, the transport network, and the core network.

ITU-R and IMT-2020

Perhaps the most prominent initiative by ITU-R is the *International Mobile Telecommunications* (IMT) project. IMT is the generic term the ITU community uses to designate broadband mobile systems. It encompasses *IMT-2000*, *IMT-Advanced*, and *IMT-2020* collectively, which correspond to 3G, 4G, and 5G, respectively.

A foundational document in the definition of IMT-2020 is *ITU-R Recommendation M.2083*^[1]. In broad strokes, this document develops a vision of the 5G mobile broadband connected society and future IMT. The two main contributions of this recommendation are a set of target values for key capabilities and a definition of usage scenarios, discussed subsequently.

M.2083 lists the eight key capabilities for IMT, together with the minimum requirements for each. The objectives that determined these target values follow:

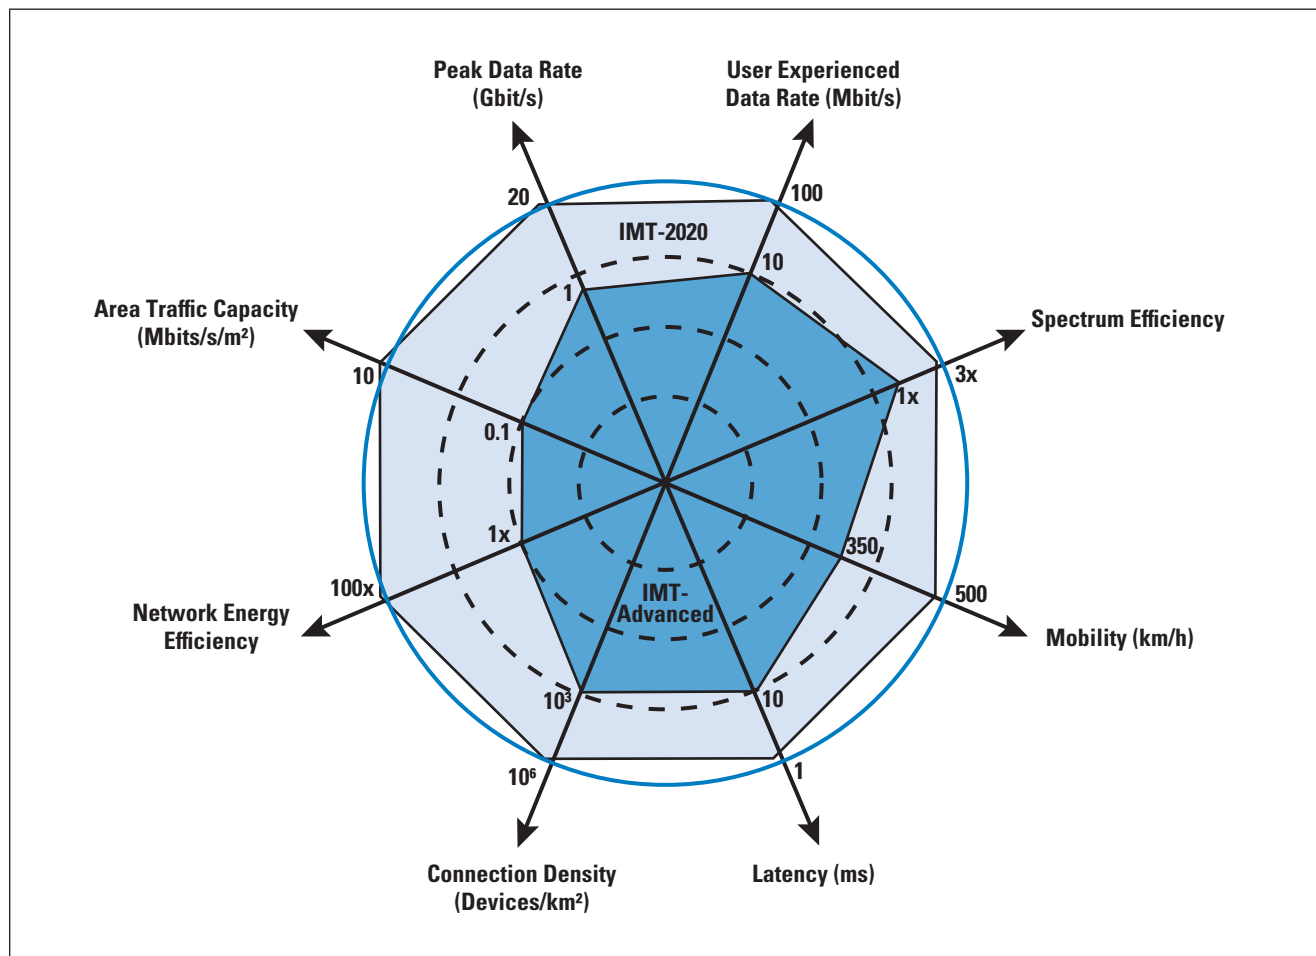

- The user experience with IMT-2020 using a mobile device should match—to the extent possible—the experience with fixed networks. The enhancement will be realized by increased peak and user experienced data rate, enhanced spectrum efficiency, reduced latency, and enhanced mobility support.
- IMT-2020 should support massive machine-to-machine interconnections, for a variety of IoT environments.
- IMT-2020 should be able to provide these capabilities without undue burden in terms of energy consumption, network equipment cost, and deployment cost to make future IMT sustainable and affordable.

Figure 2, from M.2083, compares the capability requirements of IMT-2020 (5G) to those of IMT-Advanced (4G). It shows that substantial improvements are mandated for all eight capabilities, with the most substantial required improvements in the areas of traffic capacity and network energy efficiency.

The target values were published in 2015, with the admonition that they are presented for purposes of research and development and may be revised in light of future studies and implementation experience. This list was expanded and refined in 2017 into 13 technical performance requirements in ITU-R Report M.2410^[2]. The purpose of these performance requirements is to assure that there should be a noticeable improvement of user *Quality of Experience* (QoE) for legacy 4G services and applications, and a high QoE for emerging 5G services and applications. Two terms should be distinguished:

- *Quality of Service* (QoS): The measurable end-to-end performance properties of a network service, which can be guaranteed in advance by a *Service-Level Agreement* (SLA) between a user and a service provider, so as to satisfy specific customer application requirements. Note: These properties may include throughput (bandwidth), transit delay (latency), error rates, priority, security, packet loss, and packet jitter.
- *Quality of Experience* (QoE): A subjective measure of performance in a system. QoE relies on human opinion and differs from QoS, which you can measure precisely.

Figure 2: Enhancement of Key Capabilities from IMT-Advanced to IMT-2020

In essence, the performance requirements for 5G are QoS measures designed to produce a high QoE. The M.2410 minimum technical performance requirements are as follows:

- **Peak Data Rate:** The maximum achievable data rate under ideal conditions per user/device (in Gbps). The minimum target values are downlink peak data rate of 20 Gbps and uplink peak data rate of 10 Gbps.
- **Peak Spectral Efficiency:** The maximum data rate under ideal conditions normalized by channel bandwidth (in bits/s/Hz). Another way of expressing this term is that it is the maximum data rate that can be transmitted over a given bandwidth. The relationship can be expressed as follows: $R_p = W \times SE_p$, where R_p is peak data rate, W is the available bandwidth, and SE_p is peak spectral efficiency. The minimum for peak spectral efficiencies is a downlink of 30 bps/Hz and uplink of 15 bps/Hz.
- **User-Experienced Data Rate:** The achievable data rate that is available ubiquitously across the coverage area to a mobile user/device (in Mbps or Gbps). This rate will depend the type of environment.

- *5th Percentile User Spectral Efficiency*: The 5% point of the cumulative distribution function of the normalized user throughput. The normalized user throughput is defined as the number of correctly received bits, that is, the number of bits contained in the *Service Data Units* (SDUs) delivered to Layer 3, over a certain period of time, divided by the channel bandwidth; it is measured in bits/s/Hz.
- *Average Spectral Efficiency*: The average data throughput per unit of spectrum resource and per cell (bits/s/Hz). The goal is a spectral efficiency of three times higher than IMT-Advanced.
- *Area Traffic Capacity*: The total traffic throughput served per geographic area (in Mbps/m²).
- *Latency*: Deals with transmission delays introduced by the network. Report M.2410 considers two types of latency:
 - *User-Plane Latency*: The contribution by the radio network to the time from when the source sends a packet to when the destination receives it (in ms).
 - *Control-Plane Latency*: Refers to the transition time from a most “battery efficient” state (for example, Idle state) to the start of continuous data transfer (for example, Active State). The minimum requirement is 20 ms.
- *Connection Density*: The total number of connected and/or accessible devices per unit area (per km²) that fulfills a specific QoS. The minimum requirement is 106/km².
- *Energy Efficiency*: In general terms, the relation between useful output and energy consumption. In the context of M.2410, this parameter has two aspects:
 - *Network Energy Efficiency*: Refers to the quantity of information bits transmitted to/received from users, per unit of energy consumption of the RAN (in bits/Joule). The objective is efficient data transmission when the load on the network is substantial. The energy consumption for the RAN of IMT-2020 should not be greater than for IMT-Advanced, while delivering the enhanced capabilities. The network energy efficiency should therefore be improved by a factor at least as great as the envisaged traffic capacity increase of IMT-2020 relative to IMT-Advanced.
 - *Device Energy Efficiency*: Refers to a quantity of information bits per unit of energy consumption of the communication module (in bits/Joule). The objective is low-energy consumption when no data is being sent or received.
- *Reliability*: The probability of successful transmission of a Layer 2/3 packet within a required maximum time, which is the time it takes to deliver a small data packet from the radio protocol Layer 2/3 SDU ingress point to the radio protocol Layer 2/3 SDU egress point of the radio interface at a certain channel quality.

- *Mobility*: the maximum speed at which a defined QoS and seamless transfer between radio nodes that may belong to different layers and/or radio-access technologies (multi-layer/-RAT) can be achieved (in km/h). The following classes of mobility are defined:
 - *Stationary*: 0 km/hr
 - *Pedestrian*: 0 to 10 km/hr
 - *Vehicular*: 10 to 120 km/hr
 - *High-Speed Vehicular*: 120 to 5000 km/hr
- *Mobility Interruption Time*: The smallest time delay the system supports, during which the end-user device cannot exchange packets with any base stations during transmissions. The mobility interruption time includes the time required to execute any RAN procedure, radio resource control signaling protocol, or other message exchanges between the mobile station and the RAN. The minimum requirement is 0 ms.
- *Bandwidth*: The maximum aggregated system bandwidth. The minimum requirement is 100 MHz.

ITU-T and IMT-2020 “Softwarization”

As mentioned previously, the role of ITU-T in defining requirements and developing standards for IMT-2020 is complementary to that of ITU-R. ITU-T; it specifies requirements for overall non-radio aspects of the IMT-2020 network, especially with respect to network operations and support of service requirements. ITU-T Recommendations cover the core, RAN, and transport networks. ITU-T Y.3101^[3] lists the following objectives with respect to IMT-2020:

1. Minimized dependency on access network technologies
2. Coping with traffic explosion in urban areas
3. Easy incorporation of future emerging services
4. Provision of a cost-efficient infrastructure
5. Expansion of the geographic reach of the network

The ITU-T approach to achieving these objectives depends in large part on the introduction of *network softwarization* in IMT-2020 network components. Y.3101 defines network softwarization as an overall approach for designing, implementing, deploying, managing, and maintaining network equipment and/or network components by software programming. It enables you to use modular network functions that you can deploy and scale on demand to accommodate various use cases easily and cost-efficiently.

Four aspects of network softwarization are important in 5G networks and are reflected in the ITU-T documents:

- *Software-Defined Networking* (SDN): An approach to designing, building, and operating large-scale networks based on programming the forwarding decisions in routers and switches with software from a central server. SDN differs from traditional networking, which requires configuring each device separately and relies on protocols that you cannot alter.

- *Network Functions Virtualization (NFV)*^[18]: The virtualization of compute, storage, and network functions by implementing these functions in software and running them on virtual machines. NFV decouples network functions, such as routing, firewalling, intrusion detection, and network address translation from proprietary hardware platforms and implements these functions in software. It uses standard virtualization technologies that run on high-performance hardware to virtualize network functions. It is applicable to any data-plane processing or control-plane function in both wired and wireless network infrastructures.
- *Edge Computing*: A distributed *Information Technology (IT)* architecture in which client data is processed at the periphery of the network, as close to the originating source as possible.
- *Cloud-Edge Computing*: A form of edge computing that offers application developers and service providers cloud computing capabilities, as well as an IT service environment, at the edge of a network. The aim is to deliver compute, storage, and bandwidth much closer to data inputs and/or end users.

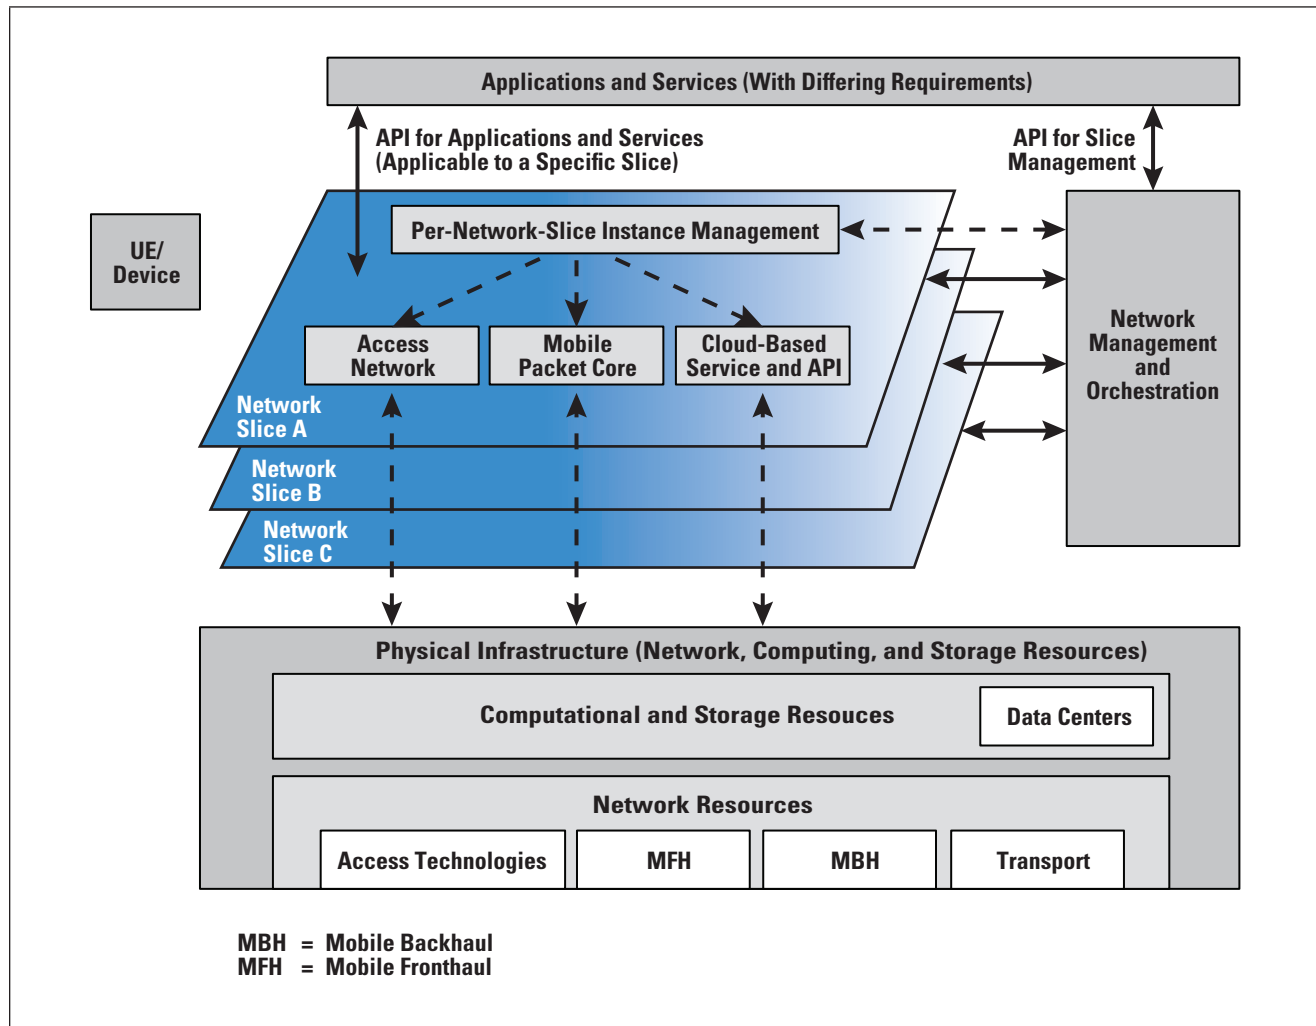

Network softwarization allows you to implement one of the essential features of 5G networks: *network slicing*. Network slicing permits you to separate a physical network into multiple virtual networks (logical segments) that can support different QoS requirements from applications and end users. Network slicing involves the selection and reservation of resources in the air interface, the RAN, the transport network, and the core network.

In essence, network slicing allows you to create multiple virtual networks atop a shared physical infrastructure. In this virtualized network scenario, physical components are secondary and logical (software-based) partitions are paramount, devoting capacity to certain purposes dynamically, according to your need. As your needs change, so can your devoted resources. Using common resources such as storage and processors, network slicing enables you to create slices devoted to logical, self-contained, and partitioned network functions. Network slicing supports the creation of virtual networks to provide a given QoS, such as guaranteed delay, throughput, reliability, and/or priority.

Figure 3, from ITU-T Recommendation Y.3150^[4], illustrates how network softwarization is incorporated in the design of IMT-2020 networks. The underlying physical infrastructure consists of a heterogeneous collection of network, computing, and storage resources. The figure shows four network resource categories. The access technologies consist of the resources at the air interface, including bandwidth, access protocol, channel coding, and modulation scheme. The mobile fronthaul refers to network paths between centralized radio controllers and remote radio units of a base-station function. The mobile backhaul refers to the network path between base-station systems and a core network. The transport resources consist of the switching hardware and software for routing data packets in the transport and core networks; an SDN controller manages these packets.

Using NFV, these underlying resources are abstracted to virtual resources used to create network slices, under the control of the management and orchestration function. Individual network slices can have specific characteristics that reflect various different requirements derived from application and services.

Figure 3: Network Softwarization for IMT-2020

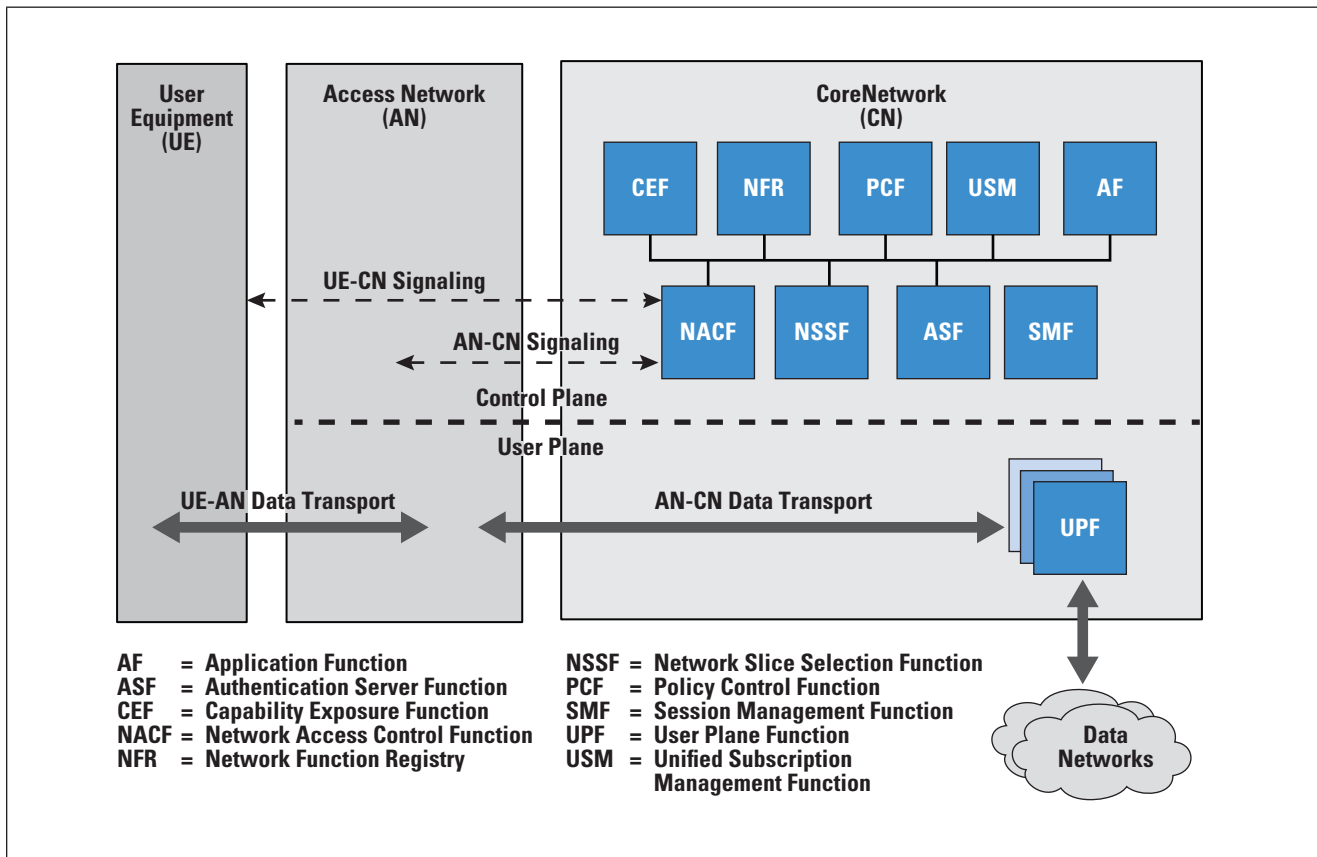

ITU-T IMT-2020 Core Network Framework

ITU-T Recommendation Y.3102^[5] provides the framework for overall non-radio aspects of the IMT-2020 network. Figure 4, from Y.3102, illustrates the interactions between the network functions for providing network service.

The framework delineates three domains. The *User Equipment* (UE) domain consists of devices that transmit and receive data over the IMT-2020 network. The *Access Network* (AN) domain is the wireless connection between the UE and the *Core Network* (CN), defined by the ITU-R radio interface recommendations.

The framework diagram also depicts the division between a control plane and a user plane, which cuts across the AN and CN.

Figure 4: Framework of the IMT-2020 Network

The *Control Plane* performs the call and connection control functions. For this purpose, a signaling connection between the UE and the CN exchanges signaling messages that manage the signaling connection and the call established for the UE. The Control-Plane functions are requested and managed via control signals that are exchanged between UE and the AN, and between the AN and the CN. Through signaling, the control plane sets up and releases connections, and may restore a connection if a failure occurs. The control plane also performs other functions that support call and connection control, such as routing information dissemination.

The core network includes the following functional elements:

- *Network Access Control Function (NACF)*: Provides access to the CN services for the AN and UE. NACF includes:
 - *Registration Management*: Enables UE to register for network access. NACF performs, but is not limited to, network slice instance selection, UE authentication, authorization of network access and network services, and network access policy control.
 - *Connection Management*: Establishes and releases a signaling connection between the UE and the core network.

- *Session Management Function Selection*: Determines the session management function that is most appropriate to establish and manage a session. In the context of IMT-2020, a session is an association between UE and a data network that provides a *Protocol Data Unit* (PDU) connectivity service.
- *Session Management Function* (SMF): Sets up and manages one or more sessions that provide connectivity between the local UE and a remote UE. This function deals with user path selection and enforcement of policies, including QoS policy and charging policy.
- *Policy Control Function* (PCF): Provides for control and management of policy rules.
- *Capability Exposure Function* (CEF): Enables the exposure of network functions and network slices as a service to third parties.
- *Network Function Registry Function* (NRF): Assists the discovery and selection of required network functions.
- *Unified Subscription Management Function* (USM): Stores and manages UE context and subscription information including, but not limited to, UE information on registration and mobility management, information on network functions that serve the UE, and information on session management. USM also provides UE authentication information to the *Authentication Server Function* (ASF).
- *Network Slice Selection Function* (NSSF): When UE requests registration with the network, NSSF sends a network slice selection request to NSSF with preferred network slice selection information. The NSSF responds with a message including the list of appropriate network slice instances for the UE.
- *Authentication Server Function* (ASF): Performs authentication between UE and the network.
- *Application Function* (AF): Interacts with application services that require dynamic policy control. AF extracts session-related information (for example, QoS requirements) from application signaling and provides it to PCF in support of its rule generation.

The user plane refers to the set of traffic forwarding components through which traffic flows. Its principal function is to provide transfer of end-user information.

The sole functional element in the user plane is the *User Plane Function* (UPF). This function includes traffic routing and forwarding, *Protocol Data Unit* (PDU) session tunnel management, and QoS enforcement. The PDU session tunnels are used between AN and UPF(s) as well as between different UPFs as user-plane data transport for PDU sessions. UPF also provides optional functions including packet inspection and collection of *User-Plane* (UP) traffic for lawful intercept. In order to accommodate the diversity of network scenarios, UPF may also provide interworking functions among different network segments, for example, interworking between the IP-based core network and the non-IP-based access network.

Y.3102 also lists the primary network services that the supported core network framework supports. They include:

- *Registration Management* (RM): Register or deregister UE with the IMT-2020 network and establish the user context in the network.
- *Connection Management* (CM): Establish and release the signaling connection between the UE and NACF.
- *Session Management* (SM): Manages PDU sessions including control of PDU session tunnel establishment, modification, and release.
- *User-Plane Management* (UPM): Forward user traffic, including user traffic rerouting between UPFs because of the serving UPF relocation and enforcement of QoS policies.
- *Mobility Management* (MM): Used to handle all aspects related to UE mobility. Mobility management aspects include, but are not limited to, UE reachability and handover management.

3GPP

The *3rd Generation Partnership Project* (3GPP) was formed in 1998 by a global consortium of regional *Standards Development Organizations* (SDOs) to develop technology specifications for 3G cellular networks. Because it involved the efforts of the world's leading national standards organizations, 3GPP became the dominant agent in the development of specifications for 3G, then 4G, and now 5G cellular networks.

3GPP began work in 2016 on defining 5G technical specifications for a new radio access technology, known as 5G NR (New Radio) and a next-generation network architecture (5G NextGen). Unlike previous generations, competing standards bodies are no longer working on potential solutions for 5G.

Figure 5 shows the key players in the 3GPP process and their relationships to one another. Within the 3GPP organization is a *Project Coordination Group* (PCG). It is responsible for overall time frame and management of technical work to ensure that the 3GPP specifications are produced in a timely manner as required by the marketplace. Subordinate to the PCG are three *Technical Specification Groups* (TSGs). Each TSG has the responsibility to prepare, approve, and maintain the specifications within its terms of reference; it may organize its work in *Working Groups* (WGs) and liaise with other groups as appropriate. The TSGs report to the PCG.

Key to the 3GPP process are the *organizational partners*. An organizational partner is a standards organization with a national, regional, or other officially recognized status (in its country or region) that has the capability and authority to publish standards nationally or regionally. Associated with organizational partners are individual members, which are member companies affiliated with one of the organizational partners.

Finally, there are *market-representation partners*, which are organizations invited to participate by the organizational partners to offer market advice to 3GPP and to bring into 3GPP a consensus view of market requirements (for example, services, features, and functions) falling within the 3GPP scope.

Figure 5: 3GPP Process

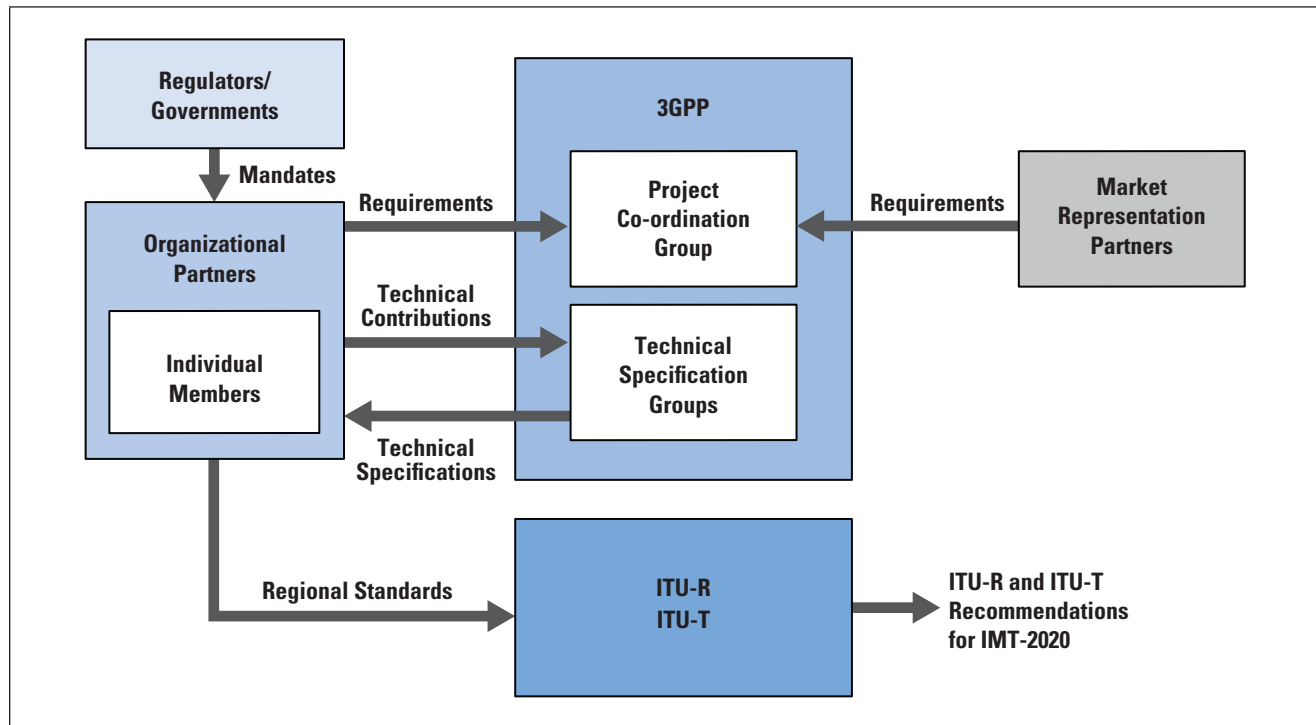

Figure 5 shows, in general terms, the flow of information between the previously mentioned entities. The PCG plans the work of 3GPP based on requirements provided by the organizational partners and the market representation partners. The organizational partners are influenced particularly by their respective national and regional governments and regulators, whereas the market representation partners generate requirements dictated by the potential market. Individual members provide technical contributions to the TSGs, which ultimately result in technical specifications. These specifications are transmitted from the TSGs to the organizational partners, who translate them into national and regional standards. Finally, these standards serve as input to ITU in the development of 5G-related Recommendations.

3GPP Releases

3GPP uses a system of parallel *Releases* that provide developers with a stable platform for the implementation of features at a given point and then allow for the addition of new functions in subsequent Releases. Releases are staggered and work is done on multiple Releases in parallel at different stages. When a Release is finalized, it means that all new features are functionally frozen and ready for implementation. Furthermore, each 3GPP Release is self-contained, meaning that you can build a cellular system based on the set of frozen specifications in that Release.

As such, Releases do not just contain the newly implemented features, but instead are introduced in a highly iterative manner that builds upon previous Releases. Table 1 provides information on the three releases relating to 5G that are completed at the time of this writing. Release 15 provided an early definition of useful 5G features to enable deployment by 2020. Subsequent releases add progressively more functions. Release 16 should closely resemble the initial set of IMT-2020 Recommendations issued by ITU in 2020.

Table 1. 3GPP Releases for 5G

Release #	Status	Functional Freeze	End Date
Release 17	Frozen	2022-03-18	2022-06-10
Release 16	Frozen	2020-07-03	2020-07-03
Release 15	Frozen	2019-03-22	2019-06-07

When a Release is frozen, the TSGs can add no additional functions to the specifications. However, detailed protocol specifications may not yet be complete. The end date shown in Table 1 is indicative only, since for each Release, a considerable number of refinements and corrections can be expected for at least two years following this date.

3GPP Requirements for 5G

The 3GPP documents include a description of 5G requirements that are significantly more detailed than those provided in the ITU documents. As such, they provide an important guide to implementers of 5G networks, components, and systems as to what the market requirements are for 5G success (Refer to Figure 6).

Figure 6: 3GPP Basic Capability Requirements

Network Slicing Diverse Mobility Magement Multiple Access Technologies Resource Efficiency Efficient User Plane Efficient Content Delivery Priority, QoS, and Policy Control Dynamic Policy Control Connectivity Models Network Capability Exposure Context Aware Network Self-Backhaul Flexible Broadcast/Multicast Service	Subscription Aspects Energy Efficiency Markets Requiring Minimal Service Levels Extreme Long-Range Coverage in Low-Density Areas Multi-Network Connectivity and Service Delivery Across Operators 3GPP Access Network Selection eV2X Aspects NG-RAN Sharing Unified Access Control QoS Monitoring Ethernet Transport Services	Non-Public Networks 5G LAN-Type Service Positioning Services Cyber-Physical Control Applications in Vertical Domains Messaging Aspects Steering of Roaming Minimization of Service Interruption UAV Aspects Video, Imaging, and Audio for Professional Applications Critical Medical Applications

eV2X = Enhanced Vehicle-to-Everything

UAV = Unmanned Aerial Vehicle

3GPP Technical Specification TS 22.261^[6] defines requirements for 34 basic capabilities to be provided by a 5G network; they are listed in Figure 6. For each capability, TS 22.261 provides a description and elaborates on the requirements for that capability.

TS 22.261 also lists performance requirements that are more detailed and more demanding than those defined in ITU-R Report M.2410. The requirements cover the following categories:

- *High Data Rates and Traffic Densities*: Several 5G scenarios require the support of very high data rates or traffic densities, including urban and rural areas, office and home, and special deployments (for example, massive gatherings, broadcast, residential, and high-speed vehicles).
- *Low Latency and High Reliability*: Some scenarios require the support of very low latency and very high communications service availability, which in turn implies very high reliability. The overall service latency depends on the delay on the radio interface, transmission within the 5G system, transmission to a server that may be outside the 5G system, and data processing. Some of these factors depend directly on the 5G system itself, whereas for others the impact can be reduced by suitable interconnections between the 5G system and services or servers outside of the 5G system, for example, to allow local hosting of the services. TS 22.261 provides an overview of potential scenarios and references other technical specifications for specific requirements.
- *High Accuracy Positioning*: The 5G System shall provide different 5G positioning services with configurable performances working points (for example, accuracy, positioning service availability, positioning service latency, energy consumption, update rate, and time to first fix) according to the needs of users, operators, and third parties. TS 22.261 lists quantitative requirements for numerous indoor and outdoor scenarios.
- *Key Performance Indicators (KPIs) for a 5G System with Satellite Access*: In some contexts, a 5G access network will use at least one satellite link. KPIs defined in TS 22.261 include minimum and maximum UE-to-satellite delay for various earth orbits, as well as maximum propagation delay.
- *High Availability IoT Traffic*: This requirement is concerned specifically with medical monitoring but is applicable to other scenarios that require highly reliable machine-type communication in both stationary and highly mobile settings.
- *High Data Rate and Low Latency*: This requirement defines data and latency requirements for such scenarios as audio-visual interaction, gaming, and virtual reality.
- *KPIs for UE-to-Network Relaying in 5G System*: In several scenarios, it can be beneficial to relay communication between one UE and the network via one or more other UEs. This category includes performance requirements for various scenarios.

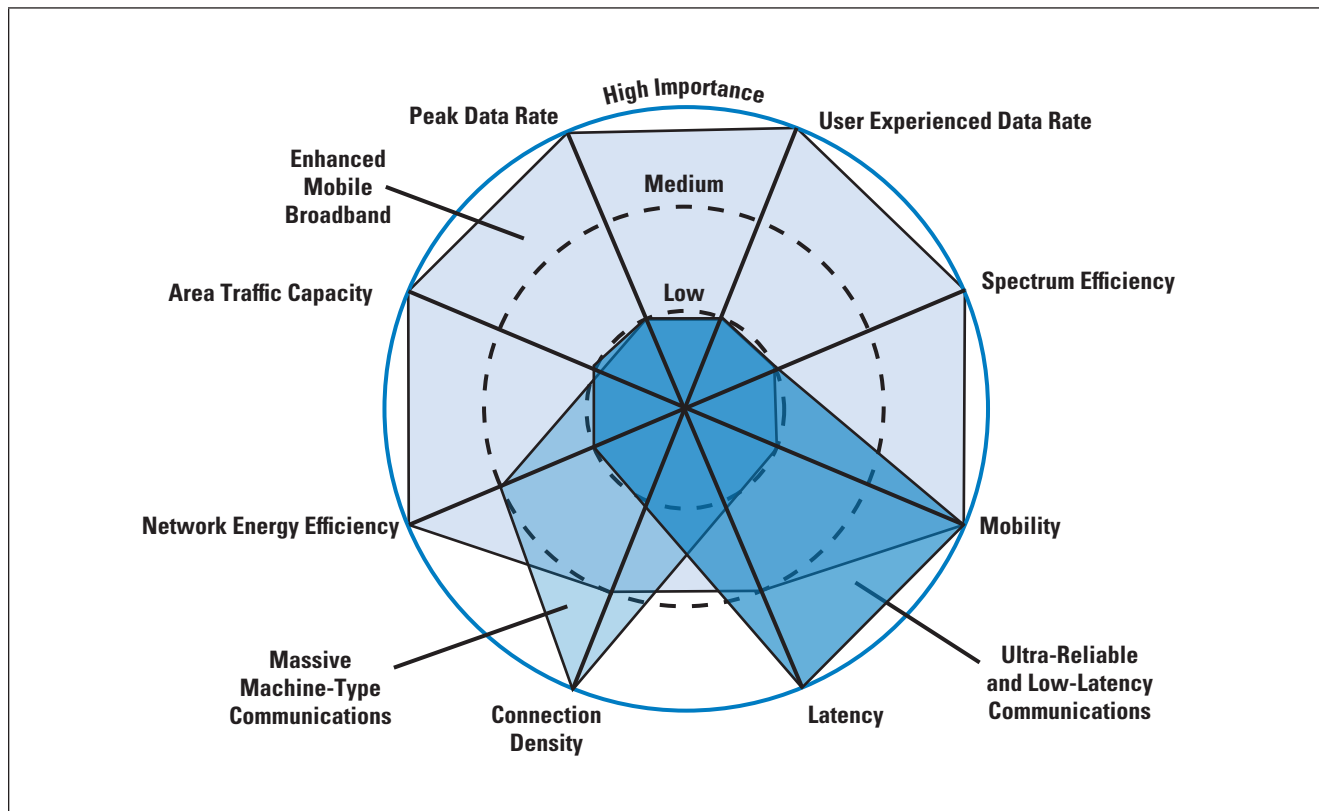

Usage Scenarios and Use Cases

Two important concepts in ITU-R Recommendation M.2083 and related documents are *Usage Scenario* and *Use Case*. No ITU document defines these terms, but the following definitions should suffice for this article.

- *Usage Scenario*: A general description of a way in which an IMT network is used. A usage scenario dictates various performance and technical requirements. A wide but nevertheless constrained variety of use cases are encompassed by a usage scenario.
- *Use Case*: A specific application or way of using an IMT network; also, a general account of a situation or course of actions that use an IMT network. It is described from the end user's perspective and illustrates fundamental characteristics. A use case dictates more specific and refined performance and technical requirements than the corresponding usage scenario.

M.2083 defines three usage scenarios: enhanced mobile broadband, massive machine-type communications, and ultra-reliable and low-latency communications. Figure 7, from M.2083, indicates the relative importance of the key capabilities for the three usage scenarios.

Figure 7: The Importance of Key Capabilities in Different Usage Scenarios

Enhanced Mobile Broadband

Enhanced Mobile Broadband (eMBB) is the 5G feature that provides a significant increase in data rate over 4G for a normal mobile Internet user. Enhanced mobile broadband services allow users to experience high-speed and high-quality multimedia services such as virtual reality, *Augmented Reality* (AR), and 4,000-pixels horizontal resolution (4K) video, at any time and place.

These applications require reasonably low-latency and good connection density, with a high demand on the other six key capabilities. In addition to the consumption of multimedia content for entertainment purposes, eMBB supports numerous business applications. They include cloud access apps for commuters and other off-site employees, the ability of remote workers to communicate with the back office, or indeed an entire smart office where all devices are wirelessly and seamlessly connected.

Of the three usage scenarios defined in M.2083, eMBB is the only general-purpose case, and it is the one that is most familiar to current 4G users. In essence, eMBB is an enhanced version of 4G, providing improved performance and an increasingly seamless user experience.

ITU-R Report M.2410 lists three deployment options that characterize the scope of eMBB and that are used for purposes of evaluation of candidate specifications: indoor hotspot, dense urban, and rural. The remainder of this section provides a brief overview of all three.

ITU-R Report M.2412^[7] defines *Indoor Hotspot* as “...an indoor isolated environment at offices and/or in shopping malls based on stationary and pedestrian users with very high user density.” This deployment scenario focuses on small coverage per site/*Transmission and Reception Point* (TRxP) and high user throughput or user density in buildings. The key characteristics of this deployment scenario are high capacity, high user density, and consistent user experience indoors.

5G capabilities should enable a seamless interface for users moving into and out of the indoor zone, without the necessity of joining a Wi-Fi network for indoor use. Types of demand include frequent upload and download of data from a company’s servers and real-time video meetings with local as well as remote participants.

One of the main challenges for supporting 5G use cases in the indoor environment is a consequence of the use of much higher-frequency bands for 5G than are used for 4G and earlier generations. These higher bands lead to greater link losses. For example, outdoor signals on the C band will be subject to an 8- to 13-dB link loss when penetrating through one concrete wall. The signals on the higher-mm wave band will experience difficulty in penetrating through a wall as the link loss exceeds 60 dB. It is a considerable challenge for outdoor 5G macro signals to cover indoor areas, and a dedicated 5G network consisting of interconnected base stations will be required for indoor environments.

An example use case in the indoor hotspot category is the smart office. The installation of 5G networks in the office environment can enable dramatic changes in the capabilities that businesses can exploit.

Examples of features now in use or that may soon be in use in 5G-enabled workplaces include:

- Facial recognition can be used for entrance security. The employee need not carry an identification tag or use some sort of token to gain entrance.
- A 5G virtual desktop infrastructure enables workers to connect their mobile device on a docking pad to a cloud computing system.
- Workers can convene remote conferences, talking to each other's avatars in cyberspace.
- Security systems can use high-definition video to monitor in greater detail and expand the ability to scan for security threats.
- Workers have faster access to a broader selection of apps.
- 5G enables real-time collaboration between people and things, possibly including augmented reality features.
- Real-time video interaction will become standard. This access allows capabilities such as real-time troubleshooting and ad hoc meetings.
- Synchronization of local data with the cloud becomes almost instantaneous, further enhancing collaboration.
- Sensors or facial recognition can tell if people are in the building and where they are at any given moment.

In essence, the smart office use case is characterized by heavy data use, with a particular reliance on high-definition video, in an indoor environment with low mobility requirements. In this use case scenario hundreds of users require ultra-high bandwidth to serve intense bandwidth applications. To some extent, Wi-Fi supports these capabilities, but with the increasing demands for high traffic volume, high density of users, and seamless integration of local and wide-area communications, a unified 5G solution has inherent advantages over a mixed Wi-Fi/cellular environment.

ITU-R Report M.2412^[7] defines *Dense Urban* as "...an urban environment with high user density and traffic loads focusing on pedestrian and vehicular users." The dense urban microcellular deployment scenario focuses on macro TRxPs with or without micro TRxPs and high user densities and traffic loads in city centers and dense urban areas. The key characteristics of this deployment scenario are high traffic loads and outdoor-to-outdoor and outdoor-to-indoor coverage.

The dense urban environment for 5G is characterized by the use of a dense collection of small cells to supplement macro cells for two reasons^[8]:

- The concentrated collection of stationary, pedestrian, and vehicular users, with 5G use cases, generates a tremendous traffic load.
- 5G-mm Wave networks are predominantly noise-limited. The result is that only small cell sizes can be supported.

An example use case in this category is provided by the EU project METIS (*Mobile and wireless communications Enablers for the Twenty-twenty Information Society*)^[9]. It refers to the connectivity and data rates required for users of high-volume services at any place and at any time in a dense urban environment, including both user interaction with cloud services and data- and device-centric services.

5G enables enhanced cloud services beyond the traditional services of web browsing, file download, and social media. Enhanced services include high-definition video streaming and video sharing. Enhanced device-centric services include augmented reality with information fetched from sensors, smart phones, wirelessly connected cameras, and other sources. The main features of this use case follow:

- High traffic loads
- Low mobility
- High data rate
- Outdoor coverage
- Outdoor-to-indoor coverage
- Support for both low and high frequency
- Limited interference
- High user density

This use case presents two unique challenges:

- Users expect the same QoE in any context, including at their workplace, enjoying leisure activities such as shopping or being on the move, on foot, or in a vehicle.
- Users in urban environments tend to dynamically cluster. Examples include people waiting at a traffic light or bus stop and conference room meetings at the workplace. These clusters lead to sudden peaks of geographically concentrated mobile broadband demand.

ITU-R Report M.2412^[7] defines *Rural-eMBB* as “...a rural environment with larger and continuous wide area coverage, supporting pedestrian, vehicular and high-speed vehicular users.” The rural deployment scenario focuses on larger and continuous coverage. The key characteristics of this scenario are continuous wide area coverage supporting high-speed vehicles. This scenario uses macro TRxPs, and is noise- and/or interference-limited.

The rural deployment also supports last-mile service to residences and other subscribers to provide telephone and Internet access. Many homes may be near a fiber connection, but the deployment of the last mile of the cabling can be very expensive and not necessarily cost-effective. The addition of new subscribers, or households, may be very expensive if new cables need to be installed. It may also require the operator to support two distinct systems, each with its own subscription management, for wired and wireless subscribers. To address this problem, delivering the last mile wirelessly may be a viable option. Such solutions are known as *Wireless Local Loop* (WLL), where the last mile is delivered wirelessly.

Massive Machine Type Communications

Massive Machine Type Communications (mMTC) is characterized by a very large number of connected devices typically transmitting a relatively low volume of non-delay-sensitive data. However, the machine-to-machine communications involves a range of performance and operational requirements. Devices are required to be low-cost and have a very long battery life, such as five years or longer.

The mMTC usage scenario defined by ITU-R represents a subset of the total IoT universe. A white paper from Ericsson^[10] lists four segments that comprise IoT:

- *Massive IoT*: Massive IoT is characterized by huge volumes of constrained devices that send and/or receive messages infrequently. The traffic is often tolerant of delay. Examples of use cases include low-cost sensors, meters, wearables, and trackers. Such devices are often deployed in challenging radio conditions such as in the basement of a building. Therefore, they require extended coverage and may rely solely on a battery power supply that puts extreme requirements on the life of the battery.
- *Broadband IoT*: Broadband IoT is an application of eMBB to the IoT environment, providing high data rates and relatively low latencies. Examples of use cases are in the areas of automotive, drones, *Augmented Reality/Virtual Reality* (AR/VR), utilities, manufacturing, and wearables.
- *Critical IoT*: Critical IoT is an application of *Ultra Reliable and Low Latency Communications* (URLCC) to the IoT environment, providing extremely low latencies and ultra-high reliability at a variety of data rates. In contrast to Broadband IoT, which achieves low latency on best effort, critical IoT is intended to deliver data within strict latency bounds with required guarantee levels, even in heavily loaded networks. Examples of use cases are in the areas of intelligent transportation systems, smart utilities, remote healthcare, smart manufacturing, and fully immersive AR/VR.
- *Industrial Automation IoT*: This segment supports seamless integration of cellular connectivity into the wired industrial infrastructure used for real-time advanced automation. These applications have extremely demanding requirements such as very accurate indoor positioning and time synchronization across devices and networks.

Massive IoT, as defined by Ericsson, is equivalent to mMTC defined by ITU-R. In terms of the number of connections, mMTC is the most rapidly growing segment of IoT^[11]. Table 2, based on a 2020 Ericsson white paper^[12], indicates likely mMTC use cases that 5G supports.

Table 2: Industry and Society Applications Enabled by Massive IoT

Application Area	Use Cases
Transport and Logistics	Fleet Management Goods Tracking
Agriculture	Climate / Agriculture Monitoring Livestock Tracking
Environment	Process Monitoring and Control Maintenance Monitoring
Industrial	Process Monitoring and Control Maintenance Monitoring
Utilities	Smart Metering Smart Grid Management
Smart Cities	Parking Sensors Smart Bicycles Waste Management Smart Lighting
Smart Buildings	Smoke Detectors Alarm Systems Home Automation
Consumers	Wearables Children/Elderly Tracking Medical Monitoring

An important group of mMTC use cases are in the general category of smart cities. ITU-T 4900^[13] defines a *Smart Sustainable City*, or simply *Smart City*, as follows: A smart sustainable city is an innovative city that uses *Information and Communication Technologies* (ICTs) and other means to improve quality of life, efficiency of urban operation and services, and competitiveness, while ensuring that it meets the needs of present and future generations with respect to economic, social, environmental, and cultural aspects.

The sustainability of a smart city is based on four main aspects:

- *Economic*: The ability to generate income and employment for the livelihood of the inhabitants.
- *Social*: The ability to ensure that the welfare (safety, health, education) of the citizens can be equally delivered despite differences in class, race, or gender.
- *Environmental*: The ability to protect future quality and reproducibility of natural resources.
- *Governance*: The ability to maintain social conditions of stability, democracy, participation, and justice.

Some smart-city use cases, such as *Public Protection and Disaster Relief* (PPDR), fit into the URLCC usage scenario, but many others fall into the mMTC usage scenario category.

As examples, *ITU-T Series Y Supplement 56*^[14] lists the following mMTC demonstration examples of smart-city use cases:

- *Pedestrian Monitoring for Decisive Disaster Response*: Involves the installation of surveillance cameras throughout a city that can monitor crowd size and behavior and transmit this information to a central monitoring/management source. The cameras monitor locations that are likely to draw large groups of people, such as near a railroad or subway station or near a school. If a disaster occurs near one of these sites, the system provides real-time information about the size of the crowd at risk. In addition, the pedestrian monitoring system facilitates the understanding of the behavior of crowds and the detection of abnormal situations by analyzing images captured by surveillance cameras. If it detects any abnormality, the system automatically provides information or instructions for evacuation from the disaster site or for prevention of accidents.
- *Citizens' Safety Services*: Involves interworking between smart-city operation centers and fire and police stations for the citizens' safety services. Surveillance cameras are deployed throughout the city to provide extensive coverage with a minimum number of cameras. IoT-enabled traffic sensors deployed throughout the city can measure rate and volume of traffic. The operations center connects wirelessly to the cameras and sensors to provide a central source of information. The operations center provides traffic information to the first responders to enable them to take the best route to the scene of an emergency.
- *Lift Monitoring Services*: Involves monitoring lifts, or elevators, throughout a city. One such system developed by Surbana Jurong is deployed in Singapore and other Asian cities. The system consists of a central *Lift Monitoring System* (LMS) and IoT-enabled sensors installed in lifts throughout the city. The installation in Singapore monitors more than 26,000 lifts across 10,000 housing units. The system enables rapid response to elevator malfunction. In addition, the sensor devices capture data on an ongoing basis. This data, using machine-learning algorithms, is used to predict future failures, allowing for optimized maintenance and reduced downtime.
- *Infrastructure Monitoring*: Involves using IoT sensor devices to monitor aging infrastructure elements to support automated inspection, diagnosis, confirmation of repair effort, and subsequent status check. The scheme can be applied to bridges, tunnels, and paved roads.
- *Citizen Identification System Using Biometric*: Has objective to provide a digital identity to the entire population to serve as the basis for accessing social services and interacting with the government at various levels. One such system, called *Aadhaar*, is deployed nationwide in India and currently has over one billion people registered. In any large Indian city, there are tens or even hundreds of thousands of Aadhaar devices in use for registration and service access. These devices form a massive IoT network connected to a central server.

Ultra-Reliable and Low-Latency Communications

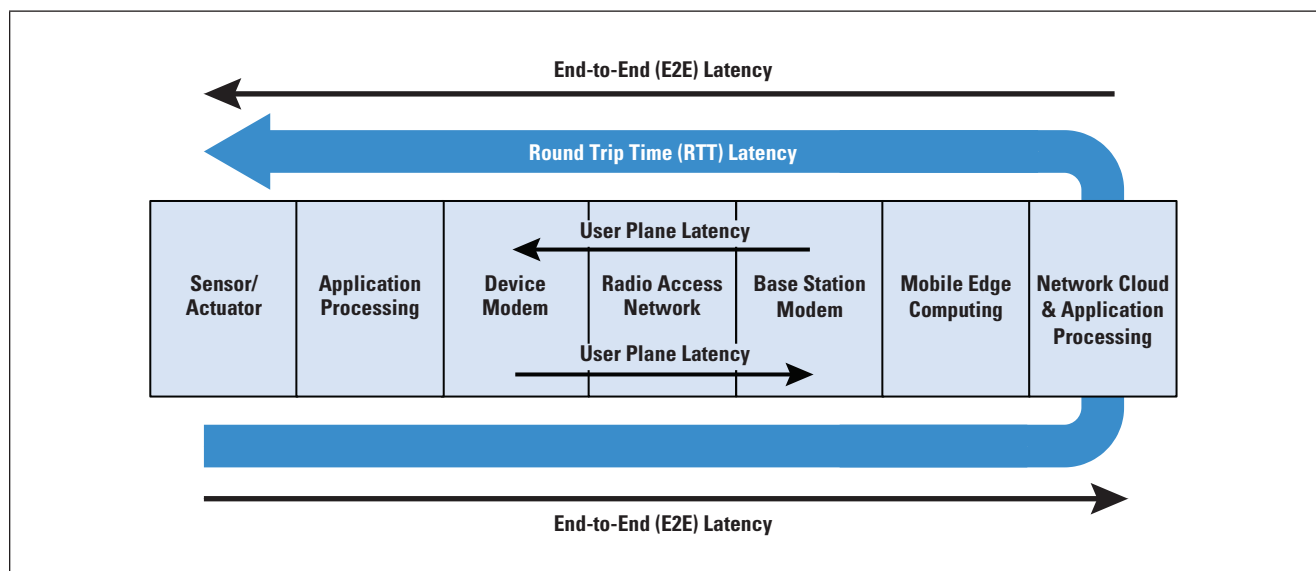

URLLC is a form of machine-to-machine communications that enables delay-sensitive and mission-critical services that require very low end-to-end delay, such as tactile Internet, remote control of medical or industrial robots, driverless cars, and real-time traffic control.

Figure 7 (earlier in this article) indicates that two parameters are of high importance for URLLC: *latency* and *mobility*. ITU-R Report M.2410 breaks the latency requirement into two parts:

- *User-Plane Latency*: is the contribution by the radio network to the time from when the source sends a packet to when the destination receives it (in ms). It is defined as the one-way time it takes to successfully deliver an application layer packet/message from the radio protocol Layer 2/3 SDU ingress point to the radio protocol Layer 2/3 SDU egress point of the radio interface in either uplink or downlink in the network for a given service in unloaded conditions, assuming the mobile station is in the active state. The minimum requirement (that is, the maximum allowable value) is 1 ms assuming unloaded conditions (that is, a single user) for small IP packets (for example, 0-byte payload + IP header), for both downlink and uplink.
- *Control-Plane Latency*: refers to the transition time from a most battery efficient state (for example, Idle state) to the start of continuous data transfer (for example, Active state). The minimum requirement is 20 ms.

User-Plane latency, however, is only one component that UE experiences overall, as illustrated in Figure 8. The *End-to-End* (E2E) latency is generally defined as the time it takes from when a data packet is sent from the transmitting end to when it is received at the receiving entity; for example, Internet server or other device. The measurement reference is the interface between Layers 2 and 3. It is also referred to as *One-Trip Time* (OTT). It includes the user-plane latency in one direction, transport network delays, and application processing time.

Figure 8: E2E Latency and Round-Trip Time Latency

A related measure is *Round-Trip Time* (RTT), which is the time from when a data packet is sent from a source device until an acknowledgment or response is received from the destination device. Unfortunately, E2E latency is sometimes equal to RTT latency in the literature, even in some 3GPP documents. However, the implication in most standards and specification documents is that E2E latency refers to one-way latency, not round-trip.

Mobility is the maximum UE speed (in km/h) at which a QoS can be achieved. Mobility assumes a seamless transfer between radio nodes that may belong to different layers and/or radio access technologies (multi-layer/RAT) can be achieved. The following classes of mobility are defined:

- *Stationary*: 0 km/h
- *Pedestrian*: 0 to 10 km/h
- *Vehicular*: 10 to 120 km/h
- *High-speed vehicular*: 120 to 500 km/h

M.2410 does not provide a specific measure of QoS. Report ITU-R M.2412 defines QoS as successful delivery of 99% of messages within 10s.

Another aspect of mobility addressed in M.2410 is *Mobility Interruption Time*, which is the shortest time duration supported by the system during which UE cannot exchange user-plane packets with any base station during transitions. This number includes the time required to execute any RAN procedure, radio resource control signaling protocol, or other message exchanges between the mobile station and the RAN. The minimum requirement for mobility interruption time is 0 ms. Thus, there should be no interruption of service when moving UE switches from one base station to another.

URLLC Use Cases

A URLLC white paper from 5G Americas^[15], one of the 3GPP market representation partners, provides a useful way of understanding the wide variety of URLLC use cases by focusing on emerging mission-critical applications that have demanding reliability and latency requirements. These use cases include:

- Smart Factory
- Ground Vehicles, Drones, and Robots
- Tactile Interaction
- Augmented Reality and Virtual Reality
- Emergency, Disasters, and Public Safety
- Urgent Health Care
- Intelligent Transportation

The area that has perhaps received the most attention as an application area that requires URLLC support is that of the *Smart Factory* or *Industrial Automation*. This application area is typified by extremely demanding reliability and latency requirements for 5G communication links between sensors, actuators, and controllers.

Traditionally, Ethernet has been used to provide network connectivity. For smart factories, wireless networks provide many advantages over Ethernet:

- Reduced cost of manufacturing, installation, and maintenance
- Higher long-term reliability as wired connections suffer from wear and tear in motion applications
- Inherent deployment flexibility

With 5G, dispersed IoT sensors, actuators, controllers, and robots driven by software command and control can expand the ability to more fully automate an industrial process.

The application area that encompasses *Ground Vehicles, Drones, and Robots* refers to remotely controlled mobile devices and robots. Such devices are in common use in factory applications, but are also deployed in other contexts, such as smart agriculture. One area of particular interest is unmanned aircraft traffic management.

Tactile Interaction refers to a level of responsiveness that works at a human scale. For example, remote health care or gaming applications may require very low round-trip times to convince human senses that the perceived touch, sight, and sound are lifelike. These use cases involve interaction between humans and systems, where humans wirelessly control real and virtual objects, and the interaction requires a tactile control signal with audio or visual feedback. Robotic controls and interaction include several scenarios with many applications in manufacturing, remote medical care, and autonomous cars. The tactile interaction requires real-time reactions on the order of a few milliseconds. Remote surgery, discussed later in this article, is perhaps the most demanding use case. Table 3 gives typical values of *Key Performance Indicators* (KPIs) for tactile Internet applications.

Table 3: Key Performance Indicators for Tactile Internet

KPI	Value
Traffic Volume Density	0.03–1 Mbps/m ² / (cell radius 100 m ²)
Experienced User Throughput	0.3–1 Mbps (UL)
Latency	User-plane latency less than 2 ms
Availability	>99.999%
Reliability	>99.999 % for healthcare or remote driving/manipulation 95 % for remote gaming or remote augmented reality

AR and VR tend to have relatively high data-rate requirements. Some specific use cases also have URLLC requirements.

A paper from the *Next Generation Mobile Networks Alliance* (NGMN)^[16] lists three AR/VR examples with URLLC requirements:

- *Augmented Worker*: Augmented work is work that integrates digital technologies into the industrial environment to improve how work is done. Augmented work is appropriate for situations when it is not cost-effective or even possible to fully automate tasks, but it is desirable to augment the capabilities of the human worker. A good example is a task such as equipment repair where the access is difficult (for example, a hazardous environment) or the expert is at a remote place. The remote worker can be equipped with an AR headset and some sort of tactile interface for remote control. Sensor information from the remote target location in terms of audio, video, and haptic (tactile) enables the remote operator to control actuators at the target location to achieve the required work.
- *360 Panoramic VR View Video Broadcasting*: 360-degree videos are video recordings where a view in every direction is recorded at the same time, shot using an omnidirectional camera or a collection of cameras. With 360 panoramic VR view video broadcasting, the video is broadcast in real time. Remote users with VR headsets can view the live video feed, and by turning their head, see the point of view change in real time.
- *AR and MR Cloud Gaming*: A good example of an application in the AR/VR area that requires URLLC performance is AR and *Mixed Reality* (MR) cloud gaming, which is real-time game playing using a thin client with the bulk of the software on edge servers. This online gaming service provides on-demand streaming of games onto computers, consoles, and mobile devices. Thus, the user does not have to upgrade frequently and to deal with compatibility issues. Highly interactive games with tight QoS requirements generate the need for low-latency network performance.

Use cases in the category of *Emergency, Disasters, and Public Safety* generally require high reliability to enable response to natural disasters and emergencies. Accurate position location and very low latency to enable rapid response are also often critical requirements.

The *Urgent Health Care* category refers to applications involving remote diagnosis and treatment. A white paper from 5G Americas^[17] lists the following examples in this category:

- *Remote Patient Monitoring*: This use case involves remote patient monitoring via communication with devices that measure certain health indicators, such as pulse, blood glucose, blood pressure, and temperature. On an individual basis, the data rate and latency requirements are modest. However, for this use case to become pervasive, 5G is needed to support the massive increase in the number of connections per square meter while still maintaining the requisite QoS.

- *Remote Health Care*: This use case provides for individualized consultation, treatment, and patient monitoring built on a video linkup capability. The video conferencing can be augmented with remote transfer of health-related data in real time. Treatment could also be offered using smart pharmaceutical devices that correctly administer approved dosages of a drug on a schedule specified by the physician or practitioner.
- *Remote Surgery*: More demanding is remote surgery via control of robotic devices. This application area may be appropriate in ambulances, disaster sites, and remote areas. Important requirements are precise control and very low latency, very high reliability, and tight security.

The *Next Generation Mobile Networks Alliance*^[16] lists the following examples in the Intelligent Transportation category:

- *Assisted Driving*: 5G enables the delivery of advanced driver-assistance features that reduce fatal accidents and traffic congestion. These features include real-time maps for navigation, speed warnings, road hazards, vulnerabilities, heads-up display systems, and sensor data sharing. These features will enable the vehicle to dynamically change its course on the road under certain scenarios and conditions. *Vehicle-to-Network* (V2N) communication is necessary for this use case. Information from the vehicle enables the remote application to perform short-range modelling and recognition of surrounding objects and vehicles plus mid- to long-range modelling of the surroundings using information on the latest digital maps, traffic signs, traffic-signal locations, road construction, and traffic congestion.
- *Autonomous Driving*: Fully autonomous driving involves the capability of a vehicle to sense its environment and navigate without human input under all scenarios and conditions. A 5G network with URLLC capability enables numerous necessary features, including the use of complex algorithms to distinguish between different cars on the road and identify appropriate navigation paths given obstacles and considering the rules of the road, and the exchange of information in real time between thousands of cars connected in the same area.
- *Tele-operated Driving*: This use case refers to the use of remote driver assistance in areas where automatic driving is not possible. This assistance can provide enhanced safety for disabled people, elderly populations, and drivers in complex traffic situations. Typical application scenarios include disaster areas and unexpected and difficult terrains for manual driving such as in mining and construction. Tele-operated driving requires the wireless network to support V2N communication of video, sound feed information, and diagnostics from the vehicle, along with environmental information, to the remote driver. The network must support transmitting control commands from the remote driver to the vehicle to maneuver the vehicle in real time.

Low Earth Orbit Satellite Systems for Internet Access

by Dan York, Internet Society, and Geoff Huston, APNIC

Satellites have been providing Internet connectivity for a few decades now, but new technologies using satellites in *Low Earth Orbit* (LEO) have created a race to offer space-based Internet access that provides ubiquitous, high-speed, and low-latency connectivity. This article explores what is happening, what is new, and why our planet may soon be circled with 50,000 to 90,000 new satellites!

Understanding Orbits

To understand the excitement over LEOs, you need to first understand the orbits of satellites (Figure 1).

Figure 1: Orbital Altitudes

Geostationary Orbit

If you fire a projectile at a speed greater than the Earth’s “escape velocity,” (11.2 km/s) it will head away from the Earth. If you reduce the speed slightly, the projectile will be caught by the Earth’s gravity and try to fall back to Earth. If you also incline the aiming trajectory, then instead of falling back to Earth, it will settle into an orbit around the Earth. The orbital speed relative to the Earth is a function of the altitude of the object. At very high altitudes, such as the moon, the orbital period is slower than the Earth’s rotation, while at very low altitudes the orbital period is down to a small number of hours, implying that there is a mid-spot where the orbital period is the same as the Earth’s rotation. If you launch a satellite to an altitude of 35,768 km above the equator, orbiting in the same direction as the Earth on the equatorial plane, then from the Earth the spacecraft appears to sit in a stationary position when observed from the Earth’s surface; this orbit is a *Geostationary Orbit* (GEO)^[0]. This geometry is what allows people to set up a satellite send/receive dish and point it at a specific location in the sky where the satellite is positioned—and never change the orientation of the dish.

GEO satellites are sufficiently distant that they can cover an entire hemisphere of the Earth's surface. However, they are normally equipped with a collection of transponders, most of which are focused on smaller areas, allowing the satellite to service multiple specific target regions at once, with greater total capacity as a result. A satellite operator can achieve global coverage with as few as three satellites. In addition to global service platforms, many nations have launched GEO satellites that are stationed over their country to provide communication services across their region.

These satellites are typically the size of a large bus and are expensive in terms of both construction costs and launch cost. Both the Moon and the Sun exert gravitational effects on the satellite, and, to a lesser extent, solar radiation pressure, all causing the satellite to drift away from its geosynchronous position. To counter this drift, the satellite is equipped with thrusters and some form of propellant. The total amount of onboard fuel defines an upper limit to the time that station position can be maintained, and these satellites typically have an operational lifespan of around 15–20 years.

In order to keep the level of radio interference between adjacent satellites to an acceptably low level, there are a limited number of geostationary orbit locations. Typically, geosynchronous satellite stations are separated by 2 degrees of angle as seen from the Earth, or 1,471 km apart in orbit. Disputes between nations over the deployment of satellites in this orbit are addressed through the coordination work hosted by the *International Telecommunications Union Radiocommunications Sector* (ITU-R).

A challenge with using GEO satellites for Internet access is that they are so far away from Earth. It takes a minimum of 238 ms for a signal to travel from the surface of the Earth to a satellite positioned 35,768 km away and back again. The *Round Trip Time* (RTT) to propagate an outbound packet via a GEO satellite and receive a reply is a minimum of 476 ms. The distance to the satellite increases as you move away from the position directly underneath the satellite on the Earth's equator, and the propagation time for the round-trip approaches 560 ms as you approach the limit of clear signal access near the polar areas. When you add delays for signal encoding, switching, and other terrestrial elements, the delivered performance of a service based on geosynchronous satellites is a typical RTT of around 660 ms, or two-thirds of a second. For many applications that are tuned to operate efficiently on faster terrestrial paths, this extended delay often causes the application to be sluggish and unresponsive in terms of its performance.

It is also the case that at this altitude the Earth's magnetic field provides far less shielding from solar radiation via the *Van Allen Belt*, so the electronics for GEO satellites need to have appropriate shielding, and the onboard electronics must tolerate a certain amount of radiation exposure.

Low Earth Orbit

An orbiting spacecraft needs to be positioned at least 160 km above the surface of the Earth, or it will encounter significant drag from the top of the Earth's atmosphere and its orbit will quickly decay, with an inevitable result. Above this altitude, it is viable to position orbiting spacecraft without needing to provide large quantities of continual propulsion (although some residual drag is experienced in orbital altitudes up to 500 km or so). For example, the International Space Station orbits at an altitude 400 km, with an orbital period of some 90 minutes. This region of space, where the orbits are higher than around 160 km and below 2,000 km, is termed the *Low Earth Orbit* (LEO) region. This is the region where we've positioned most of our satellites, as they are more accessible in terms of launch cost.

LEO satellites are close enough to the Earth's surface that signal propagation time to the satellite and back can be between 4 and 8 ms, which gives a range of RTT measurements for packet transmission via LEO services in the range 10–50 ms, a range comparable to that of terrestrial systems. With per-access service capacities of between 10 and 200 Mbps, LEO services can support most forms of modern real-time communication and online interaction^[1].

However, LEO-based satellite services require more complexity. At an altitude of 550 km, for example, a satellite will be visible from the Earth's surface in a circular area with a radius of some 900 km. Its orbital path is such that its velocity will be some 27,000 km/h, and each spacecraft will be visible from a fixed point on the Earth's surface for 5 minutes. In other words, to provide a continuous service over a fixed point, an evenly distributed collection of a minimum of 21 spacecraft would be needed in an orbital plane to ensure that as one satellite falls below the horizon, another is rising from the opposite horizon. Higher numbers of satellites in the orbital plane ensure a more reliable service and allow the Earth stations to avoid using spacecraft that are low in the horizon. To cover the entire Earth's surface, you need a minimum of 21 such orbital planes if you are using a 550-km altitude. The result is that, instead of just three satellites to provide a GEO service to anywhere on the planet, you would need hundreds or even thousands of satellites to provide the same comprehensive coverage. However, this scenario has some benefits in that the total capacity available from the system would also be many thousands of times greater in aggregate than the sparse GEO arrangement (refer to Figure 2).

LEO satellite systems may also be in multiple “shells” at different altitudes. For example, at the time of this article in July 2023, SpaceX's Starlink has launched 3,982 satellites into shells from 550 to 570 km, and another 750 satellites into shells from 525 to 535 km. Another provider, OneWeb, has launched 634 satellites into shells at 1,200 km in altitude^[2].

Figure 2: LEO Satellite Geometry

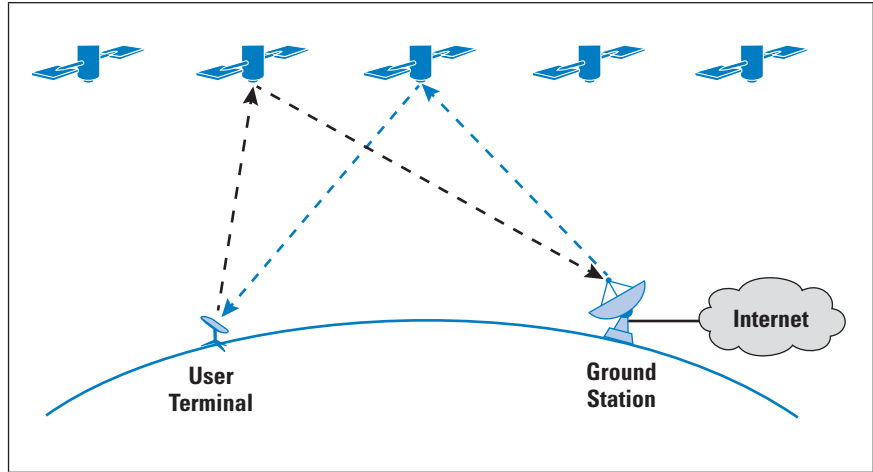

The closer a constellation is to the Earth's surface, the larger the number of satellites that are required for global coverage. OneWeb, orbiting at 1,200 km, needs only around 600 satellites, whereas SpaceX, orbiting around 550 km, needs around 3,000 satellites for continuous coverage. (They continue to launch more to provide additional capacity.) The counterpoint is that the closer satellites are to Earth, the lower the latency and the greater the potential access capacity.

LEO satellites are much smaller than GEO satellites and less expensive to manufacture and insert into orbit. For example, when SpaceX launches Starlink satellites into a LEO orbit, each Falcon 9 rocket usually carries 40 to 50 satellites. The development of reusable rockets has significantly affected the launch costs, bringing the launch cost on the SpaceX Falcon rockets to below USD 2,000 per kg. Other rocket systems have launch costs of between double to 20 times this cost.^[3]

A challenge with LEO satellites is that because they are closer to the Earth, they are subject to periods of atmospheric drag when increased solar activity expands the extent of the upper atmosphere into the LEO orbital plane. Similar to GEO satellites, a LEO satellite must carry sufficient propellant to maintain its orbit and compensate for the gravitational influences of the Moon and the Sun that will otherwise pull it out of its orbital plane over time. Additionally, the operational lifespan of LEO satellites is typically around 5 years, so when it reaches its end of life it must have enough propellant in reserve to thrust the spacecraft down from its orbital plane ("de-orbit") and burn up in the upper atmosphere. When a LEO constellation is in active service, the system operator must employ a constant process of launching replacement satellites.

Tracking a LEO satellite using Earth equipment is challenging, because the tracking equipment must swing from horizon to horizon in approximately 5-minute intervals. Conventional parabolic dish antennae with mechanical pivots have been replaced by phased array antennae to allow the antenna unit to track satellites using electronic phase control. The ability to perform rapid phase shifts across the antenna array allows not only the tracking of these rapidly moving objects, but also rapid transitions from one satellite to the next to support connection handoffs between satellites (Figure 3).

Figure 3: Satellite Handoff

Medium Earth Orbit

The region of space between 2,000 and 36,000 km above the Earth is referred to as *Medium Earth Orbit* (MEO). At the low end of this range, 2,000 km, the orbital period is around 2 hours, and the time to pass a signal up to the spacecraft and back is around 13 ms if you are located directly under the spacecraft. The higher the altitude the longer the orbital period, which, in turn reduces the number of spacecraft required to support a continuously available service. The transmission time to bounce a signal off the spacecraft at an altitude of 20,000 km is around 140 ms.

This zone encompasses the inner and outer Van Allen belts, which are belts of energetic charged particles that are trapped into an Earth orbit because of the Earth's magnetic field. The good news is that these belts protect the Earth's atmosphere from being blown away by solar radiation (as appears to have happened to Mars when its inner core solidified). The not-so-good news for satellites is that orbiting in this belt is like wandering through a firing range—there is always the possibility the sensitive electronics are damaged by a strike from one of these energetic particles. The outer belt is less dense, but the particles can have significantly higher energy levels. Beyond the Van Allen belts spacecraft encounter far higher levels of risk of damage from cosmic rays and solar radiation.

A region between the inner and outer Van Allen belts lies approximately between 12,000 and 24,000 km in altitude, which has a lower incidence of such energetic particles. The belts fluctuate in size and shape due to changes in the levels of solar radiation. The Earth itself acts as a shield, so that the belt is more compressed facing towards the Sun and extends further out on the “dark” side of the Earth.

The major satellites in this region are the satellite systems that support navigation, such as the *Global Positioning System* (GPS) using 31 spacecraft orbiting at some 20,200 km, *Galileo* with 24 active spacecraft at 23,222 km, *GLONASS* using 24 orbiting spacecraft at an altitude of 19,100 km, and *BeiDou* with 30 MEO satellites at 21,150 km.

For Internet access, the only major provider currently operating in MEO is the O3b network of around 20 satellites, operating at an altitude of approximately 8,000 km. O3b (which originally stood for “other 3 billion,” referring to the number of people still offline) began offering Internet connectivity in 2014 and was acquired by SES in 2016. SES is continuing to expand the service and is in the process of launching a new generation of 11 “O3b mPOWER” satellites into MEO, with promises to offer speeds up to multiple gigabits per second to its commercial customers.

Signal latency is higher than for LEOs, but significantly less than that of GEOs. Presumably feeling the competitive pressure from the LEO industry, SES has been working with many of the GEO providers to provide “multi-orbit” connectivity options that combine both MEO and GEO systems.

MEOs are a compromise in many ways. The Earth equipment still needs to perform tracking of the satellite, and that limits the power and sensitivity of the MEO antennae, yet the increased distance limits the performance and capacity of the system. The higher altitude provides greater coverage per satellite, allowing for broad coverage of the Earth’s surface with fewer spacecraft in the constellation, but the smaller number of satellites limits the overall capacity of the system.

If launch costs had remained high, then MEO systems made more sense in terms of minimizing the initial cost of the operation and maximizing the potential user base for the MEO satellite service, but the dramatic change in launch costs for LEO systems coupled with the use of phased array low-power steerable antennae has shifted the position quite dramatically in favor of LEO services. While GEO and MEO services tend to operate as wholesale services to a limited set of commercial customers using a conventional leased circuit service model, LEO systems have entered the consumer market, operating a direct access service as a retail service.

User Equipment

Consumers who want to connect to a LEO service for Internet access need to purchase what the satellite industry calls a *User Terminal*. This equipment includes the antenna and some access terminal, such as a small Ethernet switch or Wi-Fi access point. The phased-array antennas are compact, lightweight, and user-installable. Amazon has demonstrated some prototype user terminals that are small enough to fit in a backpack, and some mobile carriers have entered into agreements with Starlink to provide mobile handset access services directly from the handset to the satellite system (presumably with a significantly lower service capacity because of the limitations of the radio antenna on the handset).

There are more-complex user terminals that use parabolic dish antennae. These systems can achieve higher capacity and superior performance, but they require some form of mechanical steering to track the LEO satellite.

You can achieve the satellite-to-satellite handover function using dual antennae terminals, with one tracking the satellite for the active connection while the second pivots to focus on the next satellite in sequence.

Earth Stations and Inter-Satellite Connections

Satellite communications systems have conventionally operated as a “mirror in the sky.” The satellite receives a signal sent up from a user terminal and switches to a sending transponder that beams the signal back to an Earth station, which then passes the signal into the terrestrial network. With communications systems based on a GEO configuration it was possible to use just three Earth stations to service the entire system, given the hemispherical visibility of GEO satellites.

MEO and LEO satellites have more limited visibility, and in a “mirror” mode of operation, the density of Earth stations depends on the satellite altitude. For Starlink satellites at a 550-km altitude, Earth stations would need to be configured in a grid with around a 1,000-km spacing. This setup may be feasible in some locales, but if the intended service coverage includes more remote areas and coverage across oceans, then a different approach to Earth stations would be needed for LEO systems. An interesting technical development with LEO constellations to respond to this situation is the development of *Inter-Satellite Lasers* (ISLs) to send data between satellites within a constellation.

With the use of ISLs in the Starlink constellation, connections can now be passed from one satellite to another, and they do so in a relay form until they can drop down to an Earth station or user terminal. For example, SpaceX used this solution in early 2023 to connect remote Antarctic research stations, without having any ground stations on Antarctica^[4]. Details of Starlink’s ISL system, including capacity and configuration, are not yet published, but there have been recent service announcements that show service availability in regions where no Earth stations exist.

A simple approach to ISLs would be to link adjacent satellites in a common orbital plane (Figure 4). A more flexible approach might be to link adjacent satellites across different orbital paths, but the relative closing speeds of satellites on different orbital planes may well be beyond the capabilities of steerable laser systems. For example, a spacecraft travelling north/south at 27,000 km/h attempting to track a satellite passing on an east-west plane at the same speed would have a closing speed of some 700 km/h and an angular velocity of one angle of degree every three seconds, which may present some challenges to an onboard laser steering system.

Spectrum and Regulatory Approvals

Satellite communication requires allocation of certain frequencies in the radio spectrum for communication from the consumer equipment (such as the antenna) to the satellites, and from the satellites to a ground station where connections are made to the Internet.

Figure 4: Inter-Satellite Lasers

Spectrum management could easily consume an entire article by itself, but at a high level, spectrum “allocations” are coordinated through the *International Telecommunication Union (ITU)*, specifically the *ITU Radiocommunication Sector (ITU-R)*. Most of the LEO systems use frequencies within the Ku (10.7–14.5 GHz) and Ka (17.3–30 GHz) bands, which are the bands that are intended for use by Broadband Satellite Services. There is also the more recently allocated Q/V band (37.5–51.4 GHz), which is available for use in this context and has been deployed already in some systems.

Initial Allocations

The world’s nations have agreed that above some altitude “outer space” began. The implication of this agreement is that the sovereign rights that apply to the defined surface parts of the Earth extend only up to the point of “outer space.” Oddly enough, the world’s nations did not agree as to where “outer space” begins, and some nations claim sovereignty up to an altitude of only 100 km, while others extend that further to 160 km or more. In any case, the result is that there is no national regime that must approve or otherwise say what a spacecraft may do in outer space in the form of “over flying” its territory. However, some conventions apply to assist various folk to coordinate their actions in space and assist in resolving any disputes that may arise. The use of GEO station slots by various nations is one such area where conventions apply, and the ITU-R assists in this coordination activity.

However, when the topic shifts to that of communications between Earth and satellites, there is a requirement to get various forms of national regulatory approval, based on the location of the Earth stations. The failure to gain such approvals for the Iridium service was the major cause of the early business failure of this venture in 2000. The approval is not quite as simple as just approval for the operation of Earth stations. When a company wants to launch a LEO satellite constellation, it conventionally obtains approval from its national regulator. For example, SpaceX and Amazon are both US companies, so they filed their requests with the US *Federal Communication Commission (FCC)*. The filings include the radio frequencies they want to use and the number, altitudes, and orbital planes at which their satellites will operate. These filings are also forwarded to the ITU.

The LEO and MEO space allocations are generally operated on a first-come, first-served basis, but to prevent people from “squatting” on spectrum and altitude allocations, the ITU requires LEO satellite constellations to have 10 percent of their constellation in orbit within the first two years after the start of deployment, 50 percent in five years, and 100 percent in seven years. This factor is part the reason why there is a great amount of heightened activity to launch LEO constellations. The various companies who have lodged applications need to meet these deployment milestones or they risk losing the exclusivity of their spectrum allocations.

For GEO satellites the ITU-R coordinates the spectrum allocations and the orbital slots. For LEO or MEO satellites, the ITU-R coordinates only the spectrum allocations, and does not coordinate the orbital planes and altitudes for these satellites. That aspect is handled entirely by national regulators.

When a company obtains the necessary spectrum and altitude allocations from its national regulator, it then can launch its satellite platforms into orbit. This launch activity requires completely separate approvals and involves processes whose descriptions fall outside the scope of this article.

National Approvals

As part of obtaining the initial spectrum allocations, a LEO system provider receives the approval to operate within its home nation. Then the provider has to go to the spectrum regulators in every country in which it wishes to operate to service and receive regulatory approval to use the spectrum in that country.

In some cases, the requested spectrum may be already in use, and the country faces the difficult decision of whether to re-configure its local use situation or be denied use of the LEO system. An example is Armenia, where a national regulator representative informed the audience of the *Armenian Internet Governance Forum 2022* that using Starlink was not possible anytime soon because the frequencies were in use by the Armenian military and government. Given that SpaceX will not change its frequencies, there probably will not be an option until the Armenian government changes its own systems to use different frequencies, which could take time and some amount of unplanned costs.

While it is technically possible for a LEO provider to offer service in a country for which it does not have permission to operate (SpaceX activated its service during the protests in Iran in late 2022^[5]), it is not legally permitted to simply bring an antenna into a country and start using it with a LEO system. The LEO providers must obtain permission to operate the service in each country before they can make their service available to customers. Additionally, the LEO providers may also need to get approval to distribute the consumer equipment, and approval to interconnect with local terrestrial infrastructure.

Standards

We have very little visibility into how the internal networks operate, but at the Internet Protocol and application layers, the LEO constellations so far seem to support all the conventional standards for Internet Protocol forwarding and Internet operations created by the *Internet Engineering Task Force* (IETF).

It seems at the moment that the major LEO operators (Starlink, OneWeb, Amazon Project Kuiper) are all pursuing their own proprietary systems for communication between their user terminals (antennas) and their satellites, and between their satellites and their ground stations. This process will require consumers to purchase completely separate user terminals in order to use each different system. Perhaps at some point this process will become standardized, but not in this initial period of deployment.

Still Many Questions

That point is perhaps a critical one. Regardless of any marketing hype, the reality is that the LEO Internet access industry is very much still in its infancy. Only SpaceX's Starlink has global coverage. OneWeb has launched sufficient satellites to attain global coverage and is in the process of getting all its satellites in position. It hopes to offer global connectivity by the end of 2023, concentrating its service on the government and enterprise sector. Amazon's Project Kuiper has been manufacturing its satellites and equipment, but is still waiting for rocket availability to get its satellites into space. Many other companies are in various stages of getting their systems underway.

There are still many open questions, many of which the Internet Society explored in a recent document about LEO satellites^[6]. What will the capacity of these LEO systems truly be? Will they be able to support all the many devices we want to connect to them? Will the systems be affordable by those who need the connectivity the most? Using space-based platforms to provide global coverage to the billions of unconnected people probably would require some significant changes in the service model, because the challenges, particularly in terms of affordability, are still significant.^[8]

Will these constellations all be able to operate without interfering with each other? Will consumers tolerate the costs of proprietary equipment and the high cost of switching? What about the problems of "space debris" resulting from collisions or inactive satellites? Do we understand the potential environmental impact of having so many satellites burning up in our upper atmosphere when they reach their five-year end-of-life? Or the impact of all the regular rocket launches needed to resupply the constellations with new satellites? Questions abound, and many of them we may not be able to answer until we have the experience with getting more LEO constellations online.

Looking Ahead

Without a doubt, the next few years will be extremely active:

- SpaceX plans to complete its “Gen1” constellation of 4,408 satellites. In addition, SpaceX has received US FCC approval for 7,500 satellites in its “Gen2” constellation, which the company hopes to grow to almost 30,000 satellites. The company has also announced numerous “direct-to-phone” services with a collection of mobile network operators.
- OneWeb aims to have its global connectivity service available by the end of 2023.
- Over the next two years, Amazon is seeking to launch its Project Kuiper, a direct competitor to Starlink in the consumer market, and have it operational in 2025.
- The Chinese government is seeking to launch its own LEO constellation, called “Guowang,” which will have almost 13,000 satellites.

Filings with the ITU show that there is a path where as many as 90,000 satellites could be launching into LEO over the next several years. Here are a few examples:

SpaceX Starlink Gen 1	4,408
SpaceX Starlink Gen 2	29,988
OneWeb, Phase 1	718
OneWeb, Phase 2	6,372
Amazon Project Kuiper	7,774
China Guowang	12,992
Astra	13,620
Boeing	5,842
Globalstar	3,080
Lynk	2,000
Telesat Lightspeed	1,969
Spin Launch	1,190
TOTAL	89,953

To put this information in perspective, LEO, MEO, and GEO orbits currently have only about 8,000 active satellites—and SpaceX operates over 4,500 of them!

Even more satellite systems are in planning stages; this article has covered only LEO satellites used for Internet access. In addition, LEO constellations are being launched for sensor networks (as in the Internet of Things), imaging/photography, and much more.

How many of these constellations will actually be launched into orbit and be used as a service is an open question. Navigating all the required regulatory approvals across all the various national regulatory regimes is very challenging. Unless you are SpaceX and own your own rockets, launching satellites into space is extremely difficult right now, as many current rocket programs are delayed or simply unavailable.

We are also seeing that the rise of the competition of space-based Internet systems is causing ground-based Internet service providers to accelerate their plans for deploying terrestrial networks. As good as LEO systems may be, fiber networks can still provide even higher speeds. There is still much in the way of potential to use fiber-based trunk networks with last-mile access provided by mobile radio technologies, and these networks are well-understood technologies with an already-dominant user base. If the terrestrial access service providers are successful in making even faster connectivity more widely available and affordable, then the competition for the user between space and terrestrial-based systems would increase in intensity, and we can anticipate that such competition will result in lower costs, wider coverage, and improved performance for consumers.

In any case, there are tremendous opportunities for LEO satellite systems to help us connect the unconnected, create more resilient networks, help coordinate disaster-relief efforts, and generally bring high-speed, low-latency Internet connectivity to everyone, everywhere. The next few years will show us whether we can make these goals a reality.

DAN YORK serves the *Internet Society* (ISOC) as the Director, Internet Technology, with his focus on helping explain the changes happening to the Internet and how we use it. He led ISOC’s 2022 *Low Earth Orbit* (LEO) satellite project and continues to monitor LEO systems as part of ISOC’s work to connect the unconnected. Dan is also active within the DNS and real-time communications areas of the *Internet Engineering Task Force* (IETF). Since the mid-1980s Dan has been working with online communication technologies and helping businesses and organizations understand how to use and participate in these new media. An author of multiple books on networking, security, IPv6, and Linux, he frequently presents at industry conferences and events. He has been blogging, writing online, and podcasting since the early 2000s. He lives in Vermont, USA. E-mail: york@isoc.org

GEOFF HUSTON AM, B.Sc., M.Sc., is the Chief Scientist at APNIC, the Regional Internet Registry serving the Asia Pacific region. He has been closely involved with the development of the Internet for many years, particularly within Australia, where he was responsible for building the Internet within the Australian academic and research sector in the early 1990s. He is author of numerous Internet-related books, and was a member of the Internet Architecture Board from 1999 until 2005. He served on the Board of Trustees of the Internet Society from 1992 until 2001. At various times Geoff has worked as an Internet researcher, an ISP systems architect, and a network operator. Letter to the Editor

On 25 years of The Internet Protocol Journal

Geoff Huston's magnum opus covering the last 25 years of the history of the Internet inspires me to reflect on those 25 years from several perspectives^[1]. The year 1998 saw the launch of two extraordinary companies resting on and extending the Internet infrastructure: Google and Akamai. Each, in its own way, survived the "dot-bust" and went on to make significant contributions to the utility of the Internet and the World Wide Web. Many other companies have come, some have gone, and some have continued to enjoy robust growth. For many of us, 2023 feels like a new inflection point in communications. Low earth-orbiting satellites promise to provide access to the Internet from every square inch of the planet. Inter-continental fiber networks continue to expand in number and capacity, and there is energizing interest in developing mesh-like infrastructure to respond to cable cuts through optical re-routing in switching units on the ocean floor.

Ironically, 1998 was also the year in which the *Interplanetary Special Interest Group* of the Internet Society was formed, and it still continues as the Interplanetary chapter (ipnsig.org). A new suite of interplanetary "Bundle Protocols" has been standardized by the IETF and by the *Consultative Committee on Space Data Systems* (CCSDS), whose standards are also part of the ISO standards library. As the *Artemis*, *LunaNet* (NASA), and *MoonLight* (ESA) missions unfold, bringing us back to the Moon, the prospect of commercial operations looms large and immediate. The governance challenges of competitive and cooperative public/private engagements will be topics of urgent discussion well before this decade is out. There will be lessons from the multi-stakeholder policy-making practices derived from the building of the Internet and neo-institutional energy as the need for new governance mechanisms emerge.

Wireless technologies continue to evolve, and edge computing and more disciplined forms of Wi-Fi are emerging. Social media and recently emerging *Large Language Model* neural networks are confounding technologists and policy makers as they seek to make the Internet a safer place while preserving its historical openness to new ideas, new applications, and new ways to share and discover knowledge. These new neural transformer networks are living up to their name by transforming our awareness of the importance of reliable information sources in a sea of misinformation and disinformation. Preservation of human rights has become an ever more urgent priority in the face of scaled abuse of online resources. We can hope that the solutions to the problems of artificial intelligence will be found in the technology itself.

[1] Geoff Huston, "Twenty-Five Years Later," *The Internet Protocol Journal*, Volume 25, No. 1, June 2023.

And for all those years, *The Internet Protocol Journal* has consistently shed light on the conundrums that confound Internet engineers, scientists, operators, and policy makers. Hats off to its long-time editor, Ole Jacobsen, for persistent and quality reporting and sharing of timely and technically sound information.

—Vint Cerf, Woodhurst, May 2023

Internet Society Launches NetLoss Calculator

The Internet Society recently launched the *NetLoss* calculator, a revolutionary tool that measures the economic impact of Internet shutdowns around the world. Hosted on the Internet Society's *Pulse* Platform that tracks and analyzes shutdowns, NetLoss uses a groundbreaking econometric framework to understand the impacts of shutdowns and provides an unprecedented level of rigor and precision in estimating their economic damage.

Internet shutdowns globally reached a record high in 2022, with governments around the world ordering Internet access and services to be restricted or blocked during civil unrest, school exams, and during elections, which resulted in major economic consequences.

According to the NetLoss calculator:

- The shutdown in Sudan in April 2023 is estimated to have cost the country more than \$3 million USD, as well as the loss of 560 jobs.
- The shutdown in Pakistan in May 2023 is estimated to have cost more than \$13 million USD, as well as increased unemployment.
- The shutdown in Guinea in June 2023 is estimated to have cost the country nearly half a million USD and job losses.

Governments often mistakenly believe that Internet shutdowns will quell unrest, stop the spread of misinformation, or reduce harm from cybersecurity threats. But shutdowns are extremely disruptive to economic activity: they halt e-commerce, generate losses in time-sensitive transactions, increase unemployment, interrupt business-customer communications, and create financial and reputational risks for companies. They also hurt a country's growth as research shows Internet adoption positively impacts *Gross Domestic Product* (GDP).

The Internet Society has long opposed the practice of Internet shutdowns, and urges all governments to refrain from implementing them due to the damage they inflict on a nation's economy, civil society, and Internet infrastructure. With NetLoss, organizations and advocates can demonstrate to governments and regulators how a shutdown will negatively impact their nation's economy.

In addition to the estimated cost of an Internet shutdown (that is, the loss in GDP), the Internet Society NetLoss calculator also estimates:

- The change in the unemployment rate due to a shutdown.
- The amount of *Foreign Direct Investment* (FDI) lost due to a shutdown.
- Risk of a shutdown: the probability that a country will experience a shutdown.

“The global rise in Internet shutdowns shows that governments continue to ignore the negative consequences of undermining the open, accessible, and secure nature of the global Internet. The calculator is a major step forward for the community of journalists, policymakers, technologists, and other stakeholders who are pushing back against the damaging practice of Internet shutdowns. Its groundbreaking and fully transparent methodology will help show governments around the world that shutting down the Internet is never a solution,” said Andrew Sullivan, President and CEO, of The Internet Society.

The calculator considers a wide range of economic impacts beyond traditional measures of economic output, such as GDP, to demonstrate the financial impact of an Internet shutdown. It also includes the change in the unemployment rate, the amount of FDI lost, and the risk of a future shutdowns.

In addition to its primary indicators, the NetLoss calculator’s methodology also takes into account other factors that can impact country-specific economic outcomes, including the age dependency ratio (percentage of working 18–65 years old to total population), the fraction of the population residing in urban areas, and the percentage of the labor force with basic education.

By using the following open data sets, the NetLoss calculator’s methodology is reproducible and transparent:

- *Shutdown Data*: Includes detailed event-level data on government-mandated shutdown events.
- *Protests and Civil Unrest*: Includes detailed event-level data on various events, their start and end dates, involved parties, and associated fatalities.
- *Elections*: The Constituency-Level Elections Archive maintained by Yale University provides elections data from 150 countries since 1960.
- *Socioeconomic Indicators*: The World Bank provides data on economic indicators including GDP per capita, employment, inflation, and foreign investment.

The framework used in the NetLoss calculator builds on the Internet Society’s longstanding research and advocacy on this issue via the Pulse Platform. Launched in December 2020, Internet Society Pulse consolidates trusted third-party Internet measurement data from various sources into a single platform to examine Internet trends and tell data-driven stories so that policymakers, researchers, journalists, network operators, civil society groups and others can better understand the health, availability, and evolution of the Internet. The source of data for NetLoss is the World Bank’s *World Development Indicators*, which typically corrects for minor statistical changes. Data used in the calculator is updated quarterly.

The NetLoss calculator can be found on the Pulse platform:
<https://pulse.internetsociety.org/netloss>

Reflections on Ten Years Past the Snowden Revelations

Authored by Stephen Farrell, Farzaneh Badii, Bruce Schneier, and Steven M. Bellovin, RFC 9446 contains the thoughts and recountings of events that transpired during and after the release of information about the United States *National Security Agency* (NSA) by Edward Snowden in 2013. There are four perspectives: that of someone who was involved with sifting through the information to responsibly inform the public, that of a security area director of the IETF, that of a human rights expert, and that of a computer science and affiliate law professor. The purpose of this memo is to provide some historical perspective, while at the same time offering a view as to what security and privacy challenges the technical community should consider. These essays do not represent a consensus view, but that of the individual authors. The RFC can be found here: <https://www.rfc-editor.org/info/rfc9446>

APNIC Celebrates 30 Years

This year, the *Asia Pacific Network Information Centre* (APNIC) enters its third decade. Starting from a tiny office in Tokyo in 1992—with three people and a spreadsheet serving less than 600 delegated entities—APNIC has grown to a community of nearly 24,000 organizations across 56 economies. The APNIC of today serves 2.6 billion Internet users, more than half the global Internet. APNIC economies also comprise more than half the global IPv6 capability.

Despite many changes in technology and policy worldwide, APNIC has remained committed to: “A global, open, stable, and secure Internet.” The Asia Pacific is home to nine of the world’s 46 Least Developed Countries (as defined by the United Nations). Fifteen states and seven affiliated economies of APNIC Members are *Small Island Developing States* (SIDS), characterized by low population, distance and remoteness. However, the region also includes global economic superpowers and some of the most populated economies on Earth.

The combination of language, culture, distance, isolation and the different scale of the region’s communities magnifies the importance of consensus policy making on an equal basis. The APNIC community has developed policy that reflects and enables Internet growth across our region, and has ensured an Asia Pacific voice has been heard at a global level.

To mark this 30-year milestone, the *APNIC Blog* will run a series looking back at the past and into the future. The intention is to share stories, anecdotes, milestones and insights that capture some of the essence of the last 30 years. For more information visit:

<https://blog.apnic.net/2023/08/08/apnic-celebrates-30-years/>

Thank You!

Publication of IPJ is made possible by organizations and individuals around the world dedicated to the design, growth, evolution, and operation of the global Internet and private networks built on the Internet Protocol. Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at **ole@protocoljournal.org** or **olejacobsen@me.com**

ISSN 1944-1134

In our previous issue, we published Part One of “Introduction to 5G” by William Stallings. Part One introduced the standards and specifications that define 5G and described the usage scenarios that 5G supports. Part Two, included in this issue, provides an overview of the structure and function of 5G networks. A third article, on *Network Slicing*, which is closely related to 5G, will be published in a future edition of this journal.

This journal, as well as its predecessor *ConneXions—The Interoperability Report*, has covered numerous networking technologies over the last 35 years. Some of these technologies have become important building blocks for all networks, for example, *Ethernet*, which for more than 50 years has seen further improvements and standardization. We will publish an article on the history of Ethernet in a future issue. Other technologies have emerged, only to later fade into oblivion—an example being *Asynchronous Transfer Mode* (ATM). Our second article, by Craig Partridge, explores the reasons why ATM failed.

Modern smartphones and other mobile devices rely heavily on the use of numerous radio-based technologies such as *Near Field Communication* (NFC), Bluetooth, *Global Positioning System* (GPS), Wi-Fi, and cellular data. Our third article, by Mark Grayson, examines efforts to integrate cellular and Wi-Fi services into a single architecture.

The WHOIS protocol and its associated server were first introduced in 1982 in RFC 812. Described as “...a server ... that delivers the full name, U.S. mailing address, telephone number, and network mailbox for ARPANET users,” the protocol specification was revised and finalized in RFC 3912 in 2004. WHOIS is an essential tool for anyone seeking information about a particular domain registration. Because of personal data protection laws, many ICANN-accredited registrars are now required to redact personal data from WHOIS lookups, yet certain parties may still have a legitimate need to access non-public information. ICANN has recently launched the *Registration Data Request Service* (RDRS) to address this need. Adiel Akplogan describes RDRS in our final article.

Publication of this journal is made possible by the generous support of our donors, supporters, and sponsors. In 2023 we were pleased to welcome *.au Domain Administration Limited* (auDA) and *Flexoptix* as our newest sponsors. If you would like to donate to or sponsor IPJ, please contact us at ipj@protocoljournal.org

Introduction to 5G

Part Two: Core Network, Radio Access Network, and Air Interface

by William Stallings

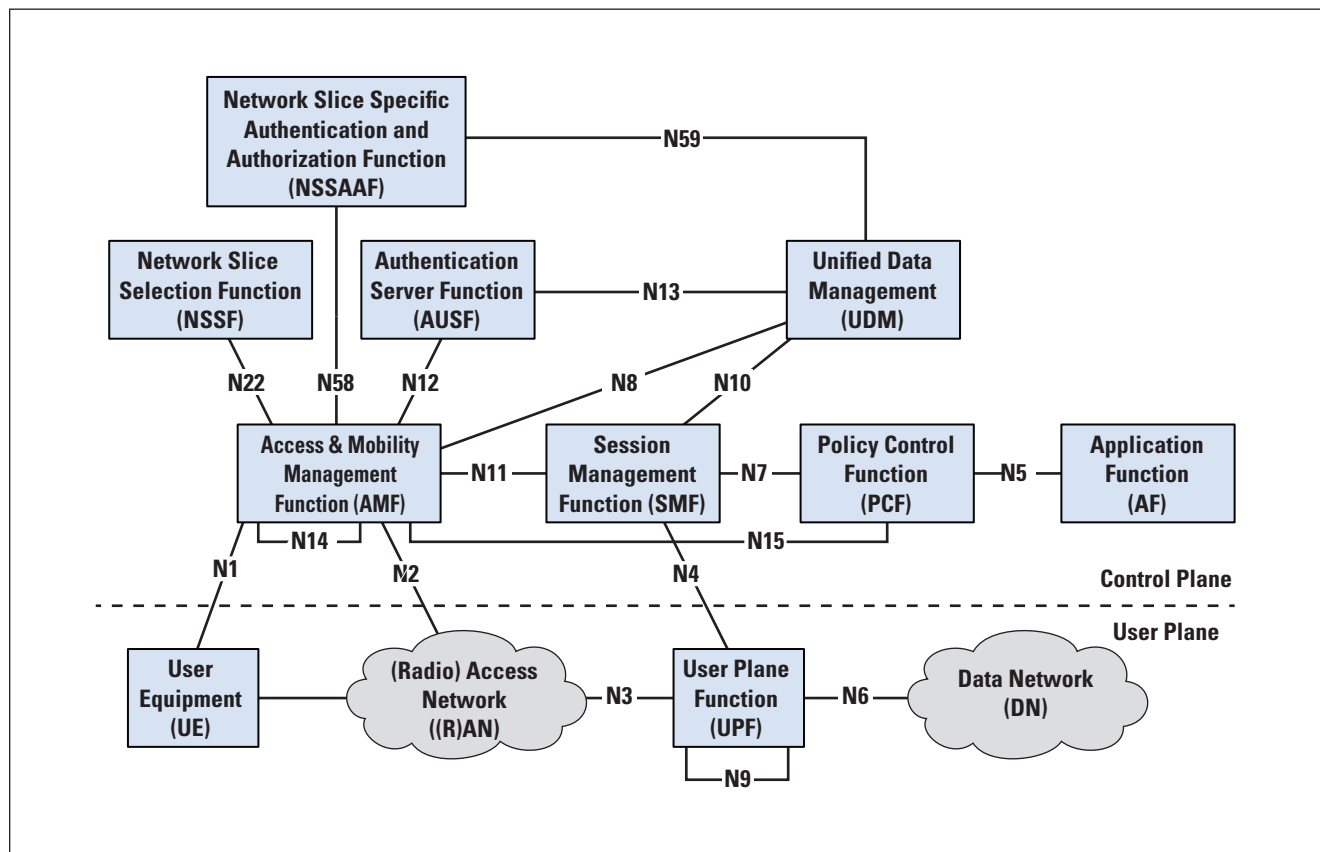

Part One of this 5G introduction^[0] addressed requirements, standards, and applications for 5G. This part provides an overview of the structure and function of 5G networks.

Core Network

Dozens of 3GPP specifications are related to the 5G core network that together describe a system of significant complexity. A key document in this collection is *3GPP Technical Specification TS 23.501*^[1]. This document, 450 pages long in its current release, provides a detailed technical overview of the core network architecture, procedures, services, and interfaces, and is the primary basis for the presentation in this article.

The core network architecture can be viewed as a set of interconnected *Network Functions* (NFs). An NF is a processing function in a network, which has defined functional behavior and interfaces. An NF can be implemented as a network element on dedicated hardware, a software instance running on dedicated hardware, or a virtualized function instantiated on an appropriate platform.

Figure 1: 5G Core Network Functional Architecture

TS 23.501 contains numerous architecture diagrams from several different points of view and at varying levels of detail. Figure 1 depicts the basic 5G architecture using a reference-point representation, showing how the NFs interact with each other.

The figure includes the following NFs and other modules:

- *Authentication Server Function* (AUSF): Performs authentication between *User Equipment* (UE) and the network
- *Access and Mobility Management Function* (AMF): Receives all connection- and session-related information from the UE (N1/N2) but is responsible only for handling connection, registration, reachability, and mobility management tasks. All messages related to session management are forwarded to the *Session Management Function* (SMF).
- *Network Exposure Function* (NEF): Provides an interface for outside applications to communicate with the 5G network to obtain network-related information about the capabilities of the network.
- *Network Repository Function* (NRF): Allows NFs to register their functionality and to discover the services offered by other NFs present in the network.
- *Network Slice Selection Function* (NSSF): Selects the set of network slice instances to accommodate the service request from a UE. When a UE requests registration with the network, AMF sends a network slice selection request to NSSF with preferred network slice selection information. The NSSF responds with a message including the list of appropriate network slice instances for the UE.
- *Network Slice-Specific Authentication and Authorization* (NSSAAF): Performs authentication and authorization specific to a slice.
- *Policy Control Function* (PCF): Provides functionalities for the control and management of policy rules including rules for *Quality of Service* (QoS) enforcement, charging, and traffic routing. PCF enables end-to-end QoS enforcement with QoS parameters (for example, maximum bit rate, guaranteed bit rate, and priority level) at the appropriate granularity (for example, per UE, per flow, and per PDU session).
- *Session Management Function* (SMF): Responsible for *Protocol Data Unit* (PDU) session establishment, modification, and release between a UE and a data network. A PDU session, or simply session, is an association between the UE and a data network that provides a PDU connectivity service. A PDU connectivity service is a service that provides for the exchange of PDUs between a UE and a data network.
- *Unified Data Management* (UDM): Responsible for access authorization and subscription management. UDM works with AMF and AUSF as follows: The AMF provides UE authentication, authorization, and mobility management services. The AUSF stores data for authentication of UEs, and the UDM stores UE subscription data.

- *User Plane Function (UPF)*: Handles the user plane path of PDU sessions. UPF functions include packet routing and forwarding, QoS handling, traffic usage reporting, and policy rule enforcement.
- *Application Function (AF)*: Provides session-related information to PCF so that SMF can ultimately use this information for session management. AF interacts with application services that require dynamic policy control. AF extracts session-related information (for example, QoS requirements) from application signaling and provides it to PCF in support of its rule generation.
- *User Equipment (UE)*: Gives users access to network services. An example is a mobile phone. For the purpose of 3GPP specifications, the interface between the UE and the network is the radio interface.
- *(Radio) Access Network [(R)AN]*: A network that provides access to a 5G core network. It includes the 5G RAN and other wireless and wired access networks.
- *Data Network (DN)*: A network to which UE is logically connected by a session. It may be the Internet, a corporate intranet, or an internal services function within the mobile network operator's core (including content-distribution networks).
- *Service Communication Proxy (SCP)*: NFs and NF services can communicate directly or indirectly via the SCP. The SCP enables multiple NFs to communicate with each other and with user plane entities in a highly distributed multi-access edge compute cloud environment. These services provide routing control, resiliency, and observability to the core network.

In Figure 1, two reference points loop back to the same function: N9 and N14. The N9 reference point is an interface between two distinct UPFs used for forwarding packets. The N14 reference point is between two AMFs, one acting as a source AMF for a data transfer and the other acting as a destination AMF.

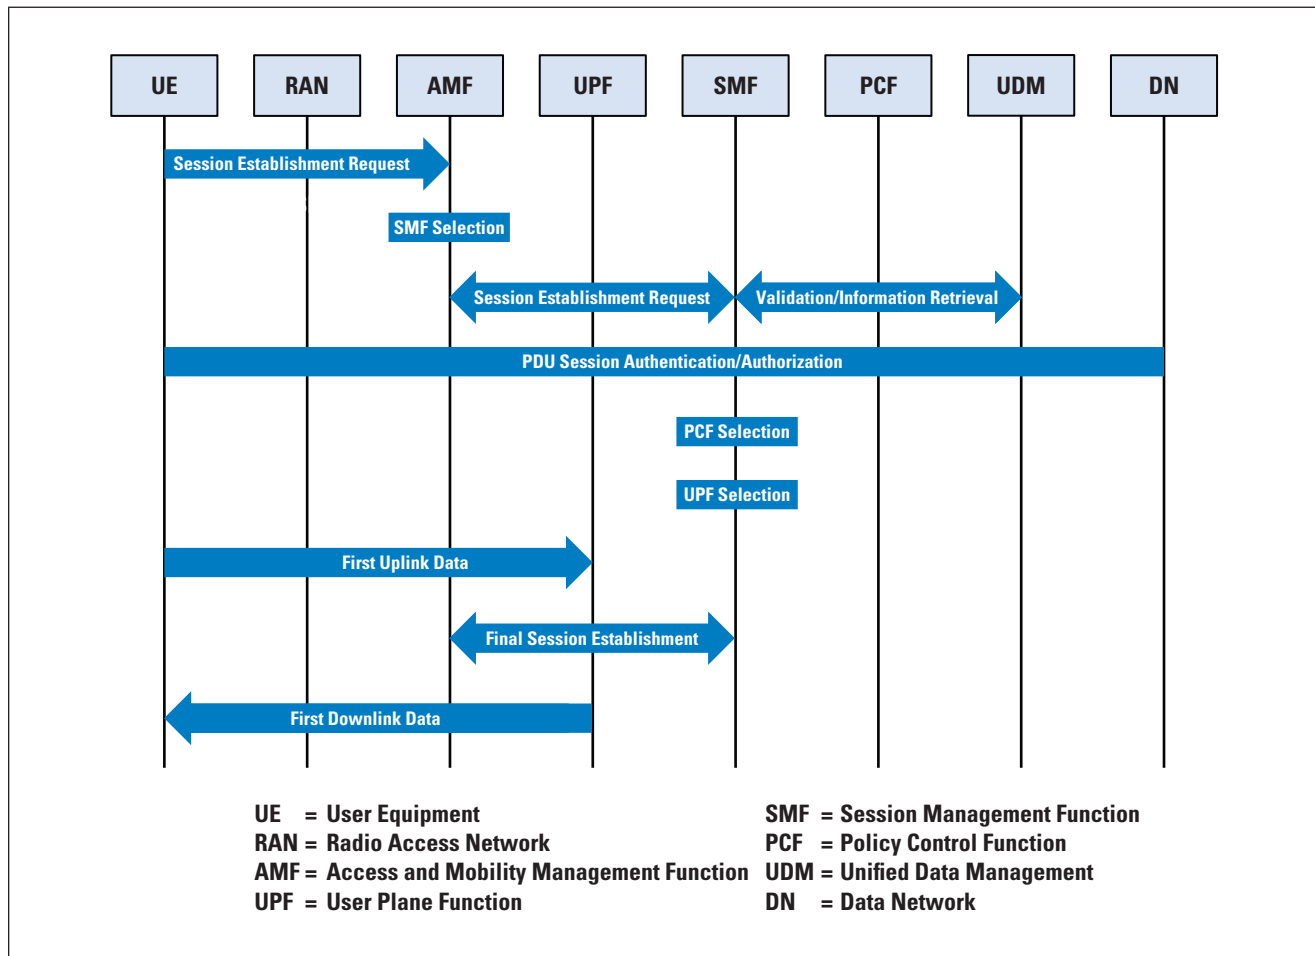

An example of the interaction of the various NFs is the session-establishment procedure, which is defined in TS 23.502^[2]. Figure 2 provides a much-simplified view of the interaction between the various network components during session establishment. Session establishment begins with a request from the UE over the RAN, which is directed to the AMF. An SMF is selected to manage the PDU session. SMF uses UDM in the process of creating a session and performing authentication and authorization. SMF selects a PCF for the session and a UPF to handle data plane PDU forwarding in both directions. SMF establishes a session with the DN. After a few more exchanges, the UE is able to communicate over a session with the DN.

SDN and NFV

Two essential enablers of 5G services provided by core networks are *Software-Defined Networking (SDN)* and *Network Functions Virtualization (NFV)*.^[15]

ITU-T Y.3300^[3] defines SDN as a set of techniques that enables users to directly program, orchestrate, control, and manage network resources, thereby facilitating the design, delivery, and operation of network services in a dynamic and scalable manner.

Figure 2: UE-Requested PDU Session Establishment

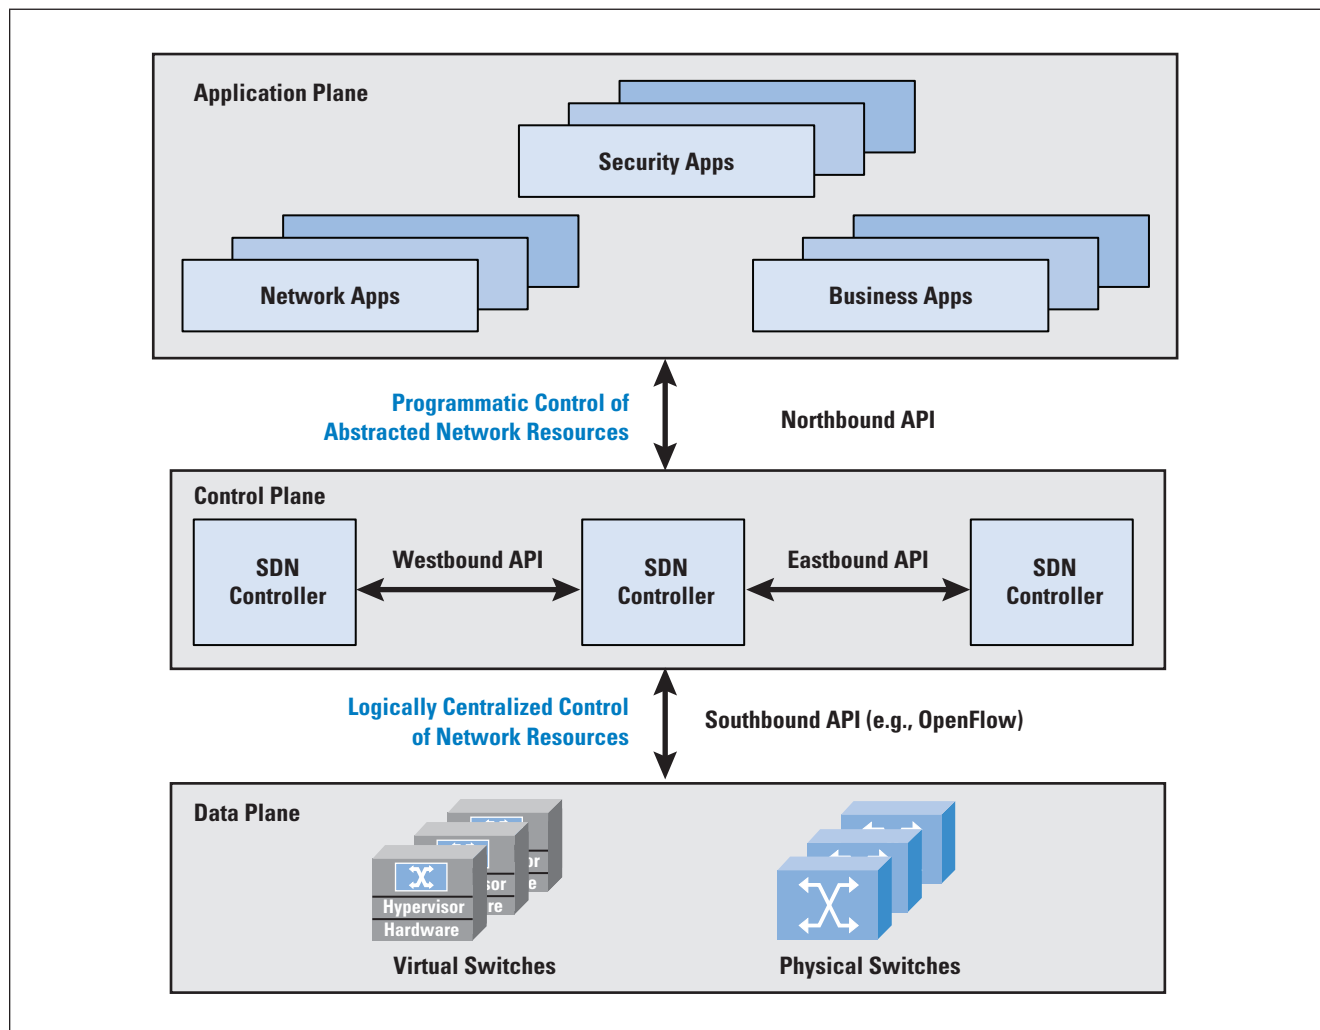

The two elements involved in forwarding packets through routers are a *control function*, which decides the route the traffic takes and the relative priority of traffic, and a *data function*, which forwards data based on control-function policy. Prior to SDN, these functions were performed in an integrated fashion at each network device (router, bridge, packet switch, etc.). Control in such a traditional network is exercised with a routing and control network protocol that is implemented in each network node. This approach is relatively inflexible and requires all of the network nodes to implement the same protocols. With SDN, a central controller performs all complex functionality, including routing, naming, policy declaration, and security checks. This central controller constitutes the SDN control plane, and consists of one or more SDN controllers. The SDN controller defines the data flows that occur in the SDN data plane. Each flow through the network is configured by the controller, which verifies that the communication is permissible by the network policy.

If the controller allows a flow requested by an end system, it computes a route for the flow to take, and adds an entry for that flow in each of the switches along the path. With all complex functions subsumed by the controller, switches simply manage flow tables whose entries can be populated only by the controller. The switches constitute the data plane. Communication between the controller and the switches uses a standardized protocol.

Figure 3 illustrates the SDN architecture. The data plane consists of physical switches and virtual switches, both of which are responsible for forwarding packets. The internal implementation of buffers, priority parameters, and other data structures related to forwarding can be vendor-dependent. However, each switch must implement a model, or an abstraction, of packet forwarding that is uniform and open to the SDN controllers. This model is defined in terms of an open *Application Programming Interface* (API) between the control plane and the data plane (that is, the southbound API).

Figure 3: SDN Architecture

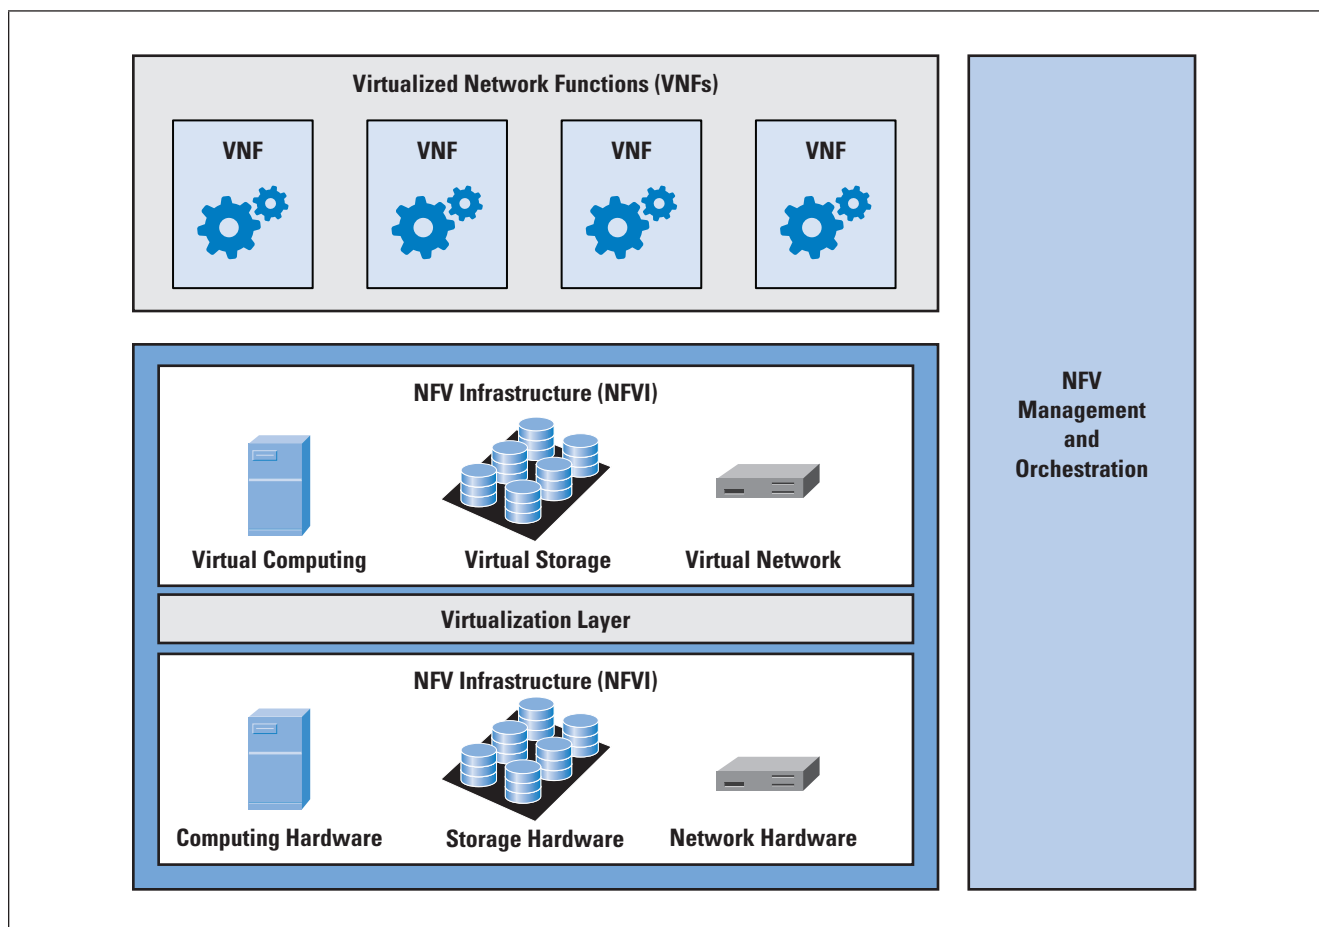

Similarly, SDN controllers can be implemented directly on a server or on a virtual server. An API is used to control the switches in the data plane. In addition, controllers use information about capacity and demand obtained from the networking equipment through which the traffic flows. SDN controllers also expose northbound APIs, meaning that developers and network managers can deploy a wide range of off-the-shelf and custom-built network applications, many of which were not feasible prior to the advent of SDN.

NFV decouples network functions, such as routing, firewalling, intrusion detection, and network address translation, from proprietary hardware platforms and implements these functions in software. It uses standard virtualization technologies that run on high-performance hardware to virtualize network functions. It is applicable to any data plane processing or control plane function in both wired and wireless network infrastructures.

Figure 4 shows a high-level view of the NFV framework, which supports the implementation of network functions as software-only VNFs.

Figure 4: High-Level NFV Framework

The NFV framework consists of three domains of operation:

- *Virtualized Network Functions* (VNFs): These functions consist of a collection of VNFs, implemented in software, run over the *NFV Infrastructure* (NFVI)
- *NFV Infrastructure* (NFVI): The NFVI performs a virtualization function on the three main categories of devices in the network service environment: computer devices, storage devices, and network devices.
- *NFV Management and Orchestration*: This domain encompasses the orchestration and lifecycle management of physical and/or software resources that support the infrastructure virtualization and the lifecycle management of VNFs. NFV management and orchestration focuses on all virtualization-specific management tasks necessary in the NFV framework.

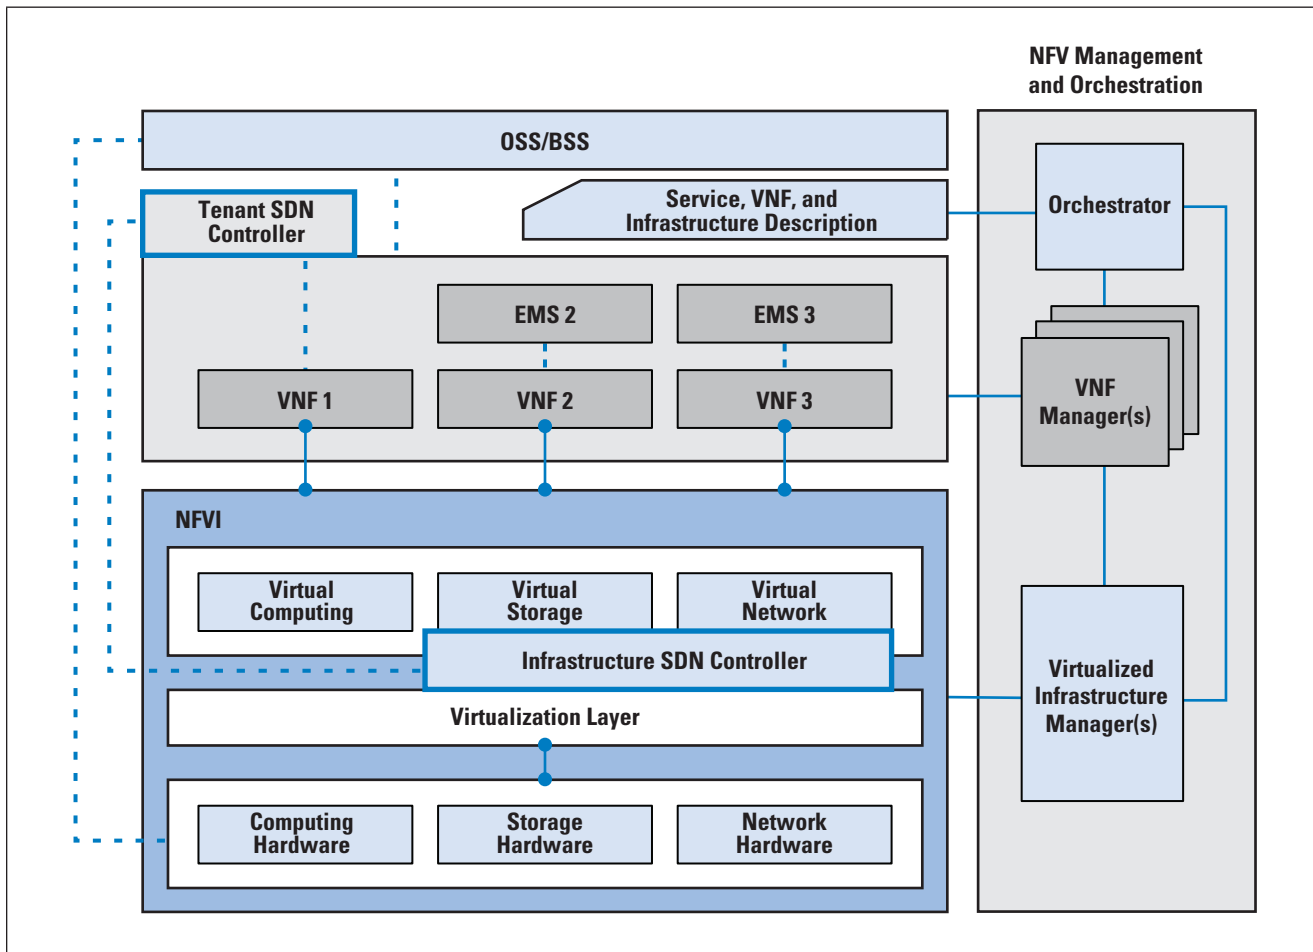

NFV and SDN are independent but complementary schemes. SDN decouples the data and control planes of network traffic control, making the control and routing of network traffic more flexible and efficient. NFV decouples network functions from specific hardware platforms via virtualization to make the provision of these functions more efficient and flexible. Virtualization can be applied to the data plane functions of the routers and other network functions, including SDN controller functions. Thus, either can be used alone, but the two can be combined to reap greater benefits.

The European Telecommunications Standards Institute (ETSI) document GS NFV-EVE 005^[4] examines the manner in which SDN can be incorporated in the NFVI to provide connectivity services.

The framework incorporates two controllers: one logically placed at the tenant level and another at the NFVI level. Each controller centralizes the control plane functionalities and provides an abstract view of all the connectivity-related components it manages. The controllers are as follows:

- *Infrastructure SDN Controller* (IC): This controller enables communication among VNFs and among their components, including the cases when those VNFs are instantiated in separated *Points of Presence* (PoPs), reachable through a WAN connection. Managed by the *Virtualized Infrastructure Manager* (VIM), this controller may change infrastructure behavior on demand according to VIM specifications adapted from tenant requests.
- *Tenant SDN Controller* (TC): Instantiated in the tenant domain as one of the VNFs or as part of the *Network Management System* (NMS), this second controller dynamically manages the pertinent VNFs used to realize the tenant's network service(s). These VNFs are the underlying forwarding plane resources of the TC. The operation and management tasks that the TC carries out are triggered by the applications running on top of it (for example, the *Operations Support System* [OSS]).

Figure 5: Integrating SDN Controllers into the Reference NFV Architectural Framework

Network Slicing

One of the most important features of 5G is *Network Slicing*. Indeed, network slicing is essential to the exploitation of the capabilities defined for 5G. Network slicing enables a 5G network operator to provide customized networks by creating multiple virtual and end-to-end networks, referred to as network slices. Each network slice can be defined according to different requirements on functionality, QoS, and specific users.

“Network Slicing for 5G: Challenges and Opportunities”^[5] lists the following advantages of slicebased networking compared with traditional networking:

- Network slicing can provide logical networks with better performance than one-size-fits-all networks.
- A network slice can scale up or down as service requirements and the number of users change.
- Network slices can isolate the network resources of one service from the others; the configurations among various slices don’t affect each other. Therefore, the reliability and security of each slice can be enhanced.
- A network slice is customized according to QoS requirements, which can optimize the allocation and use of physical network resources.

Network slicing is made possible by NFV and SDN. NFV implements the *Network Functions* (NFs) in a network slice, enabling the isolation of each network slice from all other network slices. Isolation can be achieved by one or more of the following: (1) using a different physical resource; (2) separation by virtualization, which may allow sharing of physical resources; or (3) through sharing a resource with the guidance of a respective policy that defines the access rights for each tenant. Isolation assures QoS and security requirements for that slice, independent of other slices operating on the network from the same or different users. After a network slice is defined, SDN operates to monitor and enforce QoS requirements by controlling the behavior of the QoS flow for each slice.

Figure 6, based on concepts in a *Next Generation Mobile Networks* report^[6], illustrates network slicing concepts.

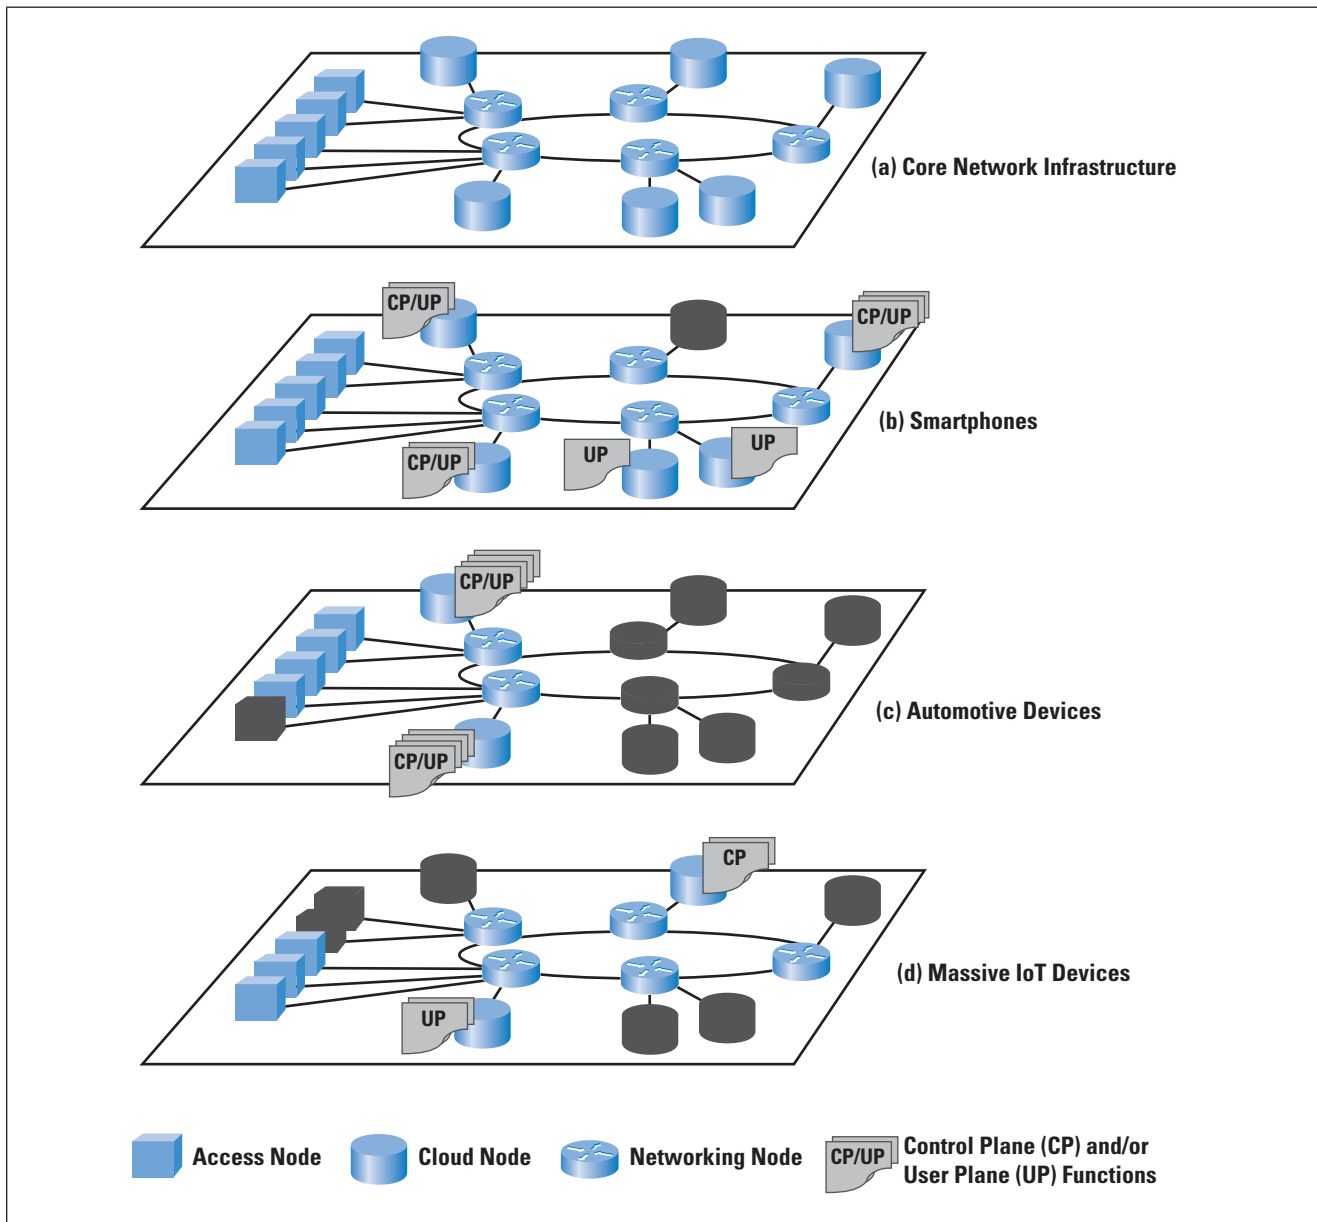

The figure shows a simple core network configuration composed of three types of devices:

1. *Cloud Nodes*: These nodes provide cloud services, software, and storage resources. There are likely to be one or more central cloud nodes that provide traditional cloud computing service. In addition, cloud-edge nodes provide low-latency and higher-security access to client devices at the edge of the network. All of these nodes include virtualization system software to support virtual machines and containers. NFV enables effective deployment of cloud resources to the appropriate edge node for a given application and given fixed or mobile user. The combination of SDN and NFV enables the movement of edge resources and services to dynamically accommodate mobile users.
2. *Networking Nodes*: These nodes are IP routers and other types of switches for implementing a physical path through the network for a 5G connection. SDN provides for flexible and dynamic creation and management of these paths.
3. *Access Nodes*: These nodes provide an interface to radio access networks, which in turn provide access to mobile UE. SDN creates paths that use an access node for one or both ends of a connection involving a wireless device.

The remainder of Figure 6 illustrates three use cases. The blacked-out core network resources represent resources not used to create the network slice. Cloud nodes that are part of the slice may include the following:

- Control plane functions associated with one or more user plane functions (for example, a reusable or common framework of control)
- Service- or service category-specific control plane and user plane function pairs (for example, a user-specific multimedia application session)

Figure 6: 5G Network Slices Implemented on the Same Infrastructure

The first network slice depicted in Figure 6 is for a typical smartphone use case. Such a slice might have fully fledged functions distributed across the network. The second network slice in the figure indicates the type of support that may be allocated for automobiles in motion. This use case emphasizes the need for security, reliability, and low latency. A configuration to achieve these needs would limit core network resources to nearby cloud edge nodes, plus the recruitment of sufficient access nodes to support the use case. The final use case illustrated in Figure 6 is for a massive *Internet of Things* (IoT) deployment, such as a huge number of sensors. The slice can contain just some specific *Control Plane* (CP) and *User Plane* (UP) functions with, for example, no mobility functions. The CP and UP functions might include filtering and preliminary data analysis at the edge and big data types of analysis at a more central node. This slice would need to engage only access nodes nearest to the IoT device deployment.

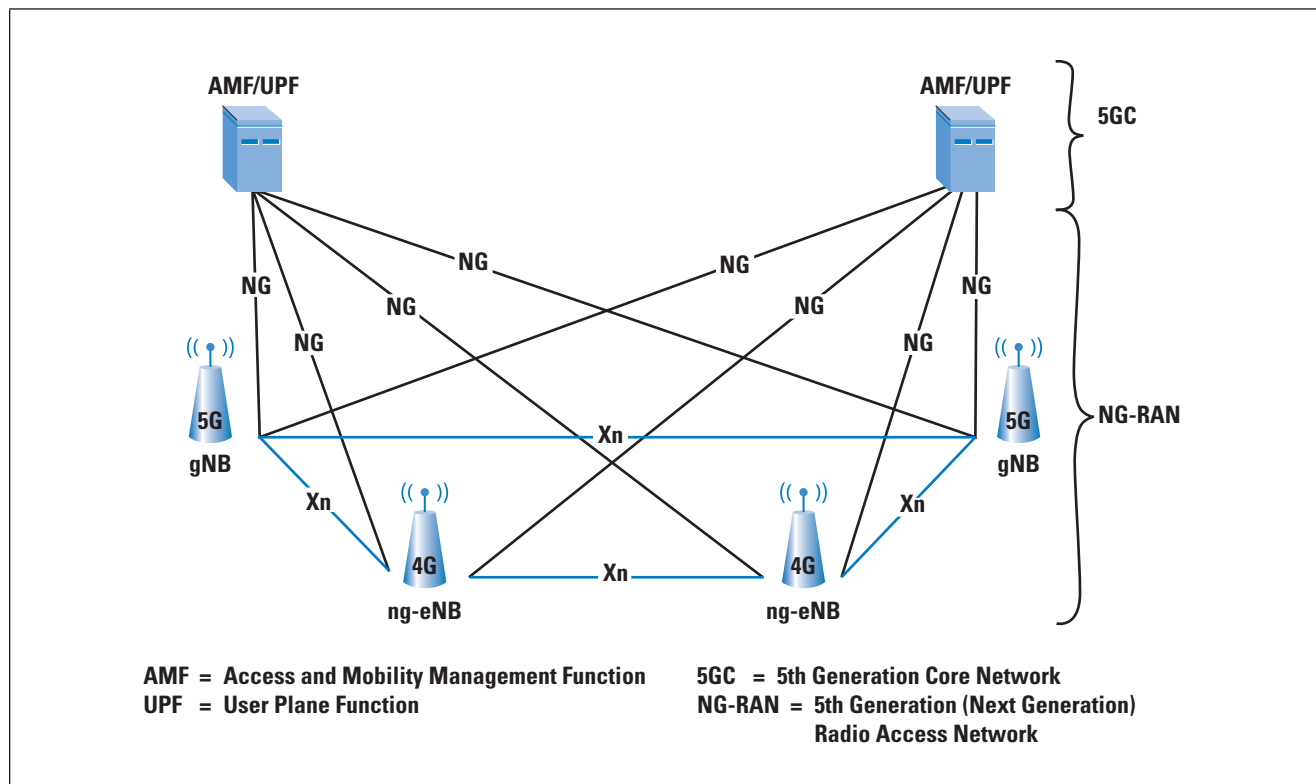

Radio Access Network

As for the 5G core network, there are dozens of 3GPP specifications related to the 5G RAN. A key document in this collection is *3GPP Technical Specification TS 38.300*^[7]. This document provides a detailed technical overview of the RAN architecture, protocols, functionality, and interfaces, and is the primary basis for the presentation in this article.

The overall RAN architecture, in terms of the deployment of base-station RAN nodes, is dictated by the need to coexist with 4G UE and 4G core networks for an extended period. In 2019, 4G became the dominant mobile technology across the world, with more than 4 billion connections, accounting for 52% of total connections (excluding licensed cellular IoT). 4G connections will continue to grow for the next few years, peaking at just under 60% of global connections by 2023^[8]. It is clear that 4G UE will form a major portion of the cellular demand for quite a few years to come.

The most important requirement for 5G carriers is to provide full support for both 4G and 5G UE. Figure 7, from TS 38.300, is a simplified view of the overall RAN architecture and its interface to the 5G core network for providing that support. The figure depicts two types of base stations. The gNB node provides 5G *New Radio* (NR) user plane and control plane protocol terminations toward the UE and connects via the NG interface to the 5GC (5G core). The ng-eNB node provides 4G, referred to as *Evolved Universal Terrestrial Radio Access* (E-UTRA) user plane and control plane protocol terminations toward the UE and connects via the NG interface to the 5GC.

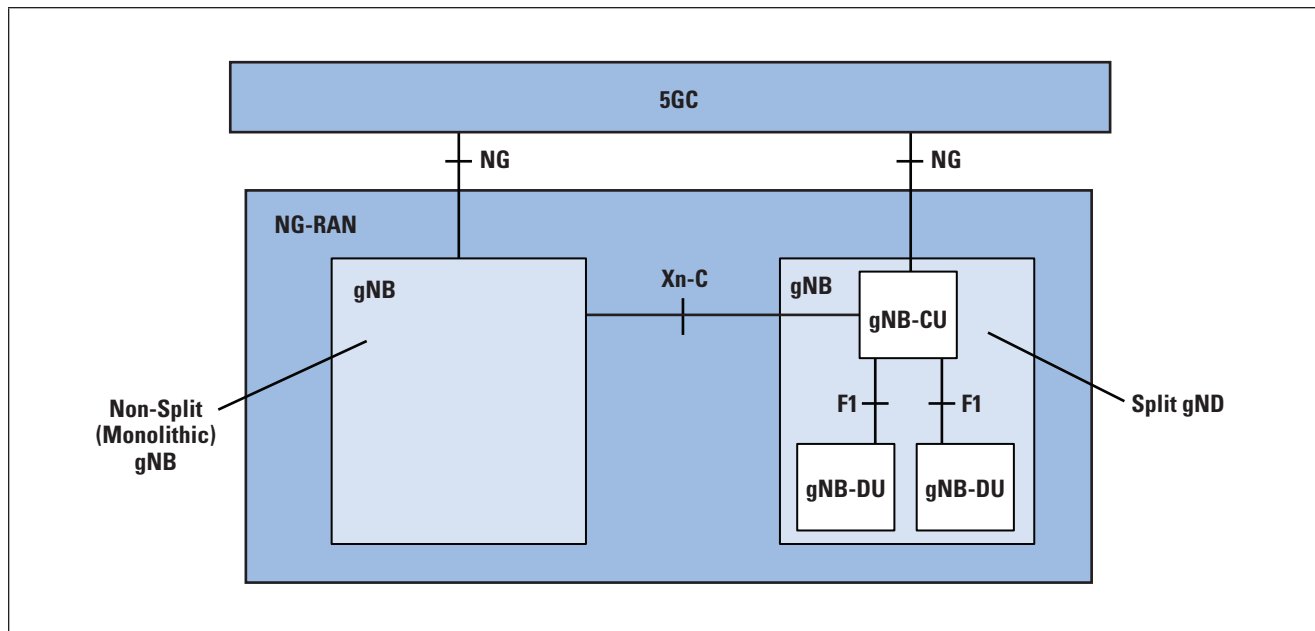

Figure 7: Overall Radio Access Network Architecture

The base stations interconnect with each other by means of the Xn interface. Base stations connect to the core network through the NG interfaces, more specifically to the AMF (access and mobility management function) by means of the NG-C interface and to the UPF by means of the NG-U interface.

Figure 8, from TS 38.401^[9], provides a different perspective on key 5G RAN interfaces. A gNB may be a single integrated system, referred to as a *monolithic* or *non-split* node. Or a gNB may be organized as a split node, consisting of a *gNB-Central Unit* (gNB-CU) and one or more *gNB-Distributed Units* (gNB-DUs). The CU processes non-real-time protocols and services, and the DU processes physical layer protocol and real-time services. One gNB-DU supports one or multiple cells. One cell is supported by only one gNB-DU. A gNB-CU and the gNB-DU units are connected via the F1 logical interface. One gNB-DU is connected to only one gNB-CU. For resiliency, a gNB-DU may also be able to connect to another gNB-CU (if the primary gNB-CU fails) through appropriate implementation. NG, Xn, and F1 are logical interfaces.

Figure 8: RAN Interfaces

Air Interface

As with other aspects of 5G, dozens of 3GPP specifications are related to the 5G RAN. However, the definitive document is *ITU-R Recommendation M.2150*^[10], issued in February 2021. The current version of the Recommendation adopts three radio interface technologies: 3GPP 5G-SRIT, 3GPP 5GRIT, and 5Gi (India/TSDSI). However, the 5Gi specification is unlikely to achieve widespread adoption outside of India^[11]. Accordingly, the coverage in this article of the air interface standards is based on the 3GPP specifications. This article summarizes three key aspects of the air interface: antennas, physical layer, and channel coding.

Antennas

5G systems use *Multiple-Input/Multiple-Output* (MIMO) antenna systems extensively. Key features are base-station antennas consisting of large arrays of antennas and the use of *Beamforming*, and *Beam Management*.

In a MIMO scheme, the transmitter and receiver employ multiple antennas. The source data stream is divided into n substreams, one for each of the n transmitting antennas. The individual substreams are the input to the transmitting antennas (multiple input). At the receiving end, m antennas receive the transmissions from the n source antennas via a combination of line-of-sight transmission and multipath. The output signals from all of the m receiving antennas (multiple output) are combined. With a lot of complex math, the result is a much better receive signal than can be achieved with either a single antenna or multiple frequency channels. Note that the terms *input* and *output* refer to the input to the transmission channel and the output from the transmission channel, respectively.

MIMO systems are characterized by the number of antennas at each end of the wireless channel. Thus, an 8×4 MIMO system has eight antennas at one end of the channel and four at the other end. In configurations with a base station, the first number typically refers to the number of antennas at the base station. There are two types of MIMO transmission schemes:

1. *Spatial Diversity*: The same data is coded and transmitted through multiple antennas, effectively increasing the power in the channel proportionally to the number of transmitting antennas. This mechanism improves the *Signal-to-Noise Ratio* (SNR) for cell edge performance. Further, diverse multipath fading offers multiple “views” of the transmitted data at the receiver, thus increasing robustness. In a multipath scenario where each receiving antenna would experience a different interference environment, there is a high probability that if one antenna suffers a high level of fading, another antenna will have sufficient signal level.
2. *Spatial Multiplexing*: A source data stream is divided among the transmitting antennas. The gain in channel capacity is proportional to the available number of antennas at the transmitter or receiver, whichever is less. Spatial multiplexing can be used when transmitting conditions are favorable and for relatively short distances compared to spatial diversity. The receiver must do considerable signal processing to sort out the incoming substreams, all of which are transmitting in the same frequency channel, and to recover the individual data streams.

Beamforming is one of the essential technologies in developing advanced cellular antenna systems. Beamforming is a technique by which an array of antennas can be steered to transmit radio signals in a specific direction. Rather than simply broadcasting energy/signals in all directions, the antenna arrays that use beamforming determine the direction of interest and send/receive a stronger beam of signals in that specific direction.

In this technique, each antenna element is fed separately with the signal to be transmitted. The phase and amplitude of each signal are then added constructively and destructively in such a way that they concentrate the energy into a narrow beam or lobe. The various transmitted signals merge in the air by normal coherence of the electromagnetic waves, thereby forming a virtual beam in a predetermined direction. To understand how this procedure works, consider a signal that is fed to different antenna elements shifted in phase different amounts for each element. Now picture the transmitted energy from each element at an angle of 45° . At any point along that 45° line, the distance traveled by electromagnetic waves from different antenna elements is not equal. If the phase shifting is such that at 45° signals from all antenna elements arrive at the same phase, then the beam is strongest in that direction.

Beam Management refers to techniques and processes used to achieve the transmission and reception of data over relatively narrow beams. Beamforming and beam management are essential for using the *millimeter-wave* (mmWave) region over the 5G air interface. Narrow beams are needed to compensate for high path loss and blockage. With the use of narrow beams, and especially if the UE is mobile, beam management provides the means for both the base-station antenna and the onboard UE antenna to “lock on” to a beam that provides an optimal path from transmitter to receiver.

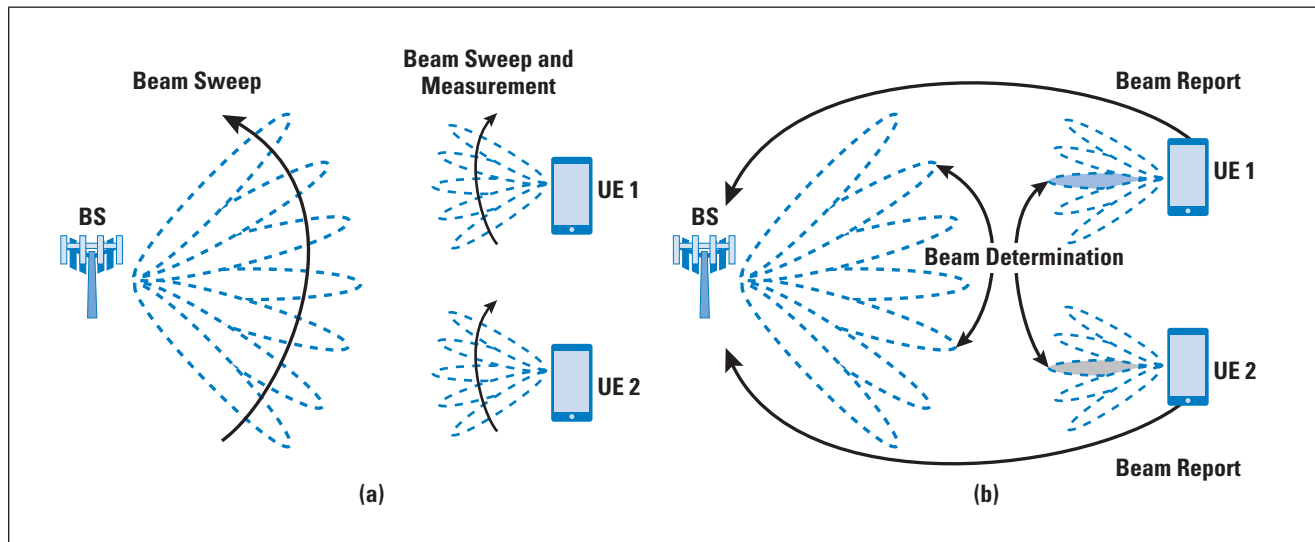

By adjusting the phase and amplitude parameters, a MIMO antenna can generate multiple beams, with each beam covering part of the cell area. For downlink transmission, the objective of beam management is to select a transmit beam to a UE so that the UE can receive the signal with the highest power and best SNR. For uplink transmission, the base station attempts to choose the receive beam for a UE with the best receive beamforming gain. Similarly, if the UE antenna system is capable of beamforming, the UE can use the beams to improve link quality.

The beam management procedure involves beamforming, beam sweeping, beam measurement, beam determination, and beam reporting, as shown in Figure 9.

This figure is taken from [12], which indicates the following elements in the context of downlink transmission:

- *Beam Sweeping*: The base-station antenna (that is, the 5G radio access network node gNB) transmits beams in a predetermined sequence for beam measurement at the UE side.
- *Beam Measurement*: The UE measures the characteristics of received beamformed signals.
- *Beam Determination*: The UE selects the optimal beam. In essence, the UE isolates the receive beam, which affords the best reception. The best results are obtained when the transmitting and receiving beam pair is optimal for the location of the UE at the time.
- *Beam Reporting*: The UE reports back to the gNB the information based on beam measurement.

Figure 9: Beam Management Procedures with Downlink Transmissions

Beam management is an ongoing dynamic process that involves selecting an initial beam pair and then modifying the selection as transmit/receive conditions change.

The term *full-dimension MIMO* (FD-MIMO), or *3D-MIMO*, refers to a MIMO antenna system that is capable of varying the direction of a beam in both horizontal (azimuth) and vertical (elevation) dimensions. Thus, FD-MIMO can project a beam in any direction in three-dimensional space. This capability has advantages, especially in dense urban environments. The ability to adjust transmitted beams in the vertical dimension can improve the received signal power of terminals deep inside high-rise buildings and help overcome some of the building penetration loss. FD beamforming is also advantageous in indoor deployments in high-rise buildings, where a single base station may be able to optimize coverage over more than one floor. Such techniques directly increase spectral efficiency.

OFDMA and SC-FDMA

An important access of the air interface is the way multiplexing and multiple access is achieved over a physical transmission channel. Two techniques are employed for the 5G air interface: *Orthogonal Frequency Division Multiple Access* (OFDMA) and *Single-Carrier Frequency Division Multiple Access* (SC-FDMA). These two schemes use the following foundational techniques:

- *Frequency-Division Multiplexing* (FDM): A physical-layer technique in which multiple baseband signals are modulated on different frequency carrier waves and added together to create a composite signal. The effect of FDM is to divide a transmission bandwidth into multiple subchannels, each of which is dedicated to a particular baseband signal.

- *Frequency-Division Multiple Access (FDMA)*: An access method at the data-link layer based on FDM principles, in which different frequency bands are allocated to different data streams, possibly from different users. The data-link layer in each station tells its physical layer to make a bandpass signal from the data passed to it. The signal must be created in the allocated band. There is no multiplexer at the physical layer. The signals created at each station are automatically bandpass-filtered. They are mixed when they are sent to the common channel. FDMA supports demand assignment, in which the assignment of frequency bands to users changes over time.

Orthogonal Frequency Division Multiplexing (OFDM), also called *Multicarrier Modulation*, is dedicated to a single data source. It uses multiple carrier signals at different frequencies, sending some of the bits on each channel. It differs from ordinary FDM in that the individual subcarriers are orthogonal to one another. In essence, signals are orthogonal to one another if the peaks of the power spectral density of each subcarrier occur at a point at which the power of other subcarriers is zero. A result of this property is that adjacent subcarriers can be packed closely together, making efficient use of the bandwidth.

OFDM has several advantages. First, frequency-selective fading affects only some subcarriers and not the whole signal. If the data stream is protected by a forward error-correcting code, this type of fading is easily handled. More importantly, OFDM overcomes *Intersymbol Interference (ISI)* in a multipath environment. ISI has a greater impact at higher bit rates because the distance between bits, or symbols, is smaller. With OFDM, the data rate is reduced by a factor of N , and this reduction increases the symbol time by a factor of N . This increase dramatically reduces the effect of ISI. As a result of these considerations, with the use of OFDM it may not be necessary to deploy equalizers, which are complex devices whose complexity increases with the number of symbols over which ISI is present.

Like OFDM, OFDMA employs multiple closely spaced subcarriers, but for OFDMA, the subcarriers are divided into groups of subcarriers. Each group is referred to as a *subchannel*. The subcarriers that form a subchannel need not be adjacent. In the downlink, a subchannel may be intended for different receivers. In the uplink, a transmitter may be assigned one or more subchannels.

Subchannelization defines subchannels that can be allocated to *Subscriber Stations (SSs)* depending on their channel conditions and data requirements. Using subchannelization within the same time slot, a *Base Station (BS)* can allocate more transmit power to user devices (SSs) with lower SNR, and less power to user devices with higher SNR. Subchannelization also enables the BS to allocate higher power to subchannels assigned to indoor SSs, resulting in better in-building coverage.

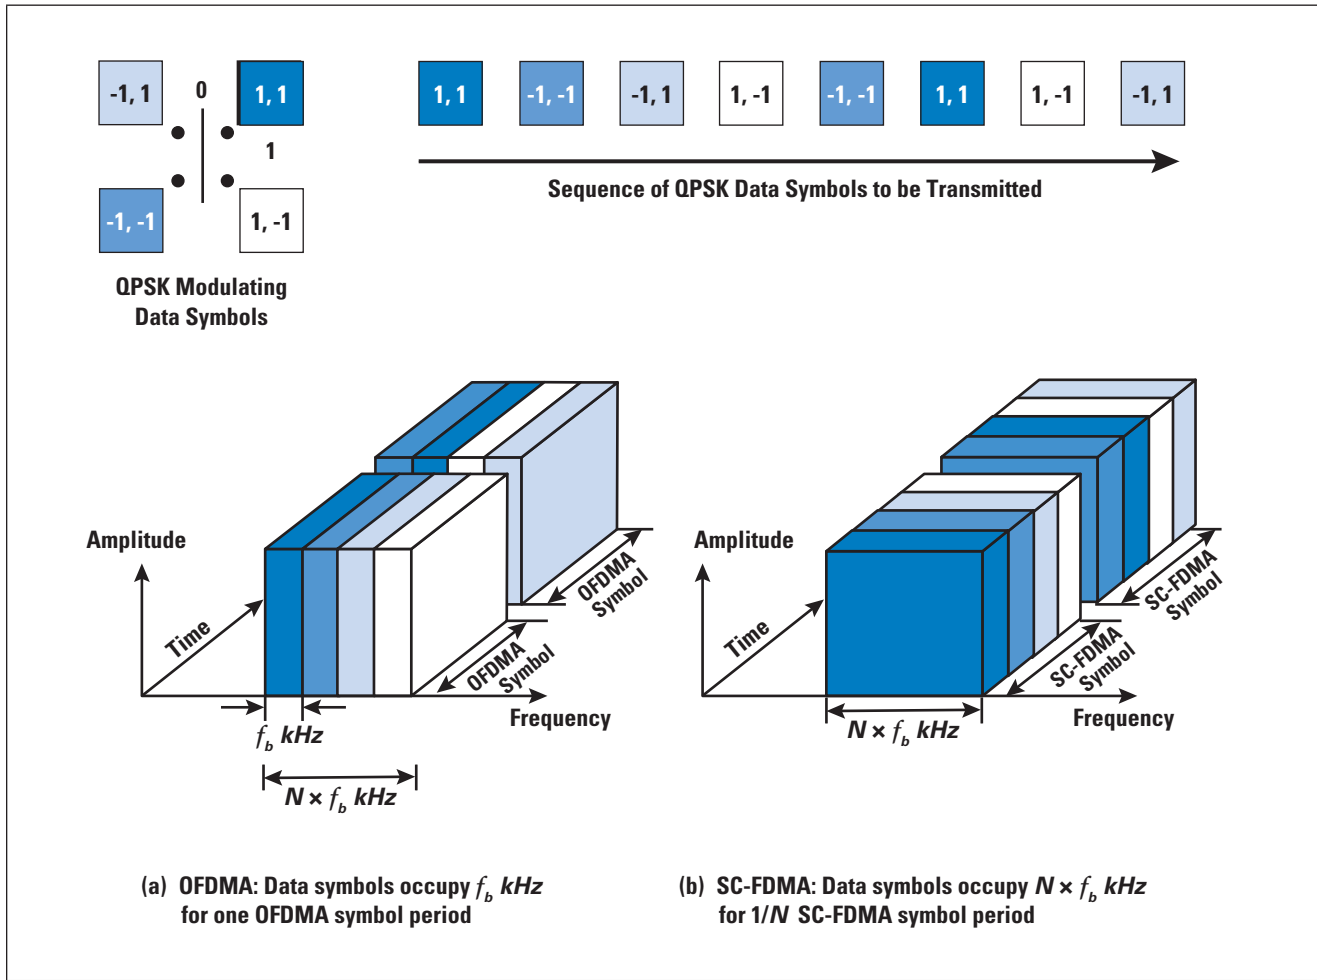

Subchannels are further grouped into *bursts*, which can be allocated to wireless users. Each burst allocation can be changed from frame to frame as well as within the modulation order. This capability allows the base station to dynamically adjust the bandwidth usage according to the current system requirements. Subchannelization in the uplink can save user-device transmit power because it can concentrate power on only certain subchannels allocated to it. This power-saving feature is particularly useful for battery-powered user devices, the likely case in mobile 4G and 5G.

SC-FDMA is a more recently developed multiple-access technique that is similar in structure and performance to OFDMA. One prominent advantage of SC-FDMA over OFDMA is the lower *Peak-to-Average Power Ratio* (PAPR) of the transmit waveform, which benefits the mobile user in terms of battery life and power efficiency. OFDM signals have a higher PAPR because, in the time domain, a multicarrier signal is the sum of many narrowband signals. At some time instances this sum is large, and at other times it is small, meaning the peak value of the signal is substantially larger than the average value. Thus, SC-FDMA is superior to OFDMA. However, it is restricted to uplink use because the increased time-domain processing of SC-FDMA would entail considerable burden on the base station.

Figure 10 provides an example of how the OFDM and SC-FDMA signals appear. As the figure illustrates, with OFDM, a source data stream is divided into N separate data streams, and these streams are modulated and transmitted in parallel on N separate subcarriers, each with bandwidth f_b . The source data stream has a data rate of R bps, and the data rate on each subcarrier is R/N bps. For SCFDMA, it appears from Figure 10 that the source data stream is modulated on a single carrier (hence the SC prefix to the name) of bandwidth $N \times f_b$ and transmitted at a data rate of R bps. The data is transmitted at a higher rate but over a wider bandwidth compared to the data rate on a single subcarrier of OFDM. However, because of the complex signal processing of SC-FDMA, the preceding description is not accurate. In effect, the source data stream is replicated N times, and each copy of the data stream is independently modulated and transmitted on a subcarrier, with a data rate on each subcarrier of R bps.

Compared with OFDM, SC-FDMA transmits at a much higher data rate on each subcarrier, but because the same data stream is on each subcarrier, it is still possible to reliably recover the original data stream at the receiver.

Figure 10: Example of OFDMA and SC-FDMA

Channel Coding

3GPP TS 38.212^[13] specifies two *Forward Error Correction* (FEC) techniques for the air interface: *Low-Density Parity-Check Coding* and *Polar Coding*. TR 38.802^[14] contains the results of a study into NR physical-layer aspects, and is useful for understanding the reasoning behind the concepts. An adequate overview of these two techniques is beyond the scope of this article, but a brief overview of the concepts is provided.

An (n, k) *parity-check code* encodes k data bits into an n -bit codeword. Typically, and without loss of generality, the convention used is that the leftmost k bits of the codeword reproduce the original k data bits, and the rightmost $(n - k)$ bits are the check bits. Such a code is defined by a set of $m = (n - k)$ simultaneous linear equations. If there are m linearly independent equations, there will be some set of k of the variables that can be arbitrarily specified such that one can solve for the other $(n - k)$ variables.

A parity-check code that produces n -bit codewords is the set of solutions to the following equations:

$$\begin{aligned}
 h_{11}c_1 \oplus h_{12}c_2 \oplus \dots \oplus h_{1n}c_n &= 0 \\
 h_{21}c_1 \oplus h_{22}c_2 \oplus \dots \oplus h_{2n}c_n &= 0 \\
 &\vdots \\
 h_{m1}c_1 \oplus h_{m2}c_2 \oplus \dots \oplus h_{mn}c_n &= 0
 \end{aligned}$$

...where the coefficients h_{ij} take on the binary values 0 or 1. The specific set of values of h_{ij} define a specific code.

The $m \times n$ matrix $H = [h_{ij}]$ is called the *Parity Check Matrix*. Each of the m rows of H corresponds to one of the individual equations. Each of the n columns of H corresponds to one bit of the codeword. If we represent the codeword by the row vector $c = [c_i]$, then the equation set can be represented as:

$$Hc^T = cH^T = 0$$

A *Low-Density Parity-Check* (LDPC) code is one in which H has a small density of 1s. That is, the elements of H are almost all equal to 0. Hence the designation *low density*. LDPC codes are enjoying increasing use in high-speed wireless specifications, including Wi-Fi, satellite, and cellular. LDPC codes exhibit performance in terms of bit error probability that is very close to the Shannon limit and can be efficiently implemented for high-speed use.

LDPC codes are suitable for larger blocks of data and are used for 5G data channels. Greater efficiency for small blocks of data is achievable with polar codes, and thus they are used for control channels. Polar codes involve a relatively complex mathematical transformation that involves splitting a communication channel into numerous synthetic bit channels, some of which have extremely low bit error rates and the remainder have high bit error rates, with the data bits being sent over the reliable bit channels. The mathematics behind this transformation is fairly complex and is not pursued here.

Why ATM Failed

by Craig Partridge, Colorado State University

In the late 1980s and early 1990s, *Asynchronous Transfer Mode* (ATM) was widely viewed as the new Internet architecture poised to take the place of the nascent Internet and to inaugurate a world-wide high-speed communications infrastructure. It didn't happen. Instead, after several years of uncertainty, the Internet swept ATM to the side and grew into the global infrastructure we know today.

Even today, 30+ years later, there are different views about how and why ATM “failed.” This essay, while acknowledging ATM had to overcome some technical hurdles, argues that the central problem was a fast-moving window of opportunity that was squandered, largely because of poor standards leadership.

Origins of ATM

Jonathan Turner's forward-looking essay “New Directions in Communications (or Which Way to the Information Age?),” published in 1986, is widely viewed as the paper that launched ATM^[1]. Turner examined the growing diversity of applications using data networks—in particular, advent of many-channel cable television. He looked at the rapidly diminishing error rates in transmission networks, thanks to the advent of fiber-optic cables.

Turner predicted that to meet future needs, our communications networks should be designed around high-performance parallel switches optimized for short packets of information sent over low-error links. Building on prior work at Bell Labs, Turner anticipated that to keep overhead (notably headers) in the short packets small, packets would contain small labels that associated the packets with established connections through the network (both point-to-point and point-to-multipoint).

That, simply, was the idea behind Asynchronous Transfer Mode: implement a futuristic network in which data was reliably transported at high speed in small, fixed-size packets called *cells* over connections.

Turner's central insights were right. Today's data communications networks are built around highly reliable transmission networks and make heavy use of high-performance parallel switches. Furthermore, those high-performance parallel switches internally move data in ways akin to Turner's proposed small packets.

When Turner made his predictions, the Internet was entering one of most difficult stages in its explosive growth. In late 1986, the Internet became plagued by congestion and routing collapses and struggled with inadequate network-management capabilities.

The Internet standards process was not up to the task of handling these concurrent challenges and, as a result, it was necessary to create the *Internet Engineering Task Force* (IETF) to coordinate the substantial efforts to convert research into standardizations. It would take until 1989 for the critical issues to get resolved and their solutions standardized.

Thus, in 1986, future-focused people in data networking saw a lot of wisdom in Turner's paper and a level of worry when they looked at the state of the Internet. Planning for a better data-communications future based on Turner's ideas was appealing.

Nonetheless, ATM, the realization of Turner's vision, failed for three reasons. First, ATM suffered from exceptionally poor standards leadership. Second, and due in part to the poor standards leadership, ATM missed the window(s) of opportunity to capture the local-area network market. Finally, ATM had difficulties matching the needs of the emerging wide-area Internet market.

The ATM Choices in 1986

Before delving into where ATM failed, it is useful to look at the futures one could envision for ATM in 1986 after reading Turner's paper. Turner suggested at least three choices, and the choices were not exclusive:

- ATM as the future universal data-networking protocol. This choice was the most intellectually popular one and, furthermore, the one the telephony industry wanted to see. In this plan, ATM, with its high performance, would sweep away the various networking alternatives such as TCP/IP, *Open Systems Interconnection* (OSI), Apple's *AppleTalk*, IBM's *Systems Network Architecture* (SNA), and Novell *Netware*. ATM would be end-to-end, from the wall jack in your home or office to the data center or business. Furthermore, ATM could also support voice and video—in ways the Internet could not yet—thus positioning the telephone industry to retain their existing voice business and take customers from the cable TV industry.
- ATM as a *Local-Area Network* (LAN) technology^[2]. In 1986, the state of local-area networks was poor. The major technology was original Ethernet, which required heavy coax cables. Interconnecting Ethernets was tedious and required hand configuration to avoid routing loops. It was just in 1986 that Digital Equipment Corporation introduced the *Spanning Tree Protocol*, which prevented loops and made it much easier to connect Ethernet segments. Thus, in 1986, LANs looked clunky, and ATM looked like a way to make it easier to build large corporate networks. This approach was particularly appealing to Silicon Valley startups, because it was relatively simple to build a 4- or 8-port ATM switch, and they could envision that if their small switches sold well, they would be positioned to move into the wide-area ATM market when that market matured.

- Finally, you could envision ATM as just-another-link layer over which you ran TCP/IP. At its simplest, the idea was that ATM would be the next-generation *Wide-Area Networking* (WAN) protocol and TCP/IP would run on top of it. This idea was popular primarily within the burgeoning TCP/IP community, but it was also acceptable in Silicon Valley, where the ATM-as-a-LAN product vendors were happy to have customers for their products, even if those customers used TCP/IP. It was, of course, anathema to the telephony community, which sought to use ATM to take control of the growing data-communications market.

Exceptionally Poor Standards Leadership

Turner's vision of the future was particularly appealing to the international telephony community, which had missed the early stages of the data-communications revolution and the cable-television revolution. Telephone companies, many of which were quasi-government owned, were (correctly) concerned that their business model centered on voice communication was going to be destroyed and their business would shrink to managing the fiber and cables over which other companies would make money selling data services.

So, the telephone companies tasked a committee of their standards organization—the *International Telecommunication Union* (ITU)—to make Turner's vision a reality. The *Consultative Committee for International Telegraphy and Telephony* (CCITT) began creating ATM. (In 1992, CCITT became the *International Telecommunication Union Telecommunication Standardization Sector* [ITU-T]).

CCITT was utterly unsuited to create data-communications standards. It was a standards group that drew its expertise largely from telephony laboratories. A senior US data-communications researcher from *Bell Communications Research* ["Bellcore"] (which had spun off from Bell Labs) attended one of the early ATM standards meetings, assessed the data-communications expertise in the room, and promptly announced to his friends that ATM was an acronym for "Another Telephony Mistake."

CCITT launched straight into standards making without doing an architectural review. Turner had assumed a world of high-speed, low-error networks, and those assumptions had architectural implications. For example, in 1990, Julio Escobar and I did a detailed study of how to do error detection and recovery for ATM in fiber-optic networks. When Julio took our results to a CCITT meeting to figure out what we had missed, he was stunned to be welcomed as the first person who had done an analysis.

CCITT assumed that the world in which the telephone, the cable TV, and the computer each had its own distinctive wall plug would persist in ATM. This assumption was at odds with Turner's vision. In his paper, Turner had pointed out that application-specific networks were a mistake.

It was widely understood in the data-communications community that all data was *bits* and, for the most part, those bits did not care about the format or the wire they were transmitted over. But CCITT's member telephone companies wanted to charge different tariffs for different services, so having a uniform protocol for all data was undesirable. Rather the notion was they would charge distinct tariffs for voice, video, and data, and enforce this differentiation by formatting the different types of data in distinct formats in ATM. Accordingly, CCITT went ahead and defined distinct cell formats, called *ATM Adaptation Layers* (AALs), for voice, video, and data. Each AAL was mapped into a standard 53-byte cell format.

The development of the AAL for data was a particular disaster. The standards group initially planned for two data AALs, AAL 3 for digital video and AAL 4 for computer data. They realized the two could be combined, and they created AAL 3/4, which was swiftly standardized, but was so badly designed that data-communications-savvy members of the standards committee consulted with members of the IETF to propose a new AAL for data, which became AAL 5^[3].

Finally, that 53-byte cell size is worth attention. It came about because of a disagreement about data rates. Telephone companies with less-developed networks were planning to offer ATM over 1.5- or 2-Mbps links (US T1, European E0), and they wanted to support voice calls over ATM. To avoid jitter, that support dictated a small cell size. In contrast, companies in the US expected to offer ATM on 155-Mbps (OC-3) or greater high-speed links and wanted larger cell sizes to reduce the cost of fragmenting data into cells. Competing proposals of 16- and 128-byte cells moved to 32 and 64 bytes, respectively, and the compromise was 48 bytes plus a 5-byte header. The result was to meet neither party's goals.

By late 1991, the failings of the ATM standards process were so severe that the emerging ATM vendor community had to step in. The vendors announced an industry-driven standards group, *The ATM Forum*. The Forum effectively took over the ATM standards process.

A Window of Opportunity in the Local Area

In the grand telephony vision, ATM was designed to be a new networking technology, delivered by the telephone company to your office or home. To achieve that dream, ATM needed to win the competition for the home and office network. In 1986, when ATM was first envisioned, its adoption looked eminently possible, because there was no home network (people dialed into their office computer [not the network, but a specific computer] using a modem) and the primary office network technology was the cumbersome original Ethernet.

But change was also coming. The first thin-wire Ethernet standard, 802.3e, was standardized in 1986. The standard for 10BASE-T, which worked over twisted pair, would come in 1990.

With the advent in 1989 of the first multi-port Ethernet switches (from Kalpana), setting up an office Ethernet became a matter of running 4-wire cables to a closet that held an Ethernet switch. Physically that was the same service ATM was planning to offer, and thanks to Ethernet bridging standards, it was easier to install and operate Ethernet than the nascent ATM LANs.

Consumers could see that more Internet-compatible technology was coming soon. Plans for *100BASE-T* (100-Mbps Ethernet) were soon well-known. It came out in 1995. Wireless networking appeared in 1990 (*WaveLAN*), and standardization efforts leading to *Wi-Fi*, which was intentionally made easy to integrate with wired Ethernet, soon followed.

Concurrently, the Internet was booming. Its major technical problems having been resolved, its user population grew 16X between 1990 and 1995. The World Wide Web appeared in 1991. The Internet was built around Ethernet at the edges and long-haul leased lines in the core. If you had joined the Internet revolution, ATM meant changing your working installed technology. If you could convince yourself that the Ethernet growth curve was good enough, then you didn't need ATM LANs.

Thus, by late 1990, ATM had serious market competition at the edge. It was clear the competition was going to increase. There was a narrow opportunity (perhaps already lost) to capture market share and make ATM the networking service at the network edge. The realization the market window was closing helps explain the vendors' desire to fix the ATM standards process and create The ATM Forum in 1991.

In retrospect, ATM never managed to grab that market window, and the advent of 100-Mbps Ethernet slammed the window shut. Corporate customers had bought a handful of ATM switches to see if they might work if Ethernet and Wi-Fi did not evolve fast enough. But Ethernet and Wi-Fi did evolve fast enough. Furthermore, experience with ATM LANs did not make a compelling case for change.

A Last Chance in the Wide Area

While ATM was rapidly losing credibility for the office and home LAN market at the start of the 1990s, it still had a viable potential role as the technology for wide-area networks. The Internet relied on telecommunications companies for its long-haul links. It was entirely possible that those long-haul links could be running ATM.

At the start of the 1990s, no one knew how to build a multigigabit Internet router. The only working devices that could move data at line speed between multiple gigabit links were ATM switches. Admittedly the switches were prototypes and vendors were waiting for ATM standards to finalize the products, but realized versions of those devices existed, whereas a multigigabit router did not.

So, in many ways, a version of Turner's vision was still alive. The difference from 1986 was that rather than seeing the whole network as running something like ATM, the vision was that there would be islands of Ethernets running IP interconnected via ATM (with no routers in the network center because the routers were too slow).

As in the LAN market, emerging technologies and market forces meant ATM needed to move swiftly to grab this opportunity. In defense of the folks working on ATM for the wide area, unlike the LAN market (where the competitive situation was obvious to anyone who wished to look), the competition for the wide area was not widely recognized. It looked as if there was plenty of time to make this vision happen. As a result, just as in the LAN market, the wide-area ATM effort did not move fast enough.

Critical to this portion of the ATM story is the rise of businesses that made their money installing and selling long-haul runs of fiber-optic links. A British company, *Cable and Wireless*, jumped into this business when AT&T was broken up in 1984, and other companies, including what would become Level 3, followed. These companies started by renting fiber-optic links to the telephone carriers, but in the early 1990s they realized there was a possible market selling links to *Internet Service Providers* (ISPs).

The links ran a point-to-point protocol using the *Synchronous Optical Network* (SONET) or *Synchronous Digital Hierarchy* (SDH) protocols (which differed in minor details). SONET/SDH deliver blocks of bytes at a range of speeds from 155 Mbps up to many gigabits.

By mid-1993, there was a draft of a standard for running IP (and other protocols) over ATM. This standard was recognized to be at least a year later than the market needed it. In this case, arguments among vendors had caused the IETF to take too long. Nonetheless, when the standard was issued, the telephone industry could have sold high-speed (155 Mbps and faster) static ATM circuits running to ISPs. There was early adopter interest in such a product. But, for reasons unclear, the telephone industry did not offer a product.

Enterprising technologists realized there was an opening to develop a competing product to meet ISPs' need to be able to transmit IP data-grams over SONET links. In mid-1994, a draft of a standard for the *Point-to-Point Protocol* (PPP) operating over SDH/SONET appeared. PPP over SONET/SDH was an appealing product because ISPs could simply lease a fiber between two points of presence and run PPP. That approach allowed the ISPs to bypass the telephone companies by renting fiber directly and running PPP. An added benefit was that PPP made better use of the link (less overhead) than ATM and was simpler to manage.

At this point, the ATM dream was nearing its end. The only remaining hope was that the TCP/IP protocols would fail to scale cleanly to gigabit speeds.

By 1994, the only challenge remaining for TCP/IP was the development of multi-gigabit (10+ Gbps and faster) Internet routers. But by early 1995, multiple router vendors were indicating to their customers that, while challenges remained, the customers should expect multi-gigabit IP routers to appear.

Conclusion

In 1996, ten years after Turner's paper, ATM as a forward-looking networking protocol was effectively dead. The IETF's IP over ATM working group held its last meeting in March 1996.^[4,5,6] Perhaps more vividly illustrating the situation, a startup named Ipsilon was marketing a product that sought to repurpose ATM switches as IP routers.

ATM had its origins in Jon Turner's clear vision of the future, and it had a 2- to 5-year head start on the protocols it would compete with. This essay suggests that the ATM community squandered that lead. A valid alternative explanation is that ATM was too complex. Creating a high-speed, circuit-switched, data-networking protocol was a difficult problem in the 1980s, and ATM struggled with challenges such as address resolution and congestion control. But those challenges were ultimately solved. I suggest they would have been solved earlier had the ATM community felt more urgency, and thus this essay focuses on missed chances rather than a technical reason for the ATM failure.

Lessons Learned from 20 Years of Cellular and Wi-Fi Integration

by Mark Grayson, Cisco Systems

By any measure, cellular and Wi-Fi wireless technologies can be viewed as having fundamentally transformed the way users consume Internet services. The number of cellular users worldwide now exceeds 7 billion^[1], and the number of Wi-Fi devices shipped now exceeds 39 billion^[2]. These numbers reflect the complementary nature of the wireless systems, with the exclusively licensed cellular systems enabling cellular operators to provide Internet access over wide geographic coverage and the shared unlicensed Wi-Fi systems enabling businesses and individuals to provide targeted local-area coverage.

Whereas the default approach is for these two wireless systems to simply co-exist while supporting their respective value propositions, there have been various attempts over the last 20 years to integrate the two technologies into a single “converged” architecture. Over those 20 years, and the different “Gs,” a myriad of architectural approaches has been specified by the *3rd Generation Partnership Project* (3GPP) to integrate Wi-Fi and cellular architectures.

This article looks at some of the key takeaways from the last 20 years of attempting to converge cellular and Wi-Fi systems.

3GPP Specifications

Efforts started in December 2003, when 3GPP approved its first work item for “UMTS-WLAN Interworking”^[3]. The justification behind the work item highlighted the complementary nature of cellular and Wi-Fi deployments:

“WLAN technology can complement 3GPP based networks in deployment environments with high user density and demand for higher data rates. However, in order to provide flexible use of both technologies in these environments and to provide mobility of services between the two technologies it is sensible that some degree of interworking exists between the two technologies/systems.”

Fast forward 20 years and there now have been over a dozen different approaches specified that look to “converge” cellular. These are listed in Table 1, with some of the architectures illustrated in Figure 1.

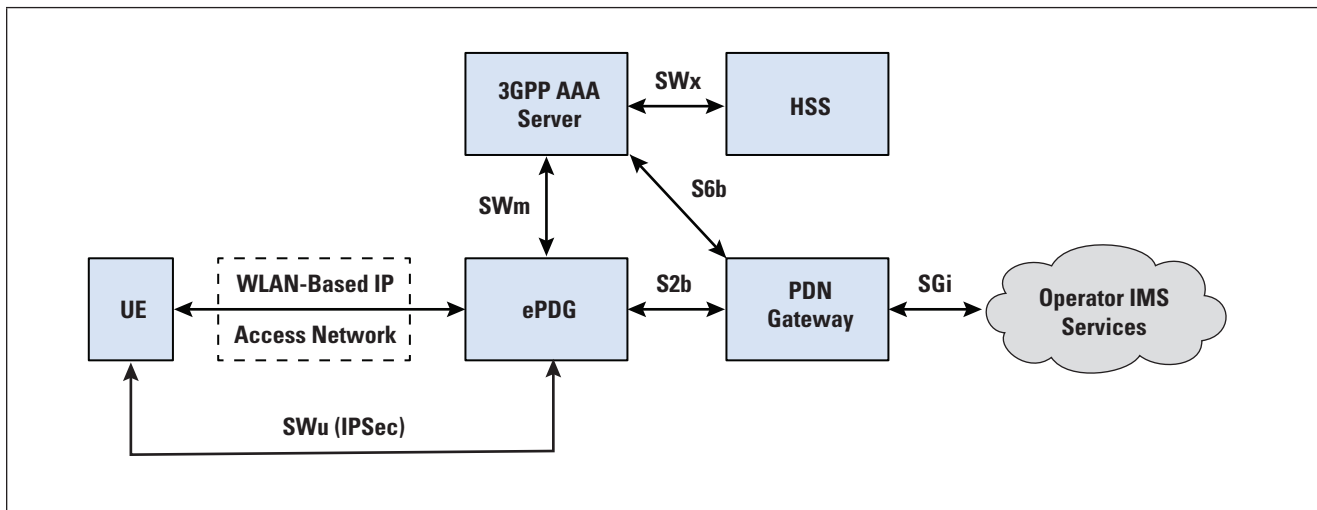

Table 1: A range of 3GPP approaches for converging 3GPP and Wi-Fi systems.

2G-Based	Generic Access Network
3G-Based	Interworking WLAN
4G-Based	Access Network Discovery and Selection Function, evolved Packet Data Gateway, Dual Stack Mobile IPv6, IP Flow Mobility and Seamless WLAN offload, Proxy Mobile IPv6 Trusted WLAN, S2a GPRS Tunnelling Protocol Trusted WLAN, LTE WLAN Aggregation, LTE/WLAN Radio Level Integration with IPsec Tunnel, Network-Based IP Flow Mobility
5G-Based	Non-3GPP Interworking Function, 5G Access Traffic Steering Switching and Splitting

Whereas the majority of these architectures have failed to see wide-scale adoption, the one solution that has seen significant deployment is the evolved *Packet Data Gateway* (ePDG) used to support *Wi-Fi Calling*, illustrated in Figure 1.

Although standardized in 2008^[4], it wasn't until 2014 with the launch of Apple iOS 8 and its native Wi-Fi Calling capability that the functionality became widely adopted, allowing transparent access to *IP Multimedia Subsystem* (IMS)-based rich media communications over both *Long-Term Evolution* (LTE) and Wi-Fi access networks. This type of deployment leverages enhanced *User Equipment* (UE) functionality to use an *IP Security* (IPSec) tunnel between the UE and ePDG to support the IMS-based services. Figure 1 shows the architecture of 3GPP.

Figure 1: 3GPP's ePDG Architecture

GSMA IR.67^[5] and 3GPP TS23.003^[6] have defined a standard realm that mobile operators may use in their Wi-Fi Calling deployments to enable their ePDGs to be discoverable over the public Internet. The *Fully Qualified Domain Name* (FQDN) is of the form:

epdg.epc.mnc<MNC>.mcc<MCC>.pub.3gppnetwork.org

...where <MCC> represents an E.212 *Mobile Country Code* and <MNC> represents the E.212 *Mobile Network Code* allocated to the mobile operator.

Wi-Fi Calling Adoption

In June 2023, the list of allocated MCC and MNC values published at <http://mcc-mnc.com/> was used to determine whether the operator that had been allocated a particular MCC and MNC had configured a *Domain Name System* (DNS) entry to enable its ePDG to be discovered. Table 2 shows the results, which indicate that over 100 countries have deployed Wi-Fi Calling where the ePDG is discoverable using the standard FQDNs defined by 3GPP.

Table 2: Countries where at least one operator has configured a standard DNS entry for ePDG discovery (Source: Cisco Systems)

Albania	Colombia	Iceland	Morocco	Saint Lucia
Anguilla	Croatia	India	Myanmar	Saint Vincent and the Grenadines
Antigua and Barbuda	Cyprus	Indonesia	Namibia	Saudi Arabia
Argentina	Czech Republic	International Networks	Nepal	Singapore
Armenia	Denmark	Ireland	Netherlands	Slovakia
Australia	Dominica	Israel	New Zealand	Slovenia
Austria	Dominican Republic	Italy	Norway	South Africa
Bahamas	Ecuador	Jamaica	Oman	Spain
Bahrain	Egypt	Japan	Pakistan	Sri Lanka
Bangladesh	Estonia	Jordan	Panama	Sudan
Barbados	Faroe Islands	Kazakhstan	Paraguay	Sweden
Belarus	Finland	Kuwait	Peru	Switzerland
Belgium	France	Latvia	Philippines	Taiwan
Brazil	Germany	Liechtenstein	Poland	Thailand
British Virgin Islands	Ghana	Lithuania	Portugal	Türkiye
Brunei	Greece	Luxembourg	Puerto Rico	Turks and Caicos Islands
Bulgaria	Grenada	Malaysia	Qatar	Ukraine
Cambodia	Guadeloupe and Martinique and French Guiana	Maldives	Reunion	United Arab Emirates
Canada	Guam	Monaco	Romania	United Kingdom
Cayman Islands	Hong Kong	Montenegro	Russia	United States of America
Chile	Hungary	Montserrat	Saint Kitts and Nevis	Vietnam

There is clearly a disparity in adoption of the different 3GPP approaches for converging 3GPP and Wi-Fi systems. For instance, in contrast to the over 100 countries that have launched ePDG-based integration, the *Global Mobile Suppliers Association* (www.gsacom.com) reports that only a single operator has invested in LTE WLAN Aggregation.

IMS-based Wi-Fi Calling Observations

Compared to the alternative “trusted” solutions defined by 3GPP for integrating Wi-Fi, the ePDG-based integration can leverage any suitable Wi-Fi network. The result of this leverage may be one of the key reasons that has led to its rapid adoption.

When looking at the Wi-Fi market as a whole, Dell’Oro reports that around 6% of all Wi-Fi equipment revenue is associated with the Service Provider segment^[7]. Only Manufacturing and Logistics segments have lower overall market share, with the Wi-Fi markets for K-12 Education, Higher Education, Finance, Healthcare, Government, Hospitality, and Retail all exceeding the Wi-Fi Service Provider market.

The first lesson learned is to avoid restricting your target market. By enabling all segments deploying Wi-Fi to benefit from ePDG-based integration, the Wi-Fi Calling approach offers the broadest market reach.

The next key observation is that the majority of smartphone data is being sent over connections that use Wi-Fi rather than mobile networks (2G, 3G, 4G, or 5G). The latest data from UK regulator *Ofcom* indicates that nearly three-quarters of all smartphone data is sent over Wi-Fi rather than mobile^[8]. Increasingly these Wi-Fi systems are being dimensioned to deliver gigabit-based services over the fixed network. When comparing data from Ofcom’s latest *Communications Market Report*^[9], the average volume for fixed broadband, where Wi-Fi dominates, is 453 GB a month, which is 75 times the 6 GB a month for the average cellular subscription.

These figures mean that the smartphone traffic transported over Wi-Fi equates to around 1% of the total fixed broadband traffic that can easily be accommodated. Equally important is the focus of ePDG-based integration on delivering seamless connectivity for IMS-based services, enabling users to receive mobile calls when out of cell tower coverage. With Ofcom reporting that the average UK cellphone user calls for 200 minutes of use a month, and a conservative 128 Kbps for the IMS call over Wi-Fi, the impact of Wi-Fi Calling on the cellphone network can be estimated:

$$\begin{aligned} \text{Total 200 minutes (cellular and Wi-Fi)} &\times 75\% = 150 \text{ minutes over Wi-Fi} \\ 150 \times 60 &= 9000 \text{ seconds} \\ 9000 \times 128 \text{ Kb} &= 1.1\text{Gb} = 144 \text{ MB} \end{aligned}$$

Importantly, the 144 MB/month of voice-over-Wi-Fi traffic corresponds to a 2.5% traffic increase compared with the average 6 GB/month used by a cellular subscriber.

This information can be contrasted with other integration approaches that focus on “trusted integration,” where all traffic sent over Wi-Fi is integrated into the cellular provider’s gateway. With 75% of traffic being carried over Wi-Fi, these approaches may result in a 300% increase in traffic across the cellular network. Whether the cellular operators can derive sufficient value from the 300% increase in traffic to cover the additional costs in supporting such is an open issue. However, the increasing adoption of encrypted flows over the Internet has already impacted an operator’s ability to derive value from observing data sent over cellular networks.

The second lesson learned is to avoid thinking of Wi-Fi and cellular as symmetrical services. Wi-Fi is already being dimensioned to support 75 times the traffic load of cellular, and the majority of smartphone traffic continues to be carried on Wi-Fi. Hence, there appears to be advantages to focus integration efforts on systems that avoid transporting the bulk of Wi-Fi data over cellphone networks, such as enabled by IMS-focused ePDG-based integration.

Integrating Native IP-based Services

In the 20 years since 3GPP embarked on the journey to converge 3GPP and Wi-Fi, there has been a significant transition in how Internet services are consumed. Early attempts at convergence were hampered by the binding of sockets to physical interfaces, with applications often stalling as devices made the switch from cellular to Wi-Fi. Hence, initial architectures looked to mask transitions from client-side applications, including the use of Mobile IP client functionality that bound sockets to logical instead of physical interfaces.

In 2023, the Internet is continuing to transition. Not only is over 90% of Internet traffic encrypted, in certain regions of the world we observe that nearly 50% of the traffic has transitioned from regular TCP to HTTP3 transported over *User Datagram Protocol* (UDP)-based QUIC^[10]. Critically, instead of having to mask different paths, the QUIC transport protocol supports native connection migration. Existing connections continue to operate as devices change their endpoint IP addresses when they switch between different networks.

Since 2022, hyperscaler offerings have included native support for HTTP3 and connection migration capability, and the device ecosystem has similarly enabled application developers to benefit from it^[11].

The third lesson learned is to avoid thinking of situations where multiple accesses and multiple paths are available to devices as peculiar. Convergence solutions shouldn't be a "bolt-on" to address specific corner cases. Instead, accept that the Internet has already started its transition to natively support such scenarios.

The Complexities of Path-Selection Policy

Path-selection policy in a heterogeneous environment is a complex issue. Instead of the network-controlled handover approach used in homogeneous cellular networks, the characteristics of Wi-Fi and cellular connections may vary dramatically in terms of costs, quality, and, for moving users, coverage persistence. However, some of the convergence architectures look to expand service providers' cellular network-controlled approach to accommodate Wi-Fi, enabling service providers to define rules that include packet-flow descriptors, access-selection criteria, as well as how to control the steering of flows between Wi-Fi and cellular.

But there is now increasing acceptance that the network provider is but one stakeholder in the complex decision process that is path selection. Identity providers may have preferred relationships that lead them to prioritize the usage of specific paths.

Users are important stakeholders in path selection, including whether the path corresponds to an unmetered private connection or a metered network that may lead to additional charges. Operating System and device vendors can base their preference on near real-time visibility of access networks and associated metrics, and battery levels can be used to drive preference for paths that consume lower energy. Application providers know the metrics that result in the best application experience, whether that is lowest latency for interactive applications or highest throughput for applications that consume significant amounts of data. Applications know in advance the likely duration of application flows and whether it is worth migrating already established flows or waiting for the establishment of new flows over a newly preferred path.

The device ecosystem is looking to meet the needs of their application providers by delivering frameworks that enable applications to configure how multiple paths should be employed, enabling applications developers to easily benefit from the HTTP3 connection migration capability.

The final lesson learned is that a single command-and-control approach to path-selection policy cannot accommodate all stakeholder requirements. And we should recognize that value is continuing to migrate towards the application; application loyalty is the new brand loyalty. So, the goal should be about how to best deliver those application experiences, and what hints and instrumentation can be exchanged between stakeholders to enable better decisions to be made.

Summary

The last two decades have seen significant investment and innovation in the development of cellular and Wi-Fi integration for the delivery of enhanced mobile services. This article has looked at some of the key takeaways from the journey and the lessons learned along the way. In summary: embracing an approach that facilitates integration with the 94% of non-service provider Wi-Fi deployments and leverages the native connection migration support provided by HTTP3, while ensuring that application stakeholders can exchange hints to enable better decisions, is the best route for delivering enhanced services across combined Wi-Fi and cellular networks.

MARK GRAYSON holds an B.Eng. in Electronic and Communication Engineering from the University of Birmingham (England), and a Ph.D. in Wireless Communications from University of Hull. Since 2000, he has worked for Cisco Systems on a variety of wireless-related projects, including early EAP-SIM implementations, 3GPP standardization of Inter-working WLAN and Cisco’s Service Provider Wi-Fi Solutions. He has served on the board of the *Small Cell Forum* where he was responsible for the small cell virtualization efforts that led to the specification of the nFAPI-based split 6. He now serves as co-chair of *O-RAN Alliance’s Fronthaul Working Group*, and is rapporteur for the deliverables dealing with the YANG-based management of the O-RAN Radio Units. He is also the chair of the *Wireless Broadband Alliance’s OpenRoaming Wi-Fi Federation* aimed at lowering barriers to roaming onto private networks and is a Fellow of the *Institute of Engineering and Technology* (IET). He can be reached at: mg@cisco.com

A New and Simplified Way to Request Nonpublic gTLD Registration Data

By Adiel Akplogan, ICANN

The Internet Corporation for Assigned Names and Numbers (ICANN) has recently launched the *Registration Data Request Service* (RDRS). This new service handles requests for access to nonpublic registration data related to *generic Top-Level Domains* (gTLDs). The RDRS is a free and global service that can be an important resource for ICANN-accredited registrars and those who have a legitimate interest in nonpublic data like law enforcement, intellectual property professionals, cybersecurity professionals, consumer-protection advocates, and government officials. The service introduces a more consistent and standardized format for handling these unique requests.

Because of personal data protection laws, many ICANN-accredited registrars are now required to redact personal data from public records such as WHOIS^[1] lookups. With no one way to request or access such data, it can be difficult for interested parties to get the information they need. The RDRS will help ease this problem by providing a simple and standardized process to make these types of requests with benefits for both registrars and requestors.

The RDRS is not only an important tool for the Internet community at large but for the ICANN Board as well. The service was implemented at the direction of the ICANN Board to gather relevant usage data to help inform policy decisions related to a *System for Standardized Access/Disclosure*^[2]. The more registrars and requestors that use the RDRS, the more accurate and valuable the data collected will be toward making that decision. ICANN-accredited registrars are encouraged to opt-in to the service. More information is available at the end of this article.

What Is the RDRS?

The RDRS is a free, global, one-stop-shop ticketing system that handles nonpublic gTLD registration data requests. The RDRS connects requestors of nonpublic data with the relevant ICANN-accredited registrars for gTLD domain names that participate in the service. The service streamlines and standardizes the process for submitting and receiving requests through a single platform. It is important to note that the RDRS does not guarantee access to requested registration data. All communication and data disclosure between the registrars and requestors takes place outside of the system.

Who Can Use the RDRS?

The service is intended for use by ICANN-accredited registrars and individuals and entities with a legitimate interest for access to nonpublic gTLD registration data.

Requestors include but are not limited to: law enforcement, intellectual property professionals, cybersecurity professionals, consumer protection advocates, and government officials. Use by ICANN-accredited registrars is voluntary. More information on how to opt-in to the service is available at the *Naming Services Portal for Registrars*: <https://www.icann.org/resources/pages/nsp-registrars-2018-03-26-en>

Benefits of the Service

One of the key benefits is the simplification of the request process, making it easier to identify the right registrars and provide the necessary information for efficient and timely submission and consideration of disclosure requests. Instead of filling out multiple forms with varying sets of required information, each managed by different registrars, requestors need only to complete a single, standardized form through the service.

Requestors also no longer need to look up the appropriate registrar to contact—the service will do that for them. The service also provides a centralized platform where requestors can conveniently access pending and past requests. They can create new requests, develop request templates for future use, and cancel requests when needed. Registrars can benefit from using the service as it provides a mechanism to manage and track all nonpublic data requests in a single location. Registrars can receive automated alerts anytime they receive a request. The use of a standardized submission form also makes it easier for the correct information and supporting documents to be provided to evaluate a request. For more information on the RDRS, including a flyer for requestors, visit: <https://www.icann.org/rdrs-en>

APNIC Releases Strategic Plan

The *Executive Council* (EC) of the *Asia Pacific Network Information Centre* (APNIC) is pleased to announce the availability of APNIC's new four-year strategy. The *APNIC Strategic Plan (2024-2027)*^[1] was created by the APNIC EC and Secretariat. It is informed by feedback from Members and the community. The plan sets out the future that APNIC wishes to see, the objectives and priorities that need to be achieved to help reach that future state, and the guiding principles underpinning APNIC's efforts.

The existing strategic pillars of activity (Membership, Registry, Development, Information, and Capability) have been re-cast into four new ones: Two Value Streams, Registry and Development; and two Enablers, Engagement and Capability.

The EC and Secretariat believe the new strategic pillars are the best way to group APNIC's priorities and activities over the coming four years, and the Secretariat is transitioning to a new operational staffing structure to mirror the plan's four pillars.

The strategy becomes the guide for APNIC's annual *Activity Plans*^[2], and the activities will align with the overall strategy. The first annual Activity Plan based on the strategy will be released in March 2024 at the APNIC 57 *Annual General Meeting* (AGM) in Bangkok, held in conjunction with APRICOT 2024: <https://2024.apricot.net/>

Randy Bush Receives Rob Blokzijl Award

The 2023 *Rob Blokzijl Award* was presented to Randy Bush at the RIPE 87 meeting in Rome in November for his many years of contributions to the Internet in the RIPE NCC service region and beyond, playing a vital role in establishing Internet networks in many developing countries in Africa, Latin America and the Caribbean. The award committee also recognised Randy's non-technical contributions as a dedicated mentor, for speaking the truth, and for passing on knowledge and values.

The award, bestowed by the Rob Blokzijl Foundation, honours the memory of Rob Blokzijl, the first Chair of RIPE. It recognises individuals who have made substantial technical and operational contributions to the development of the Internet in the RIPE NCC service region and supported or enabled others.

You can watch the presentation here: <https://ripe87.ripe.net/archives/video/1145/>

Thank You!

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at **ole@protocoljournal.org** or **olejacobsen@me.com**

I have just returned from the annual *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT), held this year in Bangkok, Thailand. Amongst the many interesting presentations given, there was one entitled “BGP in 2023,” by Geoff Huston. In his talk, he asked if we have reached “Peak IPv4,” noting that the overall IPv4 routing growth trends slowed down or even reversed through 2023. His presentation, as well as a YouTube video, are available on the APRICOT 2024 website.

In our two previous issues, we published a two-part set of articles under the heading “Introduction to 5G” by William Stallings. Part One introduced the standards, specifications, and usage scenarios for 5G. Part Two gave an overview of the structure and function of 5G networks. A third article, on *Network Slicing*, which is closely related to 5G, is included in this edition.

This journal, as well as its predecessor *ConneXions—The Interoperability Report*, has covered numerous networking technologies over the last 35 years. Some of these technologies have become important building blocks for all networks, for example, *Ethernet*, which for more than 50 years has seen further improvements and standardization. Our second article, by Mikael Holmberg, describes the history and future of Ethernet.

Pindar Wong has served on our Editorial Advisory Board since the inception of this journal. I have always appreciated his invaluable insight and advice, particularly on emerging technologies such as Blockchain. Pindar has indicated that he is moving on to pursue other interests and wishes to step down from his advisory role. I thank Pindar for all his contributions and wish him the best in his future endeavors.

I am also extremely honored to welcome Merike Kaeo as a new member of the Editorial Advisory Board. Merike has extensive experience in all aspects of network and information security, and I look forward to working with her on developing article topics for IPJ.

Publication of this journal is made possible by the generous support of our donors, supporters, and sponsors. We also depend on your feedback and suggestions. If you would like to comment on, donate to, or sponsor IPJ, please contact us at ipj@protocoljournal.org

Network Slicing

by William Stallings, Independent Consultant

One of the most important features of 5G is *Network Slicing*^[1,10,11]. Network slicing uses virtualization technologies, especially *Software Defined Networks* (SDN) and *Network Functions Virtualization* (NFV)^[0], which enable a 5G network operator to provide customized networks by creating multiple virtual and end-to-end networks, referred to as *network slices*. Each network slice can be defined according to different requirements on functionality, *Quality of Service* (QoS), and specific users.

The article “Network Slicing for 5G: Challenges and Opportunities,”^[2] lists the following advantages of slice-based networking compared with traditional networks:

- Network slicing can provide logical networks with better performance than one-size-fits-all networks.
- A network slice can scale up or down as service requirements and the number of users change.
- Network slices can isolate the network resources of one service from the others; the configurations among various slices don’t affect each other. Therefore, the reliability and security of each slice can be enhanced.
- A network slice is customized according to QoS requirements, which can optimize the allocation and use of physical network resources.

Network slicing is made possible by the “softwarization” techniques of NFV and SDN. NFV implements the *Network Functions* (NFs) in a network slice, enabling the isolation of each network slice from all other network slices. Isolation is achieved by (i) using a different physical resource; (ii) separating by virtualization, which may allow sharing of physical resources; or (iii) sharing a resource with the guidance of a respective policy that defines the access rights for each tenant. Isolation assures QoS and security requirements for that slice independent of other slices operating on the network from the same or different users. After a network slice is defined, SDN operates to monitor and enforce QoS requirements by controlling the behavior of the QoS flow for each slice.

Overview

Network slicing permits a physical network to be separated into multiple virtual networks (logical segments) that can support different *Radio Access Networks* (RANs) or several types of services for certain customer segments, greatly reducing network construction costs by using communication channels more efficiently. In essence, network slicing allows the creation of multiple virtual networks atop a shared physical infrastructure.

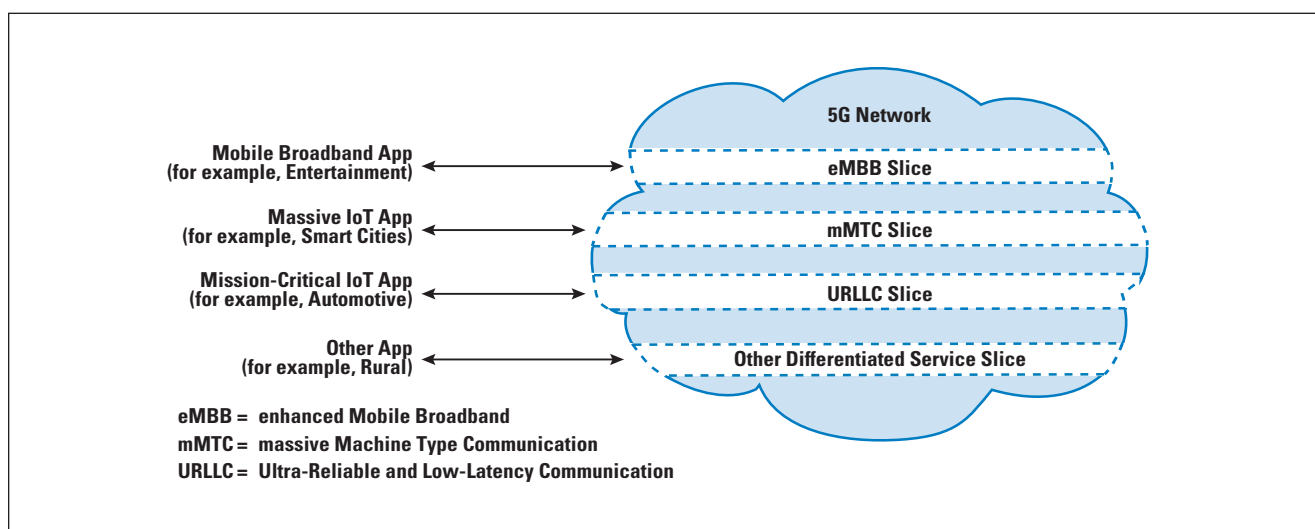

In this virtualized network scenario, physical components are secondary and logical (software-based) partitions are paramount, devoting capacity to certain purposes dynamically, according to need. As needs change, so can the devoted resources. Using common resources such as storage and processors, network slicing permits the creation of slices devoted to logical, self-contained, and partitioned network functions. Network slicing supports the creation of virtual networks to provide a given QoS, such as guaranteed delay, throughput, reliability, and/or priority.

The *International Telecommunication Union Telecommunication Standardization Sector* (ITU-T) is involved in the standardization of network slicing for 5G networks. ITU-T Recommendation Y.3112^[3] defines a network slice as a logical network that provides specific network capabilities and network characteristics. This recommendation lays out an overall framework for network slicing, defines high-level requirements, and describes core network functions relevant to network slicing.

Figure 1 illustrates the network slicing concept. The requirements of a particular application or user determine the physical and logical network resources needed to provide the desired QoS. The network slicing function dedicates the appropriate resources to support that QoS. Figure 1 illustrates the three major usage scenarios for 5G defined by *ITU Radiocommunication Sector* (ITU-R)^[4]. The scenarios include:

- *enhanced Mobile Broadband* (eMBB): Characterized by high data rates for mobile devices.
- *massive Machine-Type Communication* (mMTC): Characterized by the ability to support huge numbers of devices, such as in a large *Internet of Things* (IoT) deployment.
- *Ultra-Reliable and Low-Latency Communication* (URLLC): Characterized by the ability to support human-to-machine and machine-to-machine communications that require high reliability and/or low end-to-end delay.

Figure 1: Network Slicing Concept

Network Slicing Concepts

Network slicing permits you to separate a physical network into multiple virtual networks (logical segments) that can support different radio access networks or several types of services for certain customer segments, greatly reducing network construction costs by using communication channels more efficiently. In essence, network slicing allows you to create multiple virtual networks atop a shared physical infrastructure. This virtualized network scenario devotes capacity to certain purposes dynamically, according to need. As needs change, so can the devoted resources. Using common resources such as storage and processors, network slicing permits you to create slices devoted to logical, self-contained, and partitioned network functions. It supports the creation of virtual networks to provide a given QoS, such as guaranteed delay, throughput, reliability, and/or priority.

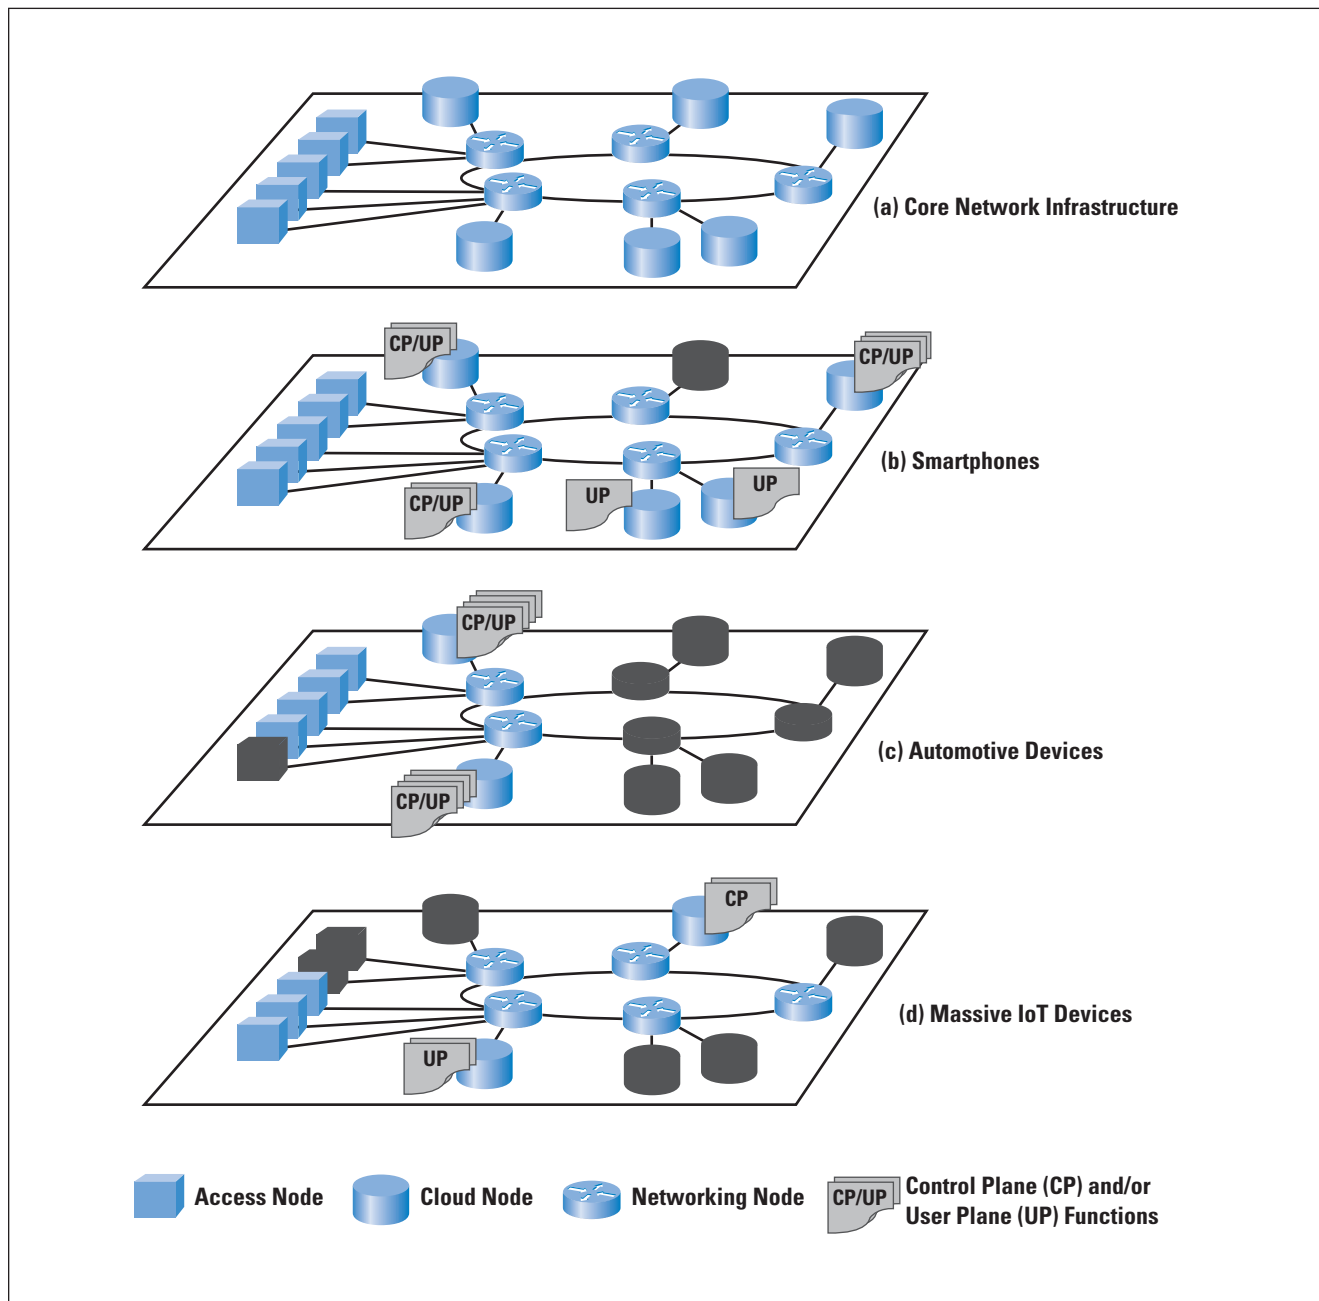

A network slice creates a partition of the core network consisting of virtualized network functions and resources running on some of the core network hardware resources. Figure 2, based on concepts in a *Next Generation Mobile Networks* (NGMN) document^[5], illustrates network slicing concepts. Figure 2a shows a simple core network configuration comprising three types of devices:

- *Cloud Nodes:* These nodes provide cloud services, software, and storage resources. There are likely to be one or more central cloud nodes that provide traditional cloud computing service. In addition, cloud-edge nodes provide low latency and higher security access to client devices at the edge of the network. All of these nodes include virtualization system software to support virtual machines and containers. NFV enables effective deployment of cloud resources to the appropriate edge node for a given application and given fixed or mobile user. The combination of SDN and NFV enables the movement of edge resources and services to dynamically accommodate mobile users.
- *Networking Nodes:* These nodes are IP routers and other types of switches for implementing a physical path through the network for a 5G connection. SDN provides for flexible and dynamic creation and management of these paths.
- *Access Nodes:* These nodes provide an interface to RANs, which in turn provide access to mobile *User Equipment* (UE). SDN creates paths that use an access node for one or both ends of a connection involving a wireless device.

The remainder of Figure 2 illustrates three use cases. The blacked-out core network resources represent resources not used to create the network slice. Cloud nodes that are part of the slice may include the following:

- Control-plane functions associated with one or more user-plane functions (for example, a reusable or common framework of control).
- Service- or service-category-specific control-plane and user-plane function pairs (for example, a user-specific multimedia application session).

Figure 2: 5G Network Slices Implemented on the Same Infrastructure

The first network slice depicted in Figure 2 is for a typical smartphone use case. Such a slice might have fully-fledged functions distributed across the network. The second network slice in Figure 2 indicates the type of support that may be allocated for automobiles in motion. This use case emphasizes the need for security, reliability, and low latency. A configuration to achieve these necessities would limit core network resources to nearby cloud-edge nodes, in addition to recruiting sufficient access nodes to support the use case.

The final use case illustrated in Figure 2 is for a massive IoT deployment, such as a huge number of sensors. The slice can contain just some specific *Control Plane* (CP) and *User Plane* (UP) functions with, for example, no mobility functions. The CP and UP functions might include filtering and preliminary data analysis at the edge and big data types of analysis at a more central node. This slice would need to engage only access nodes nearest to the IoT device deployment.

Requirements for Network Slicing

The *3rd Generation Partnership Project* (3GPP) is the organization responsible for developing specifications that are subsequently issued as ITU-T Recommendations. The 3GPP Technical Specification TS 22.261^[6] lists requirements for network slicing in two categories: *general requirements* and *management requirements*.

The general requirements for network slicing are the following:

- It must provide connectivity to home and roaming users in the same network slice.
- In a shared 5G network configuration, each operator must be able to apply all the requirements to their allocated network resources.
- It must support the *IP Multimedia Subsystem* (IMS) as part of a network slice.
- IMS support must be independent of network slices.

The IMS is a standards-based architectural framework for delivering multimedia communications services such as voice, video, and text messaging over IP networks^[7,12]. 3GPP originally developed the IMS specifications in the early 2000s to standardize access to multimedia services using cellular networks. The specifications define a complete framework and architecture that enables the convergence of video, voice, data, and mobile network technologies.

The management requirements of network slicing follow; it must:

- Allow the operator to create, modify, and delete a network slice.
- Allow the operator to define and update the set of services and capabilities supported in a network slice.
- Allow the operator to configure the information that associates a UE to a network slice.
- Allow the operator to configure the information which associates a service to a network slice.
- Allow the operator to assign a UE to a network slice, to move a UE from one network slice to another, and to remove a UE from a network slice based on subscription, UE capabilities, the access technology the UE uses, and the operator's policies and services the network slice provides.

- Support a mechanism for the *Visited Public Land Mobile Network* (VPLMN), as authorized by the *Home Public Land Mobile Network* (HPLMN), to assign a UE to a network slice with the needed services or to a default network slice.
- Enable a UE to be simultaneously assigned to and access services from more than one network slice of one operator.
- Ensure traffic and services in one network slice will have no impact on traffic and services in other network slices in the same network.
- Ensure that the creation, modification, and deletion of a network slice will have no or minimal impact on traffic and services in other network slices in the same network.
- Support scaling of a network slice, that is, adaptation of its capacity.
- Enable the network operator to define a minimum available capacity for a network slice. Ensure that scaling of other network slices on the same network will have no impact on the availability of the minimum capacity for that network slice.
- Enable the network operator to define a maximum capacity for a network slice.
- Enable the network operator to define a priority order between different network slices in case multiple network slices compete for resources on the same network.
- Support means by which the operator can differentiate policy control, functionality, and performance provided in different network slices.

Identification and Selection of a Network Slice

The *Single Network Slice Selection Assistance Information* (S-NSSAI) defines a single network slice. An S-NSSAI consists of two elements:

- *Slice/Service Type* (SST): An identifier that refers to the expected slice behavior in terms of features and services. Standardized SST values provide a way for establishing global interoperability for slicing so that 5G networks can support the roaming use case more efficiently for the most commonly used SSTs. Table 1 lists the standardized SSTs.
- *Slice Differentiator* (SD): Optional information that complements the SST to differentiate among multiple network slices of the same SST.

Table 1: Standardized Slice/Service Type Values.

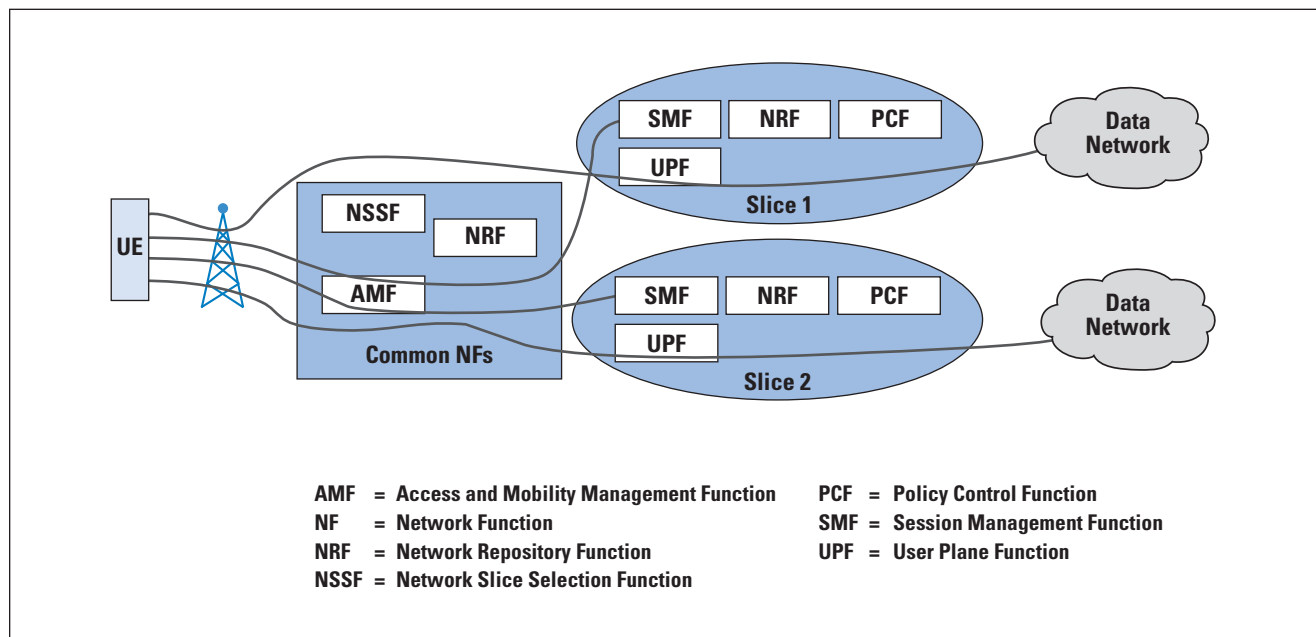

Slice/Service Type	SST Value	Characteristics
eMBB	1	Slice suitable to handle 5G-enhanced Mobile Broadband.
URLLC	2	Slice suitable to handle ultra-reliable low-latency communications.
Massive IoT (mIoT)	3	Slice suitable to handle massive IoT.
Vehicle-to-Everything (V2X)	4	Slice suitable to handle V2X services.

A UE may be served by up to eight network slices at a time, each identified by an S-NSSAI. The set of S-NSSAIs associated with a UE form a *Network Slice Selection Assistance Information* (NSSAI) data object.

Functional Aspects of Network Slicing

Figure 3 indicates the manner in which core NFs are used to implement network slices. A network function is a processing function in a network that has defined functional behavior and interfaces. You can implement a network function as a network element on dedicated hardware, as a software instance running on dedicated hardware, or as a virtualized function instantiated on an appropriate platform, for example, on a cloud infrastructure. Some NF instances support multiple network slices serving a UE, while others are specific to a given slice.

Figure 3: Network Functions that Support Network Slicing

The common NFs follow:

- *Access and Mobility Management Function* (AMF): Network slice instance selection is usually triggered as part of the registration procedure by the first AMF that receives the registration request from the UE. When a UE accesses the network, AMF provides functionalities to register and de-register the UE with the network, and it establishes the user context in the network. In the registration procedure, AMF performs, but is not limited to, network slice instance selection, UE authentication, authorization of network access and network services, and network access policy control. In addition, when AMF receives a session establishment request message from UE, it performs discovery and selection of the SMF that is the most appropriate to manage the session.

- *Network Slice Selection Function* (NSSF): The AMF retrieves the slices that the user subscription allows and interacts with the NSSF to select the appropriate network slice instance (for example, based on allowed S-NSSAIs, 5G network ID, and other parameters). The NSSF responds with a message including the list of appropriate network slice instances for the UE. As a result, the registration process may switch to another AMF if needed.
- *Network Repository Function* (NRF): During the AMF-NSSF interaction, the NSSF may return the identity of one or more NRFs to be used to select NFs and services within the selected network slice instance(s).

The slice-specific NFs follows:

- *Session Management Function* (SMF): The UE sends a message to the AMF requesting that a *Protocol Data Unit* (PDU) session be associated to one S-NSSAI and one *Data Network* (DN). The AMF selects the appropriate SMF, which manages the PDU session. The SMF sets up the PDU session for the UE and controls the user-plane operation. The SMF selects the UPF and invokes enforcement of QoS and charging policies.
- *User Plane Function* (UPF): Once a PDU session is established, QoS flows for this PDU session over this network slice pass through the UPF.
- *Policy Control Function* (PCF): The SMF gets policy information related to session establishment from the PCF.
- *Network Repository Function* (NRF): The SMF uses the NRF to discover the required NFs for the individual network slice.

Generic Slice Template

3GPP TS 28.531^[8] includes a description of the concept of the *Generic Slice Template* (GST). The *GSM Association* (GSMA) has specified the GST, which provides a standardized list of attributes that you can use to characterize different types of network slices^[9]. A *Network Slice Type* (NEST) is a GST filled with (ranges of) values. There may be two kinds of NESTs:

- *Standardized NEST* (S-NEST): Attributes are assigned (ranges of) values by *Standards-Developing Organizations* (SDOs), working groups, forums, and so forth, such as 3GPP, GSMA, *5G Automotive Association* (5GAA), and the *5G Alliance for Connected Industry and Automation* (5G-ACIA).
- *Private NEST* (P-NEST): Attributes are assigned (ranges of) values by the Network Slice Providers; these values are different from those assigned in S-NESTs.

Network Slice Providers can build their network slice product offering based on S-NESTs and/or their P-NESTs. GSMA has developed the GST to be a list of attributes sufficient for describing a wide range of NESTs that you can fully construct by allocating values (or ranges of values) to each relevant attribute in the GST. A network operator can use a NEST to identify the network resources and functions needed to instantiate network slices. The process to fill in the GST and to create a NEST comprises three steps:

1. Study use cases and derive service requirements based on discussions with the slice customers, such as vertical industries or specific enterprises.
2. Convert the service requirements identified in (1) into technical requirements.
3. Document the technical requirements produced in (2) using the NEST by filling in the values of each of the attributes of the GST.

The current version of the GST lists 35 attributes, shown in Figure 4.

Figure 4: Generic Network Slice Template Attributes

Availability	Network Functions Owned by Network Slice Customer	Supported Device Velocity
Area of Service	Maximum Number of PDU Sessions	Synchronicity
Delay Tolerance	Maximum Number of UEs	UE Density
Deterministic Communication	Performance Monitoring	Uplink Throughput per Network Slice
Downlink Throughput per Network Slice	Performance Prediction	Uplink Maximum Throughput per UE
Downlink Maximum Throughput per UE	Positioning Support	User Management Openness
Energy Efficiency	Radio Spectrum	User Data Access
Group Communication Support	Root Cause Investigation	V2X Communication Mode
Isolation Level	Session and Service Continuity Support	Latency from (last) User Plane Function (UPF) to Application Server
Maximum Supported Packet Size	Simultaneous Use of the Network Slice	Network Slice Specific Authentication and Authorization (NSSAA) Required
Mission-Critical Support	Slice Quality of Service Parameters	
Multimedia Telephony (MMTel) Support	Support for Non-IP Traffic	
NB-IoT Support		

Summary

Virtualization encompasses a variety of technologies for managing computing resources by providing a software translation layer, known as an abstraction layer, between the software and the physical hardware. Virtualization turns physical resources into logical, or virtual, resources. Virtualization enables users, applications, and management software operating above the abstraction layer to manage and use resources without needing to be aware of the physical details of the underlying resources. NFV is a key technology for implementing 5G wireless networks.

The History and Future of Ethernet

by Mikael Holmberg, *Extreme Networks*

Initially developed by *Xerox Palo Alto Research Center* (PARC) in the 1970s and ratified by the *Institute of Electrical and Electronics Engineers* (IEEE) as a standard in 1983, the evolution of Ethernet has taken this technology through many specifications and standardizations during its 50-year history.

Ethernet technology has become the backbone of modern communication and connectivity, linking billions of devices to each other and the Internet. Today, Ethernet connects *Local Area Networks* (LANs), *Wide Area Networks* (WANs), Internet, Cloud, *Internet of Things* (IoT) devices, Wi-Fi, and many other systems into one seamless global communications network.

The name *Ethernet* is based on the word “ether” as a way of describing an essential feature of the system: the physical medium (that is, a cable) carries bits to all stations, much the same way that the old “luminiferous ether” was once thought to propagate electromagnetic waves through space.

In its early days, Ethernet competed with other technologies like *Token Ring*. It was eventually chosen as the ubiquitous technology used in computer networks because of the simplicity by which the communication protocol can be deployed and its ability to incorporate modern advancements without losing backward compatibility. Ethernet continues to reign as the de facto standard for computer networking and many newly evolved applications and use cases. Just to choose one of interest, the topic that everybody talks about today is *Artificial Intelligence* (AI). As AI workloads increase, network industry giants are teaming to ensure Ethernet networks can keep pace and satisfy the AI high-performance networking requirements, among many other new use cases and applications. I will cover AI as well as a few other interesting use cases around the evolved Ethernet in this article.

In 1975, Xerox filed a patent application listing Bob Metcalfe, David Boggs, Chuck Tucker, and Butler Lampson as inventors. Then, in 1976, after the system was deployed at PARC, Metcalfe and Boggs published a seminal paper.^[1] Four gentlemen, Yogen Dalal, Ron Crane, Bob Garner, and Roy Ogus, facilitated the upgrade from the original 2.94-Mbps to the 10-Mbps protocol, which was released to the market in 1980 and ratified by the IEEE as a standard in 1983^[2]. Ethernet has become the dominant LAN technology, and five decades after its initial specification its evolution continues.^[31]

Taking a step back in time, let’s look at the progress of Ethernet technology over the past five decades and explore where experts think it could be heading in the years to come.

The Early Days of Ethernet

The evolution of Ethernet officially began in 1973 when engineer Robert Metcalfe introduced the concept in a memo he wrote while working at Xerox PARC. Metcalfe initially described Ethernet as interconnecting computing workstations, and it enabled them to communicate with each other as well as with devices like laser printers. These interconnected endpoints became the environment we now recognize as the world's first LAN.

Metcalfe was inspired by ALOHAnet^[1], an earlier networking project that began at the University of Hawaii in 1968 and aimed to connect remote workstations across the Hawaiian Islands to a central computer at the main Oahu campus.

ALOHAnet was realized by using a quite rudimentary *Additive Links On-line Hawaii Area* (ALOHA) protocol, where an end station would transmit a frame over a common data channel and then wait for confirmation that it had reached its destination successfully. If the end station didn't receive confirmation within a given period, it assumed a *collision* had occurred with another frame sent by a different end station simultaneously. In that case, that station would continue to resend the data until it achieved successful transmission. But as amounts of end stations and transmissions increased, more collisions would occur, and the network would become less efficient. An ALOHA variation named *Slotted ALOHA* aimed to minimize network contention problems by precisely coordinating individual transmissions for the end stations and assigning them designated timeslots via a beacon signal schema.

Metcalfe's Ethernet experiment, at that time referred to as the *Alto ALOHA Network*, included many revolutionary features that enabled significantly more efficient use of a computer network. This set of rules, which became known as the *Carrier Sense Multiple Access/Collision Detect* (CSMA/CD) protocol, allowed end stations to monitor the availability of a shared communication path and detect possible collisions when two end stations sent data at the same time. When frames collided, the system would discard them, leading each end station to wait for a randomly assigned length of time before trying to resend. The end station would continue this schema to pause and try to resend as many times as necessary. This process is known as *exponential back-off*.^[33]

So, the original Ethernet technology was based on a shared medium that was collision-prone, where all computers trying to communicate shared the same cable and, as such, competed with each other. The modern Ethernet implementation has a collision-free switched connection, where each computer communicates with only its own switch port, without competing for the cable with others.

By 1973, Metcalfe thought that the technology had outgrown its original name and renamed it *Ethernet*. Four years later, Metcalfe and Boggs, together with Charles Thacker and Butler Lampson, who also worked at Xerox, successfully patented Ethernet technology.^[3]

How Does Ethernet Work?

Ethernet works by breaking up data being sent to or from devices, like a personal computer, into short pieces of different-sized bits of information called *frames*. Those frames contain information such as the source and destination address that helps the frame route its way through a network.

In the past, computers on a LAN typically shared a single connection. Ethernet was built around the principle of CSMA/CD, as was briefly explained earlier in this article, where the protocol ensures that the cable is not in use before sending any frames out. Now that feature is far less important than it was in the early days of networking, as devices generally have their own private connection to a network through a *switch*. Ethernet now operates using *Full Duplex* (FDX), where the sending and receiving channels are separate, so it is impossible for collisions to occur over the same connection. As there is no error correction in Ethernet, the communication relies on upper-layer advanced protocols to ensure that everything is transmitted perfectly. Ethernet provides the basis for most digital communications, and it integrates quite easily with most higher-level protocols.

Ethernet IEEE Standardization

Xerox worked with two other vendors, Digital Equipment Corporation and Intel, to publish the first 10-Mbps Ethernet specification in 1980. Meanwhile, the *Local and Metropolitan Area Networks* (LAN/MAN) Standards Committee at the IEEE set out to develop a similar open standard. The IEEE LAN/MAN committee, which applies the number 802 to all its standards, formed an Ethernet subcommittee and named it the *IEEE 802.3 Working Group*. Through the first half of the 1980s, the Ethernet 10BASE-5 implementation used a coaxial cable 0.375 inches (9.5 mm) in diameter, also referred to as *Thick Ethernet* or *Thicknet*, and it was standardized in 1982 as 10BASE-5.

Figure 1: 10BASE-5 Ethernet

Some of us who have worked in this industry for many years might recall that on 10BASE-5, you drilled the transceiver pin (the so-called “vampire tap”) into the core of the thick coaxial cable, and if you were not careful, you might end up shortcutting the wire.

In the late 1980s, 10BASE-5 was replaced by 10BASE-2, called *Thin Ethernet* or *Thinnet*, and it used a BNC connector to connect the Ethernet *Network Interface Cards* (NICs) to a BNC-T splitter to ensure that the Ethernet segment stayed intact. It used the RG-58 coaxial cable, which is 0.2 inches (5 mm) in diameter, as media. The emphasis was on making the installation of the cable easier and less costly. This thin Ethernet was followed by twisted pair (10BASE-T) and fiber-optic (10BASE-FL).

Figure 2: 10BASE-2 Ethernet

In 1995, with the Fast Ethernet standard, the speed was upgraded to 100 Mbps, and no such speed improvement was ever made for Thinnet. By 2001, prices for Fast Ethernet cards had fallen to under \$50, and by 2003 Wi-Fi (802.11) networking equipment was widely available and affordable. Because of the immense demand for high-speed networking, the low cost of *Category 5* (Cat5) cable, and the popularity of 802.11 wireless networks, both 10BASE-2 and 10BASE-5 have become obsolete, though devices using those standards might still exist in some locations.

Also, in 1995, 100-Mbps Ethernet introduced *auto-negotiation*, which allowed for two network devices to signal each other and establish the best-shared mode of operation, including speed and duplex mode.

Three years later, a new milestone was reached when the 802.3 working group introduced *Gigabit Ethernet* [GE] (100BASE-T)^[4, 5], which was first realized over fiber-optic cable and, subsequently, over twisted-pair copper cable.

The evolution of Ethernet continued with 10-Gbps speeds in 2002, initially over fiber, then over twisted-pair copper cable, and finally, over unshielded twisted-pair cable. Then, in 2010, IEEE approved 40 GE and 100 GE, which was realized by aggregating multiple 10-Gbps lanes.

In 2016, driven by the rising demand from hyperscalers (web companies), the IEEE ratified 25 GE, which was 2.5 times faster than 10 GE but more cost-efficient than 40 GE. This standard improved throughput by increasing the capacity of a single lane, rather than aggregating multiple lower-capacity lanes, and meant that 25 GE required less cable and power and had higher port density than 40 GE. In some cases, an upgrade to 25 GE lets data-center operators extend the life of top-of-rack switches and avoid full “rip-and-replace” upgrades of cabling infrastructure. Hence, hyperscalers upgraded to 25 GE speeds in their data centers.

The following year, in late 2017, the networking industry saw the ratification of 200 and 400 GE. These standards were both based on 50-Gbps single lanes, as the cloud providers and hyperscale data centers, *Internet Service Providers* (ISPs), and specialized organizations like *Network Operations Centers* (NOCs) needed and wanted more bandwidth. Some of the challenges with 400-Gbps speeds include new cabling requirements because the current Category 5 and 5e cables don’t support such speeds.

In 2019, *Communication Service Providers* (CSPs) began deploying (or, more likely, testing) 5G^[26, 27] networks, the fifth-generation technology standard for broadband cellular networks. It is defined by the *3rd Generation Partnership Project* (3GPP), and it is the planned successor to 4G networks. Like its predecessors, 5G networks are cellular networks. All 5G wireless devices in a cell connect to the Internet and telephone network via radio waves through a local antenna in the cell. These new networks boost higher download speeds, eventually up to 10 Gbps. In addition to being faster than existing networks, 5G offers higher bandwidth, enabling it to connect a greater number of devices and improve the quality of Internet services in crowded areas. Naturally, Ethernet acts as the packet-based solution within 5G, accommodating all the essential containerized microservices required for 5G functions running on computers in all sizes of data centers with Ethernet fabric technologies.

Ethernet-based 5G cloud data-center fabrics come in various sizes, from small edge data-center fabrics implemented as Layer 2 network infrastructures to truly scalable three- and five-stage large data-center fabrics. These larger fabrics deployed as Layer 3 infrastructure with dozens or even hundreds of Ethernet switches connected in a *spine and leaf* architecture, also known as CLOS. The CLOS architecture has its origins in Charles Clos’ crossbar switches for telephone-call switching, and it is composed of leaf and spine layers where switches are used.

The most prevalent design for these cloud data-center fabrics consists of Ethernet switches that use *Virtual Extensible LAN* (VXLAN) with *Multiprotocol Extensions for BGP* (MP-BGP) and an *Ethernet Virtual Private Network* (EVPN) control plane.

All Ethernet switches are deployed in pairs to provide dual-homed redundant connectivity to computers and other switches. The leaf switch pairs interconnect to form a cluster, providing redundancy for the attached computers. *Border Leaf* (BL) switches are also deployed in pairs, ensuring dual-homed redundant connectivity to external *Provider Edge* (PE) routers and the Internet. This connectivity presents yet another interesting use case in which Ethernet serves as the foundation for cloud-native 5G mobile network applications and workloads.

Technically, the specification for 800-Gbps Ethernet also exists but is not really used outside of test environments. The interesting thing about Ethernet is that because it is such an open protocol, there is no reason to think that even the 800-Gbps speeds are anywhere near the theoretical maximum. Research is being done to set the groundwork for a 1.6-Tbps standard. Speeds like that will probably be useful only in highly specific applications.

Ethernet Cables

You can't talk about Ethernet without also talking about various cables used for Ethernet. As I previously described, the early days of Ethernet relied on coaxial cables, basically the same as were used for cable television. Coaxial cable is robust in design, having a thick internal copper wire, but it does have trade-offs, as it is heavy and difficult to work with and not very flexible. Ethernet changed to use twisted-pair cables that are still used when deploying Ethernet networks today, as are fiber-optic cables.

Many companies that manufacture Ethernet cables have moved away from the dull gray color scheme and instead offer them in a wide variety of colors that allow for improving data-center racks with different-colored cables. It also enables color-coding, so technicians can group their different network connections visually into groups based on different colors for quick troubleshooting.

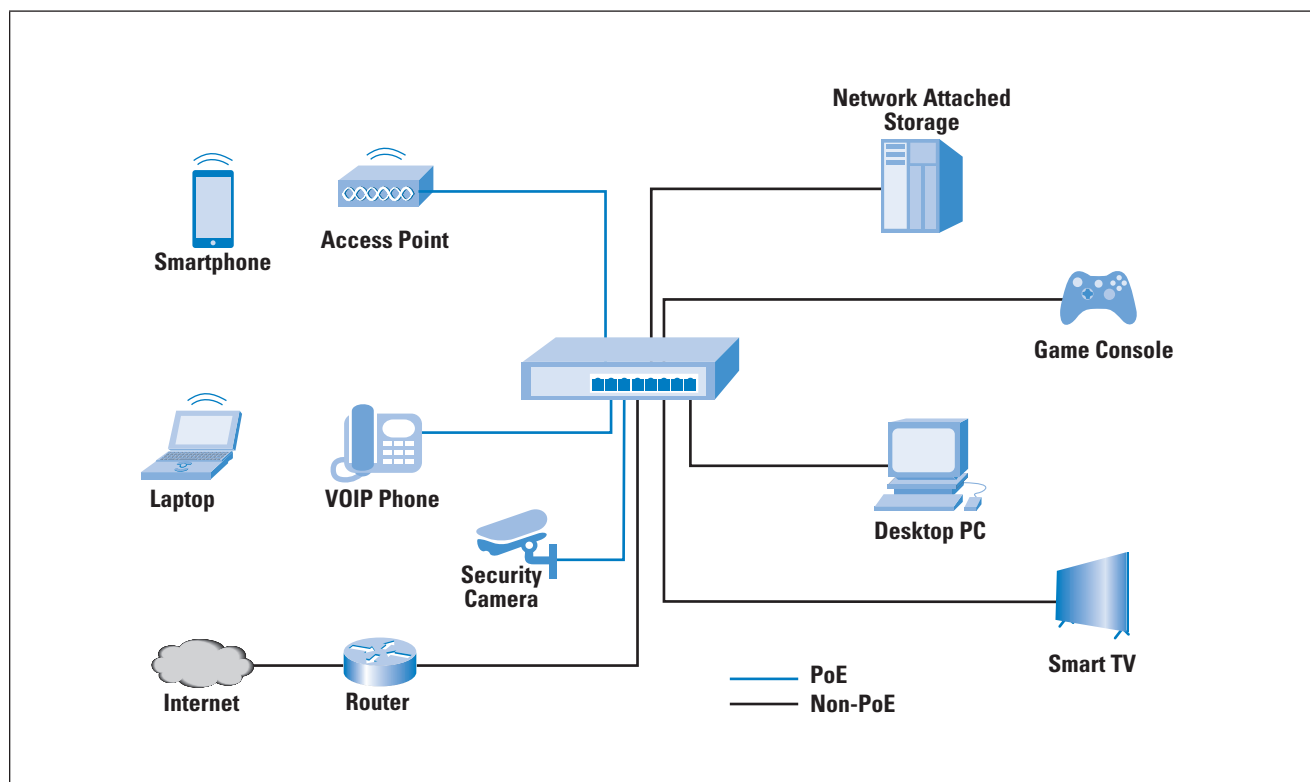

The standard plug on both ends of twisted-pair cables (RJ-45), which is very similar to the same kind of connector that wired telephone systems use (RJ-11), made it easy to just click the cables into any device that supports Ethernet connectivity. So, simply plugging in a device and attaching it to a network using one of those colored Ethernet cables is the only step required to gain connectivity. The long-time standard for Ethernet cables is *Category 5* (Cat5). The Cat5 standard has been used since 2001, and a slightly more advanced cable called *Category 5e* (Cat5e) is also used today for faster Ethernet applications. Category 5e cables are targeted at 100-Mbps Ethernet, but the design also supports higher speeds, such as Gigabit Ethernet. New *Category 6* (Cat6) cables have been introduced to support higher speeds than the Cat5 and Cat5e cables.

Several standards have been defined for *Power over Ethernet* (PoE), which allows you to connect devices with a single Ethernet cable without the need for additional power sources. Table 1 lists Ethernet cabling standards.

Table 1: Ethernet Cabling Standards

ETHERNET TYPE	BANDWIDTH	CABLE TYPE	MAXIMUM DISTANCE
10BASE-T	10Mbps	Cat 3/Cat 5 UTP	100m
100BASE-TX	100Mbps	Cat 5 UTP	100m
100BASE-TX	200Mbps	Cat 5 UTP	100m
100BASE-FX	100Mbps	Multi-mode fiber	400m
100BASE-FX	200Mbps	Multi-mode fiber	2Km
1000BASE-T	1Gbps	Cat 5e UTP	100m
1000BASE-TX	1Gbps	Cat 6 UTP	100m
1000BASE-SX	1Gbps	Multi-mode fiber	550m
1000BASE-LX	1Gbps	Single-mode fiber	2Km
10GBASE-T	10Gbps	Cat 6a/Cat 7 UTP	100m
10GBASE-LX	10Gbps	Multi-mode fiber	100m
10GBASE-LX	10Gbps	Single-mode fiber	10Km

Figure 3: Ethernet Switching, Wi-Fi, and PoE

Ethernet and Time Synchronization – Are We in Sync?

As applications continue to advance, latency has become a significant concern that we need to address. The solution to this problem lies in using *Precision Time Protocol* (PTP)^[28, 29], as we are addressing timing accuracy in the range of hundreds of nanoseconds. The use of Ethernet in mission-critical networks and the telecom industry showcases that Ethernet has now emerged as the de facto transport technology, using protocols like PTP to synchronize clocks throughout the network.

To appreciate the significance of PTP, it's important to understand that we're addressing timing accuracy in a range of hundreds of nanoseconds. This problem represents extremely tight timing requirements for certain applications and use cases. Maintaining precise timing is crucial for operating distributed systems at scale while ensuring that various operations remain synchronous. Additionally, precise timing is especially crucial when handling critical processes that govern infrastructure operations.

An excellent example of such systems can be seen in the telecom industry's 5G networks. Coordinating time between multiple servers or base stations in 5G could be compared to synchronized swimming in the Olympics, where all swimmers must perform their part of the routine at the same pace. If they perform at different paces, the routine will not look as it should. Ensuring that all servers and base stations operate in sync is vital for efficient network performance, much like how synchronized swimming relies on all swimmers to perform their parts of the routine at the same pace.

In addition to managing latency, new use cases for Ethernet also require it to become a deterministic networking technology, and as I briefly discussed 5G and PTP previously, *Time-Sensitive Networking* (TSN) comes into play, where PTP is one of the requirements for Ethernet to become a deterministic networking technology.

Ethernet and TSN for Deterministic Networking

Ethernet has evolved to incorporate various applications and technologies. TSN enables the synchronization of network elements and endpoints, such as switches and routers, to prioritize traffic classes and provide accountable delay and guaranteed bandwidth reservation. TSN is based on numerous international standards that are integrated with the Ethernet standard IEEE 802.3, where punctuality is ensured, allowing for transmission within a given period while simultaneously accommodating a mix of other communication protocols.

When discussing use cases and Ethernet, I need to mention *Industry 4.0* needs as the fourth industrial revolution that is transforming the manufacturing industry towards more efficient, connected, and flexible factories of the future. With Industry 4.0, factories will be able to rely on cloud-native technologies and connectivity based on Ethernet and TSN.

The goal of Industry 4.0 is to create full transparency across all processes and assets at all times, including both the *Information Technology* (IT) and *Operational Technology* (OT) domains based on architectures that require communication between production systems, logistics chains, people, and processes to unite these two domains into a single domain.

Ethernet has been used as the wired solution in both computer and automation networks. Ethernet open standard allows you to connect end devices quickly and simply as well as easily scale them to exchange data with other devices and functions. Ethernet was not originally designed to meet the requirements set by automation technology regarding guaranteed and real-time communication. Various bus systems in automation have evolved using Ethernet on a physical level while implementing proprietary real-time protocols such as PROFIBUS, PROFINET, and EtherCAT, to name a few. These systems often lead to the exclusive use of the network infrastructure as well as vendor dependencies. Today such networks handling time-critical data traffic are separated from networks directing less-critical data traffic. In the future, Industry 4.0 applications will require increasingly more consistent Ethernet networks, and TSN will provide a solution for that.

Traditional Ethernet networks involving sectors like manufacturing are based on a hierarchical automation model that separates information technology from operational technology. The IT domain includes enterprise-like communication with typical end devices such as computers, while the OT domain includes systems, machines, and software used for process control and automation. These two areas are fundamentally different in how they communicate, where the IT domain requires bandwidth while the OT domain requires high availability. Data traffic in the IT domain can be classified more as non-critical, while data traffic in the OT domain is critical and time-sensitive, and as such each domain uses a particular communication standard. Ethernet, as we know it in the enterprise or IT domain, relies on TCP/IP, while the OT domain relies on various bus systems, also known as *fieldbus systems*.

In the IT domain today, wireless technologies like Wi-Fi are used and could be used in some parts of the OT domain, but because of the nature of the technology, which is based on unlicensed spectra, it cannot guarantee bounded low latency with high reliability as the load increases. In certain use cases, Wi-Fi does not perform that well during uncontrolled interference because it uses an unlicensed spectrum. That may not be relevant for less-critical applications, because there will be a variety of applications with different traffic profile demands in both the Ethernet-enabled IT and OT domains within Industry 4.0.

Future of Ethernet

Our new world of AI workloads is expected to put unprecedented performance and capacity demands on networks that are based on Ethernet. Hence, we are possibly looking at a new enhancement to the well-known Ethernet technology to handle the scale and speed required by AI.

A group of vendors and operators have teamed to form the *Ultra Ethernet Consortium* (UEC)^[30], as there are concerns that today's traditional network interconnects cannot provide the required performance, scale, and bandwidth to keep up with AI demands. The consortium aims to address these concerns by adding new capabilities to the known and proven Ethernet technology specification, adding numerous new features and capabilities including:

- Multipathing and packet spraying to ensure AI workflows have access to a destination simultaneously.
- Flexible delivery order to make sure Ethernet links are optimally load-balanced while ordering is enforced only when the AI workload requires it in bandwidth-intensive operations.
- Congestion control mechanisms to ensure AI workloads avoid hotspots and spread the load evenly across multipaths within the network. These mechanisms can be designed to work in conjunction with multipath packet spraying, thus enabling a reliable transport of AI traffic.
- End-to-end telemetry to manage congestion, where information originating from the network can advise the participants of the location and cause of the congestion. In addition, shortening the congestion signalling path and providing more information to the endpoints allow more responsive congestion control.

After this journey covering some highlights after Ethernet has enjoyed five decades of existence, one might contend that Ethernet is one of the most crucial technologies today, even though it often goes unnoticed. Ethernet, as the ubiquitous network technology, powers infrastructure across the cosmos as it is used in space as well as in the deepest ocean trenches.

I named just a few examples, including the new era of cloud-native 5G data centers that provide the infrastructure for 5G applications and workloads, the industry revolution (Industry 4.0), as well as the AI challenges. But as we all know, the number of applications being developed that have substantial requirements not only around bandwidth but also latency, etc. is increasing.

This demand requires that the underlying Ethernet transport technologies can cater to such requirements; consequently, 400 GE is a reality today, and 800 GE is expected to become commonplace in the near future. Given this trend, it wouldn't be surprising to see 1-Terabyte Ethernet in use by 2030.

Based on our unending appetite for bandwidth, Ethernet, a 50-year-old technology, will soon reinvent itself once more.

Our Privacy Policy

The *General Data Protection Regulation* (GDPR) is a regulation for data protection and privacy for all individual citizens of the *European Union* (EU) and the *European Economic Area* (EEA). Its implementation in May 2018 led many organizations worldwide to post or update privacy statements regarding how they handle information collected in the course of business. Such statements tend to be long and include carefully crafted legal language. We realize that we may need to provide similar language on our website and in the printed edition, but until such a statement has been developed here is an explanation of how we use any information you have supplied relating to your subscription:

- The mailing list for *The Internet Protocol Journal* (IPJ) is entirely “opt in.” We never have and never will use mailing lists from other organizations for any purpose.
- You may unsubscribe at any time using our online subscription system or by contacting us via e-mail. We will honor any request to remove your name and contact information from our database.
- We will use your contact information only to communicate with you about your subscription; for example, to inform you that a new issue is available, that your subscription needs to be renewed, or that your printed copy has been returned to us as undeliverable by the postal authorities.
- We will never use your contact information for any other purpose or provide the subscription list to any third party other than for the purpose of distributing IPJ by post or by electronic means.
- If you make a donation in support of the journal, your name will be listed on our website and in print unless you tell us otherwise.

Letter to the Editor

Craig Partridge’s “Why ATM Failed” article in *The Internet Protocol Journal*, Volume 26, No 3, December 2023, is excellent. It prompted me to write down a few of my own recollections at the time:

I had thought that it was the work of Sandy Fraser in Bell Labs in 1974 that transformed the *Time Division Multiplexor* (TDM) theory with a label attached to the data segment that identified the now virtual timeslot of each data stream that was the precursor of ATM. My reading on this topic had noted that when this technology was presented to the Bell telephone operating companies as a scalable switching architecture that had far greater flexibility and efficiency than TDM-based architectures in the mid-1980s, the response was positive, and many expected the migration to ATM in the telephone switching fabric to be completed by 2020!

I also recall some material from Dave Sincowski and Bob Lyon from the late 1980s about the early days of ATM. At that time the experience of changing the local network architecture from common-bus 10-Mbps Ethernet to 100-Mbps *Fiber Distributed Data Interface* (FDDI) rings was challenging: It involved large-scale replacement of both the physical network media of the *Local-Area Network* (LAN) and the network interfaces in the attached workstations. The underlying concern was that the next incremental step in LAN speeds would require a similar comprehensive replacement. They were searching for a scalable LAN architecture that could offer increasing capacity without enforced replacement of large parts of the network infrastructure. Bell Lab’s Dave Sincowski proposed ATM to Sun Microsystem’s Bob Lyons as an answer to that problem, as Sun Microsystem’s workstation products had just gone through the Ethernet-to-FDDI NIC transformation. That proposal appears to be why it was the computing sector, not the telephone sector, that was behind the initial adoption of ATM in digital networking.

It wasn’t just the small buffer size in ATM switches that was an issue here for high-speed computer networks, it was the choice of the ATM cell size of 53 bytes that proved to be a problem. The cell size decision was already a compromise between a small cell size that more closely matched the TDM slot size that was ideally suited to low-jitter, low-volume voice data streams and a much larger cell size that reduced the per-cell processing overheads of a higher-speed data stream. Switching equipment initially struggled to achieve switching performance of a 10-Mbps Ethernet with a theoretical maximum packet rate of some 1,440 packets per second, so a smaller cell size would require faster processing capability in the switches.

I also recall at that time extensive debate about the “correct” internal buffer dimensioning for ATM switches. Low-jitter objectives call for very shallow internal buffers, while the congestion-loss algorithms of TCP called for delay-bandwidth-sized internal buffers.

I dimly recall a report on Doug Comer's experiments on achievable throughputs using a 155-Mbps ATM switch where the shallow buffers in ATM switches resulted in an achieved 3-Mbps data throughput from a 155-Mbps switch. The LAN market had already gained extensive experience with Ethernet switching, and ATM simply was not an effective alternative in price and performance for local networks.

Despite these issues, for a while in the early to mid 1990s ATM had some success. I vaguely recall the first 155-Mbps backbone circuits in the US used Fore ATM switches with ATM as the only available technology with a clock that was faster than 45 Mbps.

The telephone companies clung to the dream of a single multipurpose digital switched foundation for a suite of data products. The company I worked for at the time in Australia, Telstra, was using Nortel Magellan Passport ATM switches as the basis for their suite of data products as well as telephone trunks. But it was useful for only a brief period of time. When IP services wanted to use circuit transmission rates in excess of 622 Mbps, the Passport switches could not deliver, and at that point the IP product moved to sit beside the Passports and connect to the *Synchronous Digital Hierarchy* (SDH) network at first, and then directly to optical transponders shortly thereafter.

—Geoff Huston, gih@apnic.net

IAB Statement on Encryption and Mandatory Client-side Scanning of Content

The *Internet Architecture Board* (IAB) recently issued the following statement: “A secure, resilient, and interoperable Internet benefits the public interest and supports human rights^[1] to privacy and freedom of opinion and expression. This is endangered by technologies, such as recent proposals for client-side scanning, that mandate unrestricted access to private content and therefore undermine end-to-end encryption and bear the risk to become a widespread facilitator of surveillance and censorship.

This statement is a reaction to recent policy proposals in the United Kingdom^[2], European Union^[3], United States^[4], and other countries that are mandating client-side scans that require access to otherwise end-to-end encrypted content. These proposals envision client-side scanning technologies that search content on devices before it is encrypted or after decryption on receipt. This would potentially be accomplished by comparison against a database maintained by an authority or by leveraging machine learning to identify previously unseen but potentially prohibited content. These envisioned mechanisms fail to consider their broader implications for Internet security.

The *Internet Engineering Task Force* (IETF) is the leading standards development organization for the global Internet. The IAB provides long-range technical direction for Internet development, ensuring the Internet continues to grow and evolve as a platform for global communication and innovation. To create and maintain the Internet as the bedrock of current secure communication, the IETF and the IAB serve as stewards of the Internet’s communication protocols and its core values of trust, openness, and fairness that underpin secure online communication. This is accomplished through a transparent process backed by consensus that is open for anybody to participate in. We encourage the continued deployment and strengthening of mechanisms that enhance privacy and security for all users of the Internet.

The IETF and the IAB have published concerns about standardizing wiretaps^[5], backdoors^[6,7], and surveillance^[8], because these technologies reduce the security of the Internet as a whole, fail to curtail malicious actors, and reduce security for Internet users. To ensure all communication can remain properly protected, the IETF continues to develop and enhance encrypted protocols like *Internet Protocol Security* (IPsec)^[9] at the IP layer, *Transport Layer Security* (TLS)^[10] at the transport layer which is further incorporated into the *Hypertext Transfer Protocol Version 2* (HTTP/2)^[11] and QUIC^[12] protocols, and inside many application protocols such as email *Secure/Multipurpose Internet Mail Extensions* (S/MIME)^[13], *Open Specification for Pretty Good Privacy* (OpenPGP)^[14] or instant messaging *Messaging Layer Security* (MLS)^[15] and *End-to-End Signing and Object Encryption for the Extensible Messaging and Presence Protocol* (XMPP)^[16]. Recognizing that management of increasingly encrypted networks can pose operational challenges, the IAB has recently held a workshop on techniques for managing encrypted networks in ways that intend not to sacrifice security for the Internet’s end-users^[17].

The IAB has recognized surveillance of any form as a threat to Internet user privacy, where “surveillance is the observation or monitoring of an individual’s communications or activities”^[18]. As the IAB and *Internet Engineering Steering Group* (IESG) documented in 1996^[6], instituting governmental control into communication “provide[s] only a marginal or illusory benefit to law enforcement agencies” as any seemingly beneficial purpose can be equally used by malevolent actors or future authoritarian shifts in government administrations. The IETF community still holds true to these principles today.

For technologies where the intended purpose is scanning of user communication, there is by design no technical way to limit the scope and intent of scanning, nor curtail subsequent changes in scope or intent. Further, specifically when scanning for illegal content, transparency cannot be provided. Mandating such technologies impacts all users of the global Internet and creates a tool that is straightforward to abuse as a widespread facilitator of surveillance and censorship, presenting real-world dangers to the free flow of information and the security and privacy of people. Without privacy, users cannot benefit from the Internet’s virtue to connect people and support freedom of expression.

Additionally, one of the founding principles of the Internet has been its openness; the ability for any standards-compliant software to access the network of networks has been the catalyst for world-changing innovations over many decades. Mandatory use of client-side scanning, and the regulatory burden it would impose, would negatively impact this, restrict use of open-source software, and lead to a stagnant landscape where users lose choice.

The IAB shares concerns about societal harms through the distribution of illegal content and criminal action on the Internet and recognizes the need to protect Internet users from such threats. However, the IAB believes that mandating client-side scanning is in direct opposition to the safe, secure and open communication platform that the Internet provides today and undermines the core principles applied by the IAB and the IETF^[5, 6, 18] in order to secure the Internet through encryption. The IAB opposes technologies that foster surveillance as they weaken the user’s expectations of private communication which decreases the trust in the Internet as the core communication platform of today’s society. Mandatory client-side scanning creates a tool that is straightforward to abuse as a widespread facilitator of surveillance and censorship. Mandating on-device scanning of content will compromise privacy, weaken security, and imperil human rights to communication, freedom of expression and freedom of opinion.”

Achieving Greater Heights for MANRS

The *Global Cyber Alliance* (GCA) recently announced a new phase for *Mutually Agreed Norms for Routing Security* (MANRS)^[0,1]. The *Internet Society* has partnered with the GCA an international non-profit specializing in addressing cybersecurity challenges at scale by mobilizing stakeholders toward collective action. As part of this partnership, the GCA will take on the functions of the MANRS secretariat and operations, while the Internet Society will maintain significant funding, advocacy, and training functions over the next five years.

In 2014, the Internet Society recognized the industry's willingness for collaborative agreement on best practices for routing security and helped initial participants to capture and share those practices in what became MANRS. Since then, the Internet Society has advocated globally for MANRS uptake, encouraged industry collaboration, supported the evolution of the norms, and evolved to become the secretariat of MANRS.

Fast forward a decade, and MANRS has grown from nine original operators to a community of more than 1,000 participants ranging from small enterprise networks to Tier-1 transit providers, from *Internet Exchange Points* (IXPs) of various sizes to *Content Delivery Network* (CDN) and cloud providers publicly professing their commitment to the MANRS requirements. MANRS is now globally recognized as a beacon for securing global routing.

As MANRS matured, so did the community-led governance model with the establishment of the community-elected Steering Committee. The Internet Society has proudly served as the secretariat, in addition to supporting the initiative with both financial and staff resources as well as operations support to ensure MANRS' growth. In 2019 the *MANRS Observatory*, a conformance measurement tool for routing security, was launched. Since then, many new features have been added to the MANRS Observatory, such as alerts and monthly MANRS readiness reports. Growth also happened through capacity building, and over the years, thousands of network engineers have gone through online courses, virtual labs, and on-site workshops. In 2020, the Internet Society, together with the MANRS community, launched the *Mentors and Ambassadors* program promoting routing security in the areas of research, policy, and training.

MANRS has more than one thousand participating operators across three programs, as well as six network equipment vendors. The initiative has been a tremendous success, but the task of supporting MANRS has grown well beyond the scope of what was a startup initiative 10 years ago. This partnership is an important evolution of a successful initiative that the Internet Society launched, incubated, and nurtured. GCA is honored and excited to step into this role and provide the basis for the long-term sustainability and evolution of MANRS.

Routing security is one of the focus areas of GCA, and the Internet Society and GCA have been collaborating around MANRS since 2021 with excellent results. GCA conducted a survey of network operators to learn more about the state of routing security implementation, the level of concern within network operations and business decision-making, and plans for next steps.

The Internet Society is dedicated to improving routing security and ensuring the best future for MANRS. Over the next five years, the Internet Society will focus on funding and support through training and global advocacy activities, while GCA will provide the secretariat function and operate the MANRS Observatory. GCA is uniquely placed to lead the next evolution of MANRS as its focus on building communities to collectively drive action towards addressing cybersecurity challenges at scale allows it to step into this role and provide the best future home for the operational growth MANRS is experiencing.

GCA is committed to maintaining the vision of MANRS and continuing to expand its global impact. With this partnership, MANRS will continue to achieve greater heights and be further established as the globally recognized benchmark for global routing security.

The partnership builds on the strengths of both organizations—GCA’s global footprint of mobilizing communities towards collective action to deliver a secure, trustworthy Internet that enables social and economic progress for all, and the Internet Society’s training and advocacy expertise. Together, the Internet Society and GCA are committed to maintaining and expanding the vision of MANRS to continue to increase the awareness and uptake of MANRS principles and improve the Internet’s functional integrity.

Everyone who runs a network has a responsibility to ensure a globally robust and secure routing infrastructure. Your network’s safety depends on a routing infrastructure that stops bad actors and mitigates accidental misconfigurations that wreak havoc on the Internet. The more network operators work together, the fewer incidents there will be, and the less damage they can do.

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at **ole@protocoljournal.org** or **olejacobsen@me.com**

Internet access by means of *Low Earth Orbit* (LEO) satellites has become very popular in recent years, particularly in rural areas where alternative solutions are limited. We covered this technology in an article in our September 2023 issue (Volume 26, No. 2). The benefits of LEO systems include a much lower cost to launch and place the satellites into a low orbit, and a shorter *Round Trip Time* (RTT) as compared to solutions involving geosynchronous satellites. However, since LEO satellites move across the sky, a complex system of tracking and handoffs is deployed in order to provide continuous connectivity to the end user. In our first article, Geoff Huston examines the performance of Starlink from the point of view of the *Transmission Control Protocol* (TCP).

When I joined the *Network Information Center* (NIC) at SRI International in 1984, I was handed two *Request For Comments* (RFCs) describing the *Domain Name System* (DNS), and I was told that the DNS would soon be deployed across the Internet (mainly known as ARPANET and MILNET at the time). The NIC was still maintaining and publishing a host table in 1984, and it would take a couple of years before the DNS became fully operational. Our second article, also by Geoff Huston, looks at how the DNS has evolved in the last 40 years with various enhancements and extensions. The DNS is still one of the most active areas of work within the *Internet Engineering Task Force* (IETF).

As the Internet has evolved, interest by governments and intergovernmental organizations has grown to legislate and regulate various aspects of the system. These efforts, often collectively referred to as *Internet Governance*, are sometimes developed in ways that do not fully include input from the Internet technical community. One example is the *Global Digital Compact* (GDC) currently being drafted by the United Nations. In our Fragments section you will find a letter from individuals concerned about the latest GDC draft.

Publication of this journal is made possible by the generous support of our donors, supporters, and sponsors. We also depend on your feedback and suggestions. If you would like to comment on, donate to, or sponsor IPJ, please contact us at ipj@protocoljournal.org

A View of Starlink from a Transport Protocol

by Geoff Huston, APNIC

Digital communications systems always represent a collection of design trade-offs. Maximising one characteristic of a system may impair other characteristics, and various communications services may offer different performance characteristics based on the intersection of these design decisions with the physical characteristics of the communications medium. In this article I'll look at the Starlink service^[0,1], and how the *Transmission Control Protocol* (TCP)—the transport-protocol workhorse of the Internet—interacts with the Starlink service.

To start, it's useful to recall a small piece of Newtonian physics from some 340 years ago^[2]. On the surface of the earth, assuming that you are high enough to clear various mountains that may be in the way—and also assuming that the earth has no friction-inducing atmosphere—if you fire a projectile horizontally fast enough it will not return to the earth, but head into space. There is, however, a critical velocity where the projectile will be captured by the earth's gravity and neither fall to ground nor head out into space. That orbital velocity at the surface of the earth is some 40,320 km/sec. The orbital velocity decreases with altitude, and at an altitude of 35,786 km above the surface of the earth the orbital velocity of the projective relative to a point on the surface of the spinning earth is 0 km/sec. This altitude is of a geosynchronous equatorial orbit, where the object appears to sit at a fixed location in the sky.

Geosynchronous Services

Geosynchronous satellites were the favoured approach for the first wave of satellite-based communications services. Each satellite could “cover” an entire hemisphere. If the satellite was on the equatorial plane, then it was at a fixed location in the sky with respect to the earth, allowing the use of large antennas. These antennas could operate at a low signal-to-noise ratio, allowing the signal modulation to use a high density of discrete phase amplitude points, which lifted the capacity of the service. All these advantages have to be offset against the less-favourable aspects of this service.

Consideration of crosstalk interference between adjacent satellites in geosynchronous orbits resulted in international agreements that require a 2° spacing for geosynchronous satellites that use the same frequency, so this orbital slot is a limited resource: it is limited to just 180 spacecraft if they all use K band (18–27 GHz) radio. At any point on the earth there is an upper bound to the signal capacity that can be received (and sent) using geosynchronous services.

It is relatively expensive to place satellites into this orbit because it generally requires three-stage rockets to propel them into this high orbit.

Depending on whether the observer is on the equator directly beneath the satellite or further away from this point, a geosynchronous orbit satellite is between 35,760 and 42,664 km away, so a signal *Round-Trip Time* (RTT) to the satellite and back will be between 238 and 284 ms in terms of signal propagation time. In IP terms, a RTT will be between 477 and 569 ms, and signal encoding and decoding times must be added to that. In addition, the delay for the signal to be passed between the endpoints and the satellite earth station must also be added. In practice, a RTT of around two-thirds of a second (660 ms) for Internet paths that use geosynchronous satellite services is common.

This extended latency means that the endpoints need to use large buffers to hold a copy of all the unacknowledged data, as is required by the TCP protocol. TCP is a feedback-governed protocol that uses ACK pacing. The longer the RTT the greater the lag in feedback, and the slower the response from endpoints to congestion or to available capacity. The congestion considerations lead to the common use of large buffers in the systems that drive the satellite circuits, which can further exacerbate congestion-induced instability. In geosynchronous service contexts, the individual TCP sessions are more prone to instability and they experience longer recovery times following low events^[3].

Low Earth Orbit Systems

A response to this situation is to bring the satellite closer to earth. This approach has several benefits. The spinning iron core of the earth generates a magnetic field, which traps energetic charged solar particles and redirects them through what is called the *Van Allen Belt*, thus deflecting solar radiation. Not only does this deflection allow the earth to retain its atmosphere, but it also protects the electronics of orbiting satellites that use an orbital altitude below 2,000 km or so from the worst effects of solar radiation. It's far cheaper to launch satellites into a *Low Earth Orbit* (LEO), and these days SpaceX can do so using reusable rocket boosters. The reduced distance between the earth and the orbiting satellite reduces the latency in sending a signal to the satellite and back, which can improve the efficiency of the end-to-end packet-transport protocols using such satellite circuits.

This group of orbital altitudes, from some 160 to 2,000 km, are collectively termed LEOs^[4]. The objective is to keep the orbit of the satellite high enough to prevent its slowing down by grazing the denser parts of the earth's ionosphere, but not so high that it loses the radiation protection afforded by the Inner Van Allen belt. At a height of 550 km, the minimum signal propagation delay to reach the satellite and return to the surface of the earth is just 3.7 ms.

But all of these facts come with some different issues. At a height of 550 km, an orbiting satellite can be seen from only a small part of the earth. If the minimum effective elevation to establish communication is 25 degrees of elevation above the horizon, then the footprint of the satellite is a circle with a radius of 940 km, or a circle of area 2M km².

To provide continuous service to any point on the surface of the earth (510.1M km^2), the number of orbiting satellites must be a minimum of 500. This reality implies that a satellite-based service is not a simple case of sending a signal to a fixed point in the sky and having that single satellite mirror that signal down to some outer earth location. A continuous LEO satellite service must use a continual sequence of satellites as they pass overhead and switch the circuit path across to successive satellites as they come into view.

At this altitude, the satellite orbits with a relative speed of 27,000 km/hour and it passes across the sky from horizon to horizon in less than 5 minutes. Some implications for the design of the radio component of the service are evident. The satellites are close enough that there is no need to use larger dish antennas that require some mechanised steering arrangement, but this situation itself is not without its downsides. An individual signal carrier might be initially received as a weak signal (in relative terms), increase in strength as the satellite transponder and the earth antenna move into alignment, and weaken again as the satellite moves on. Starlink's services use a phased-array arrangement with a grid of smaller antennas on a planar surface, which allows the antennas to be electronically steered by altering the phase difference between each of the antennas in the grid. Even so, this arrangement is relatively coarse, so the signal quality is not consistent, implying a constantly variable signal-to-noise ratio as the phased-array antenna tracks each satellite.

The modulation of this signal uses adaptive phase amplitude modulation, and as the signal-to-noise level improves, the modulator can use a larger number of discrete code points in this phase amplitude space, thus increasing the effective capacity of the service even while using a constant-frequency carrier signal. The implication is that if the satellite service attempts to always operate at peak efficiency, then it must constantly adapt its signal modulation to take advantage of the instantaneous signal-to-noise ratio, which results in a constantly varying service capacity.

Now we have four major contributory factors for variability of the capacity of the Starlink service, namely the variance in signal modulation capability, which is a direct outcome of the variable signal-to-noise ratio of the signal, the variance in the satellite path latency due to the relative motion of the satellite and the earth antennas, and the need to perform satellite switching constantly, and the variability induced by sharing the common medium with other users.

One way to see how this variability affects the service characteristics is to use a capacity measurement tool to measure the service capacity regularly. The results of such regularity of testing are shown in Figure 1. Here the test is a Speedtest measurement test^[5], performed on a 4-hourly basis for the period January 2024 through March 2024.

The service appears to have a median value of around 120 Mbps of download capacity, with individual measurements reading as high as 370 Mbps and as low as 10 Mbps, and 15 Mbps of upload capacity, with variance of between 5 and 50 Mbps.

Figure 1: Starlink Performance

In Internet terms, *ping*^[6] is a very old tool. However, at the same time it is very useful which probably explains its longevity. Figure 2 shows a plot of a continuous (flood) *ping* across a Starlink connection from the customer-side terminal to the first IP endpoint behind the Starlink earth station.

The first major characteristic of this data is that the minimum latency changes every 15 seconds. It appears that this change correlates to the user's being assigned to a different satellite, which implies that the user equipment "tracks" each spacecraft for 15-second intervals. This period corresponds to a tracking angle of 11 degrees of arc.

The second characteristic is that loss events are seen to occur at times of switchover between satellites (as shown in Figure 3), as well as occurring less frequently as a result of obstruction, signal quality, or congestion.

Figure 2: Starlink Ping Profile

Figure 3: Starlink Ping Profile Showing Satellite Handover

The third characteristic is a major shift in latency when the user is assigned to a different spacecraft. The worst case in this data set is a shift from a minimum of 20 ms to a minimum of 40 ms.

Finally, within each satellite tracking interval the latency variation is relatively high. The average variation of jitter over successive RTT intervals is 6.7 ms. The latency spikes at handover impose an additional 30 to 50 ms, indicating the presence of deep buffers in the system to accommodate the transient issues associated with satellite handover (Figure 4).

Figure 4: Starlink Ping Profile Showing Latency Variance

The overall packet-loss rate when measured using 1-second paced *pings* over an extended period is a little over 1% as a long-term average loss rate.

TCP Protocol Performance

TCP^[7] is an instance of a sliding window positive acknowledgement protocol. The sender maintains a local copy of all data that has been passed into the communications systems and discards that data only when it has received a positive acknowledgement from the receiver.

Variants to TCP are based on the variations in the sender's control of the rate of passing data into the network and variations in the response to data loss. The classic version of TCP is one that uses a linear inflation of the sending window size while there is no loss, and halves the window in response to loss.

The algorithm is called the RENO TCP control algorithm. Its use in today's Internet has been largely supplanted by the CUBIC TCP control algorithm^[8], which uses a varying window inflation rate that attempts to stabilise the sending rate at a level just below a level that causes the buildup of network queues, which ultimately leads to packet loss.

In general terms, there is a small set of common assumptions about the characteristics of the network path for such control algorithms:

- There is a *stable* maximal capacity of the path, where the term stability describes a situation where the available path capacity is relatively constant across a number of RTT intervals.
- The amount of *jitter* (variation in end-to-end delay) is low in proportion to the RTT.
- The average packet-loss rate is low. In the case of congestion-based loss, the TCP control algorithm generally interprets packet loss as a sign that the network buffers have filled and the loss is an indication of buffer overflow.

Obviously, as we've noted, the first two conditions do not hold for end-to-end paths that include a Starlink component. The loss profile is also different. There is the potential for congestion-induced packet loss, as is the case in any non-synchronous packet-switched medium, but an additional loss component can occur during satellite handover, and other impairments can further affect the radio signal.

TCP tends to react to such environments by using conservative choices.

The RTT estimate is a smoothed average value of RTT measurements to which is added the mean deviation of individual measurements from this average. For Starlink, with its relatively high level of individual variance in RTT measurements, this estimate means that the TCP sender may operate with a RTT estimate that is too high, which in turn will result in a sending rate that is lower than the available end-to-end capacity of the system.

The occurrence of non-congestion-based loss can also detract from TCP performance. Conventionally, loss will cause the sender to quickly reduce its sending window on the basis that if this loss is caused by network buffer overflow, then the sender needs to allow these buffers to drain. The sender will then resume sending at a lower rate, which should restore coherency of the feedback control loop.

How does this mechanism work in practice?

Figure 5 shows a detailed view of a TCP CUBIC session over a Starlink circuit. The initial 2 seconds show the *slow start* TCP sending rate inflation, where the sending window doubles in size for each RTT interval, reaching a peak of 250 Mbps in 2 seconds. The sender then switches to a rapid reduction of the sending window in the next second, dropping to 50 Mbps within 1 second.

At this point the CUBIC congestion-avoidance phase appears to kick in, and the sending rate increases to 70 Mbps over the ensuing 5 seconds. A single loss event occurs that causes the sending rate to drop back to 40 Mbps in second 8. The remainder of the trace shows this same behaviour of slow sending rate inflation and intermittent rate reductions that are typical of CUBIC.

This CUBIC session managed an average transfer rate of some 45 Mbps, which is well below the peak circuit capacity of 250 Mps.

Figure 5: TCP CUBIC Over Starlink

Starlink is a shared medium, and the performance of the system in local times of light use (off peak) is significantly different from that of performance in peak times. Figure 6 shows the CUBIC performance profile during an off-peak time.

The difference between the achievable throughput between peak and off-peak times is quite significant, with the off-peak performance reaching a throughput level some 3 to 4 times greater than the peak-load performance. The slow-start phase increased the throughput to some 200 Mbps within the first second. The flow then oscillated for a second, then started a more stable congestion-avoidance behaviour by second 4. The CUBIC window inflation behaviour is visible up to second 12 and then the flow oscillates around some 200 Mbps of throughput.

Figure 6: TCP CUBIC Over Starlink – Off-Peak

Is the difference between these two profiles in Figures 5 and 6 a result of active flow management by Starlink equipment, or the result of the way in which CUBIC reaches a flow equilibrium with other concurrent flows?

We can attempt to answer this question by using a different TCP control protocol that has a completely different response to contention with other concurrent flows.

The *Bottleneck Bandwidth and Round-trip propagation time* (BBR)^[9] is a TCP congestion-control algorithm developed at Google a decade ago. BBR attempts to position the TCP flow at the onset of network queue formation rather than oscillating between full and empty queue states (as is the case in loss-based congestion-control algorithms).

Briefly, BBR makes an initial estimate of the delay-bandwidth product of the network path, and then drives the sender to send at this rate for 6 successive RTT intervals. It performs repair for dropped packets without adjusting its sending rate. The 7th RTT interval sees the sending rate increase by 25%, and the end-to-end delay is carefully measured in this interval. The final RTT interval in the cycle sees the sending rate drop by 25% from the original rate, intended to drain any network queues that may have formed in the previous RTT interval. If the end-to-end delay increases in the inflate interval, the original sending rate is maintained.

If the increased sending window does not impact the end-to-end delay, it indicates that the network path has further capacity and the delay-bandwidth estimate is increased for the next 8-RTT cycle. (There have been a couple of subsequent revisions to the BBR protocol, but in this case, I'm using the original (v1) version of BBR.)

Figure 7 shows the results of a Starlink performance test using BBR.

Figure 7: TCP BBR Over Starlink

In this case, BBR has made an initial estimate of some 250 Mbps for the path bandwidth. This estimate appears to have been revised at second 14 to 350 Mbps, and then dropped to 200 Mbps 15 seconds later for the final 10 seconds of this test. It is likely that these changes are the result of BBR responding to satellite handover in Starlink.

The same BBR test was performed in an off-peak time and had a very similar outcome (Figure 8 on the following page).

If BBR is sensitive to changes in latency, and latency is so variable in Starlink, then why does BBR perform so well?

I suspect that here BBR is not taking a single latency measurement, but measuring the RTT for all packets that are sent in this 7th RTT interval, and using the minimum RTT value as the “loaded” RTT value to determine whether to perform a send-rate adjustment. As long as the minimum RTT levels are consistent, and they—as shown in Figure 3—are consistent across each 15-second scheduling interval, then BBR will set its sending rate close to the maximum sending rate that Starlink supports.

Figure 8: TCP BBR Over Starlink – Off-Peak

Protocol Tuning for Starlink

Could you tune a variant of TCP to optimise its performance over a path that includes a Starlink component?

A promising approach would appear to be a variant of BBR. The reason for the choice of BBR is its ability to maintain its sending rate in the face of individual packet-loss events. Starlink performs a satellite handover at regular 15-second intervals. If the regular sending-rate inflation in BBR occurs at the same time as scheduled satellite handover, the BBR sender could defer its rate inflation, maintaining its current sending rate across the scheduled handover.

The issue with BBR is that, for version 1 of this protocol, it is quite aggressive in claiming network resources, and this aggression can starve other concurrent sessions of capacity. One possible response is to use the same 15-second satellite handover timer with version 3 of the BBR protocol, which is intended to be less aggressive when working with concurrent data flows.

In theory, it would be possible to adjust CUBIC in a similar manner, performing a lost packet repair using *Selective Acknowledgement* (SACK)^[10] if the packet loss occurred at the time of a scheduled satellite handover. While CUBIC is a fairer protocol with respect to sharing the path capacity with other concurrent sessions, it tends to react conservatively when faced with high jitter paths. Even with some sensitivity to scheduled satellite handovers, CUBIC is still prone to reduced efficiency in the use of network resources.

DNS Evolution

by Geoff Huston, APNIC

The *Domain Name System* (DNS) is a crucial part of today's Internet. With the fracturing of network address space as a byproduct of IPv4 address rundown and the protracted IPv6 transition, the namespace of the Internet is now the defining attribute that makes it one network. However, the DNS is not a rigid and unchanging technology. It has changed considerably over the lifetime of the Internet, and here I'd like to look at what has changed and what has remained the same.

The Early DNS

The early Internet architecture used names as a convenient alias for an IP address. Each host used a local list of name and address pairs, and an application would look up the name in this file (**hosts.txt**) and use the associated address in the subsequent packet exchange. In many ways, this file was a direct analogy to the telephone directory in a telephone network.

This simple framework has one major drawback: *scalability*. As the number of connected hosts on the network increased, the burden of distributing updated copies of the name file increased and the task of maintaining loose coherence across all these local copies of this file became more challenging. The document IEN 61^[1], describing an *Internet Name Server*, was released in 1978, and it appears to be a basic predecessor of today's DNS.

Some five years later, in 1983, RFC 882^[2] defined a hierarchical namespace using a tree-structure name hierarchy. It also defined a name server as a service that holds information about a part of the name hierarchy, and also refers to other name servers that hold information about lower parts of the name hierarchy. The document also defined a resolver that can resolve names into their stored attributes by following referrals to find the appropriate name server to query, and then obtaining this information from the server. RFC 883^[3] defined the DNS query and response protocol, a simple stateless protocol.

And that's about it.

Most of what is in today's DNS was defined in these early specifications, and what we've been doing over the intervening forty years has been filling in the details. The DNS has not really changed in any substantive manner over the intervening period.

Evolutionary Pressures

However, I think that such a perspective ignores a large body of refinement in the DNS world that has occurred. The DNS is by no means perfect; it can be extremely slow to resolve a name, and even slower to incorporate changes into the distributed data framework.

The resolution of DNS queries pays scant regard to concerns about user privacy, and any party who can observe a user's DNS query stream can readily piece together an accurate picture of the user's activities. The distributed stateless method used to resolve names is prone to various efforts to eavesdrop DNS transactions and manipulate the information being provided in DNS responses. The DNS cannot easily protect itself from disruptive attack and has been regularly used in highly effective denial-of-service attacks. It's also insecure, in that a client cannot verify the authenticity and currency of a response.

The operation of the DNS in resolving a name can be extremely opaque. The use of parallel servers and resolvers to improve the resilience of the DNS creates combinatorial explosion in the number of paths that can be used to navigate through the distributed data structure. It is not possible to tell in advance which servers may be used in the resolution of a query, or the number of additional queries a single original query may trigger. Given that resolvers can respond directly to a query with a locally cached response, it is not possible to tell in advance where the response will come from, or if the response is authentic.

For a common and fundamental service that every user not only uses, but implicitly relies upon, the DNS in practice is far from a paragon of sound operational engineering.

The evolutionary efforts have been intended to remedy some of these shortcomings, with goals to improve the speed of DNS resolution, improve aspects of privacy of DNS transactions, increase the level of trust in DNS responses, and resist efforts to subvert the integrity of DNS name-resolution transactions.

DNS Privacy

The DNS is not what you might call a discrete protocol. By default, queries are made in the clear. The IP addresses of the querier, the server being queried, and the name being queried are visible to any party that is in a position to inspect DNS traffic. These parties include not only potential eavesdroppers in the network, but also the operating system platform that hosts the application making the DNS query, the recursive resolver that receives the query, and any forwarding agent that the recursive resolver uses. Depending on the state of the local cache in the recursive resolver, the recursive resolver may need to perform some level of top-down navigation through the nameserver hierarchy, asking an authoritative server at each level the full original query name. The recursive resolver normally lists itself as the source of these queries, so the identity of the original user is occluded, but the query name is still visible.

RFC 7858 provides a specification for DNS over a *Transport Layer Security* (TLS) session (DoT)^[4]. This specification allows the client and server to securely set up a shared session key that is then used to encrypt all subsequent transactions between the two parties. TLS can also be used to authenticate the server name in order to assure the client that it is connecting to an instance of the named server.

There is some overhead to setting up a TLS session, and the most efficient use of this approach is in the stub-to-recursive DNS environment where a single TLS session can be kept open and reused for subsequent queries, amortizing the initial setup overheads across these queries. The standard specification of DoT defines the use of TCP port 853, which allows an onlooker to identify that DoT is being used and identify the two end parties by their IP addresses, but not the DNS queries or responses.

Subsequent standards work has defined *DNS over QUIC* (DoQ), RFC 9250^[5]. The encryption that QUIC provides has properties similar to those that TLS provides, while QUIC transport eliminates the head-of-line blocking issues inherent with TCP and provides more efficient packet-loss recovery than *User Datagram Protocol* (UDP).

In addition, it is possible to add a *Hypertext Transfer Protocol* (HTTP) wrapper to the DNS data object, defining *DNS over HTTPS* (DoH), RFC 8484^[6]. DoH uses port 443, using either TCP in the case of HTTP/2 or UDP with the QUIC-based HTTP/3, so the DNS transactions would be largely indistinguishable from Web traffic. HTTP adds its own ability to perform object caching, redirection, proxying, authentication, and compression beyond that provided in the conventional DNS model, although the use of such HTTP capabilities in the DNS context is not well understood. HTTP also allows a server to push content to a client. In the DoH scenario this possibility could permit the use of queryless DNS, where the server pushes DNS responses to a client without any initial triggering DNS query.

In these approaches to encrypted transport for the DNS, the remote server is aware of the client's IP address and the queries that the client is making. In the stub-to-recursive scenario, this awareness allows the recursive resolver to be privy to the user's DNS actions, even when the network path between the two parties is secure. A stronger level of privacy is obtained by using *Oblivious DNS over HTTPS*, RFC 9230^[7], where no single DNS server is simultaneously aware of the client's IP address and the content of the DNS queries. Here a double level of encryption is used in conjunction with two independent agents within the network. The client sends an encrypted DNS query to the first proxy using DoH. This proxy is aware of the client's IP identity, but is not able to decrypt the DNS query. The proxy makes its own query using the encrypted query to a separate target, again using DoH, but this time there is no record of the original client. The target can decrypt the query and function as a conventional recursive resolver.

These four specifications show that it is possible to cloak DNS transactions within a secure veil of secrecy, but it remains a topic of speculation as to the extent of uptake of these technologies. Encrypted transport sessions impose higher costs on the operation of DNS infrastructure (recursive resolvers and authoritative servers), and it is unclear how the current DNS economic models, where individual DNS queries are essentially unfunded by the client, can absorb these higher costs.

An entirely different approach to improving DNS privacy is described in DNS *Query Name Minimisation*, RFC 7816^[8]. The observation is that as a recursive resolver navigates its path through the DNS hierarchy, it uses the original query name to query authoritative name servers, essentially sharing the knowledge of the name being queried with a set of servers. The rationale for this approach is that the client does not necessarily know where a zone cut may exist in advance. Query Name Minimisation proposes to minimise the amount of information being disclosed to authoritative name servers by sending a request to the nameserver authoritative for the closest known ancestor of the original query name, and asking for a *Name Server* (NS) delegation record rather than the original query type. This approach does not impose additional overheads on DNS server infrastructure. It does not offer channel security, but it does limit the amount of information “leakage” that is a feature of the DNS name-resolution process.

On a more general level, none of these DNS privacy measures can assure users of the authenticity of the DNS response that they receive. These measures limit the ability of other parties to eavesdrop on DNS queries and responses, but detecting (and presumably rejecting) DNS responses that are inauthentic is a separate issue for the DNS.

DNS Authenticity – DNSSEC

Domain Name System Security Extensions (DNSSEC) is an extension to the DNS that associates a cryptographically-generated digital signature with each record in a DNSSEC-signed zone, specified in RFC 4033^[9]. DNSSEC does not change the DNS namespace, nor the DNS name-resolution protocol. Clients who are aware of DNSSEC can request that a DNS response should include a DNSSEC signature, if one is available for the zone, and may then validate the response using that signature.

You might think that a tool that allows the client to verify a DNS response would be immediately popular. If the relationship between the names that applications use and services and IP addresses that are used at the protocol level is disrupted, then users can be readily deceived. Yet, after close to three decades from its initial specification, DNSSEC is still struggling to achieve mainstream adoption. Part of the issue is that the strong binding of the DNS protocol to a UDP transport causes a set of problems when responses bloat in size because of attached signatures and keys. Another part of the issue lies in the care and attention required to manage cryptographic keys and the unforgiving nature of cryptographic validation. And a large part of the problem is that when the Web began using TLS as a means of verifying the identity of a remote server, many didn’t consider any marginal incremental benefit of DNSSEC in the DNS part of session creation to be worth the incremental effort and cost of using DNSSEC.

For these reasons DNSSEC continues in the DNS environment as a “work in progress.”

Evolution of Query Mechanisms

The base DNS specification uses a limited repertoire, where queries contain a query name and a query type, and, if carried over the UDP, DNS responses are limited to 512 bytes in length. The restrictions in the size of several flag fields, return codes, and label types available in the basic DNS protocol were hindering the development of DNSSEC. The chosen path to resolve this dilemma was to use a so-called *Pseudo Resource Record*, the OPT (for “options”) record that is included in the additional data section of a DNS message. To ensure backward compatibility, a responder does not use the OPT record unless it was present in the query. This is the general *Extension Mechanism for DNS*, or EDNS^[10].

EDNS options have been used so far to support DNSSEC functions, padding, TCP keepalive settings, and Client Subnet fields. It has also been used to extend the maximum size of UDP messages in the DNS by using a EDNS Buffer Size.

It is often desirable to separate the name of a service and the location of the service platform that delivers the service, and service record type that was intended to achieve that outcome. *Service Records*, or SRV records, can provide that form of flexibility, where the service is defined by a host name, a port identifier, and a protocol identifier, and the associated resource record provides the TCP or UDP port number and the canonical service name of the target service platform. Multiple service targets can be specified with an associated preference for use. The functional shift in the use of the SRV record was loading the DNS query with a service profile rather than a plain domain name, and in return receiving enough information to enable the user to then connect to the desired service without making further DNS queries.

This functional shift was further extended in the *Service Binding and Parameter Specification via the DNS* (SVCB and HTTPS Resource Records) specification, RFC 9460^[11]. By providing more information to the client before it attempts to establish a connection, these records offer potential benefits to both performance and privacy. These enhancements represent a shift in the design approach of the DNS, where the prior use of DNS resource record types was to segment the information associated with a DNS name, so that a complete collection of information about a service name was obtained by making a set of queries. The SVCB record effectively provides an “omnibus” response to a service query, so that the client can gather sufficient information to connect to a service with a single DNS transaction.

Delegation Records

One of the fundamental parts of the DNS data structure is the *delegation record*, which passes the control of an entire subtree in the DNS hierarchy from one node to another.

While this NS record has served the DNS since its inception, it has a few limitations. The target of the delegation record is one or more DNS server names, not their IP addresses.

Conventionally the IP addresses are provided as “glue records” contained in the *Additional Section* of a DNS referral response. However, the veracity of such glue records cannot be established, and this weakness has been the focal point of numerous DNS attacks over the years. The target of a NS record cannot be a CNAME alias. The NS record is shared across both the parent and child zones, and the child zone is deemed to be authoritative for this record. The implication is that while the parent-zone name servers can (and must) respond with referral responses with this NS record, it cannot provide a DNSSEC-signed response. It is not possible to provide a DNS service profile in a referral response. If the zone authoritative servers can be accessed using an encrypted transport protocol, this capability cannot be signalled by the NS record.

Work is underway in the *Internet Engineering Task Force* (IETF) in the *DNS Delegation* (deleg) Working Group to take the existing specification of service binding mapping for DNS servers, RFC 9461^[12], and see how it could be used as a more flexible delegation record that addresses some or all of these identified shortcomings in the existing NS form of delegation.

Alternate Name Systems

The Internet protocol suite can be regarded as a collection of elements, including addressing, routing, forwarding, and naming, and it's possible to substitute a different technology for one element without necessarily impacting the others. For example, the transition from IP version 4 to IP version 6 in the addressing realm does not necessitate any fundamental changes to routing, forwarding, or naming. The same can be said of the DNS name system. Alternate name systems can be used and to some extent they can coexist with the DNS.

In the traditional model of DNS resolution, users have little control over their DNS settings. Some technically literate users may choose settings that differ from the defaults, but there has been little incentive to do so, and the vast majority of users have their DNS settings configured for them by administrators via a protocol such as the *Dynamic Host Configuration Protocol* (DHCP).

Many alternative naming systems in use today come bundled with the specific applications that use them: a particular alternative naming system is often tied to a corresponding application, and this application often bypasses administrator-controlled settings and any preconfigured DNS settings. For example, the *Tor Project* uses its own naming system that bypasses traditional DNS resolution. Users can install the *Tor Browser*, and it will use the Tor naming system for names ending in **.ONION**, while forwarding any other names to the local DNS library. The application developer makes the choice of which naming system to use without users even knowing that they are using an alternative naming system, nor do they understand potential implications.

Various forms of experimentation have used decentralised models that eschew a single name hierarchy and allow individual names to exist in an unstructured flat namespace. The underlying registry framework that associates a name with an “owner” has often relied on some blockchain-like approach, where the association of a name and a public-key value is placed into the blockchain. Numerous such alternate name systems exist today, including the *Ethereum Name Service* (ENS), which uses so-called “smart contracts” in its blockchain, and *Unstoppable Domains*, which uses a blockchain platform but operates the namespace as a centrally operated space. The *GNU Name System* (GNS) is also a decentralised platform that offers name persistence, but it has no concept of a root zone. Instead GNS uses the concept of a “start zone” that is configured locally and determines where to begin resolution. Since local users have complete control over their own start zone, every GNS user can potentially use a different namespace. Thus, there is no guarantee that names will be globally unique, or that a given name will resolve the same for different users. The only guarantee is that users with the same start zone will have the same view of the namespace. Every unique start zone defines its own namespace. This scenario is similar in practice to DNS resolution using different root zones. The key innovation in GNS is to replace a search hierarchy with a distributed hash table that can include links to other hash tables.

Such alternate name systems interact with the existing DNS-defined namespace in a variety of ways. Some attempt to coexist with the DNS with the alternate names being some form of extension to the DNS namespace, potentially using a different name-resolution protocol. Other systems are completely self-contained and make no effort to coexist with the DNS. This situation is more commonly seen in an application-specific context where the application environment is exclusively associated with an alternate namespace.

Conclusions

Only a completely moribund technology is impervious to change! As digital technologies and services evolve, the demands placed on the associated namespaces also evolve in novel and unpredictable ways.

The DNS is an interesting case in that so far it has been able to respond to the evolving Internet without requiring fundamental changes to the structure of its namespace, the distributed information model, or the name-resolution protocol. Most of the evolutionary changes that have been folded into the DNS to date have been undertaken in a way that preserves backward compatibility, and the cohesion of the underlying namespace has been largely preserved.

However, maintaining this cohesion across the Internet is not an assured outcome for the future. The pressures to impose barriers to the access to content at national and regional levels are often expressed by imposing selective barriers to the resolution of content service names, and the DNS is left carrying the burden of supporting such selective fragmentation in the Internet.

The camel has undeniably poked its nose into the tent of name coherence in the form of EDNS *Client Subnet*^[13], where the response given to a query may be dependent on who is querying, as much as the name that is being used in the query, and it's likely that this more qualified and fragmented model of a namespace will persist and support an increasingly fragmented Internet.

An Open Letter to the United Nations

1 July 2024

Secretary-General António Guterres
and Envoy on Technology Amandeep Singh Gill,

Since its inception more than fifty years ago, the Internet's technical architecture has evolved and been collaboratively maintained through multistakeholder processes. While it was born in government laboratories, the Internet became a network of networks that kept expanding and required continuous work. Much of that was coordinated in the *Internet Engineering Task Force* (IETF)^[1], an open, consensus-based, bottom-up, voluntary and global standards body.

More than thirty-five years ago, the World Wide Web was born in the laboratories of CERN. It, too, quickly evolved into a global public tool, maintained and developed by a collaboration of like-minded engineers and other stakeholders at the *World Wide Web Consortium* (W3C)^[2]. It, too, is an open, bottom-up, consensus-driven, voluntary and global standards body.

The success of both IETF's and W3C's work can be measured by where the Internet is today and what it has achieved: global communication has flourished, bringing education, entertainment, information, connectivity and commerce to most of the world's population. The Internet has been a catalyst for advancing development. These communities and the way they have structured themselves have paid off.

We recognize that governments take seriously their responsibility to protect their citizens. So, as harms associated with the Internet and the Web become more apparent, there is a desire on the part of governments to act through regulation and legislation. Technical architecture can enable and influence how the Internet is used, but on its own it cannot address abuse, misinformation, inequality, or many other issues. There is nevertheless a potential danger in regulation and legislation, if it undermines the fundamentally empowering nature of the Internet.

The Internet is an unusual technology because it is fundamentally distributed. It is built up from all of the participating networks. Each network participates for its own reasons according to its own needs and priorities. And this means, necessarily, that there is no center of control on the Internet. This feature is an essential property of the Internet, and not an accident. Yet over the past few years we have noticed a willingness to address issues on the Internet and Web by attempting to insert a hierarchical model of governance over technical matters. Such proposals concern us because they represent an erosion of the basic architecture.

In particular, some proposals for the *Global Digital Compact* (GDC)^[3] can be read to mandate more centralized governance. If the final document contains such language, we believe it will be detrimental to not only the Internet and the Web, but also to the world's economies and societies.

Furthermore, we note that the GDC is being developed in a multi-lateral process between states, with very limited application of the open, inclusive and consensus-driven methods by which the Internet and Web have been developed to date. Beyond some high-level consultations, non-government stakeholders (including Internet technical standards bodies and the broader technical community) have had only weak ways to participate in the GDC process. We are concerned that the document will be largely a creation only of governments, disconnected from the Internet and the Web as people all over the world currently experience them.

Therefore, we ask that member states, the Secretary-General and the Tech Envoy seek to ensure that proposals for digital governance remain consistent with the enormously successful multistakeholder Internet governance practice that has brought us the Internet of today. Government engagement in digital and Internet governance is needed to deal with many abuses of this global system but it is our common responsibility to uphold the bottom-up, collaborative and inclusive model of Internet governance that has served the world for the past half century.

Signed,

Call for Papers: IAB Workshop on AI-Control

The *Internet Architecture Board* (IAB) is planning a workshop to explore practical opt-out mechanisms for *Artificial Intelligence* (AI), and build an understanding of use cases, requirements, and other considerations in this space. The workshop will be held in September 2024 in the Washington, DC area. Exact dates and location to be confirmed soon. The deadline for submissions is August 2nd, 2024 and invitations will be issued by August 15th, 2024.

Large Language Models (LLM) and other machine learning techniques require voluminous input data, and one common source of such data is the Internet—usually, “crawling” Web sites for publicly available content, much in the same way that search engines crawl the Web. This similarity has led to an emerging practice of allowing the *Robots Exclusion Protocol*, defined in RFC 9309, to control the behavior of AI-oriented crawlers.

This emerging practice raises many design and operational questions. It is not yet clear whether **robots.txt** (the mechanism specified by RFC 9309) is well-suited to controlling AI crawlers. A content creator or host may not be able to distinguish a crawler used for search indexing from a crawler used for LLM ingest—and indeed some crawlers may be used for both purposes. Potential use cases may extend across many different units of content, policies to be signaled, and types of content creators. Before **robots.txt** becomes a de facto solution to AI crawling opt-out, it is necessary to examine whether it is an appropriate mechanism: in particular, whether the creator of a particular unit of content can realistically and fully exercise their right to opt-out, and the scope of data ingest to which that opt-out applies.

This workshop aims to explore practical opt-out mechanisms for AI, and build an understanding of use cases, requirements, and other considerations in this space. It will focus on mechanisms to communicate the opt-out choice and their associated data models. Technical enforcement of opt-out signals is not in scope. The IAB is looking for short position papers on the following topics; however, this list is non-exhaustive and should be interpreted broadly:

- User stories, use cases, and requirements for opting content out of inclusion in large language models, from a variety of sources including but not limited to the Web
- Interactions between opt-out mechanisms and different use cases for AI
- Advantages and/or deficiencies of reusing robots.txt for controlling AI crawlers on the Web
- Comparisons of use cases for crawling opt-out
- Desired properties of an AI opt-out mechanism
- Potential developments in AI that may require adjustments in opt-out mechanisms
- Implications of legal/policy frameworks (for example, copyright, privacy, research ethics) and requirements on the design of opt-out mechanisms
- Evolution of opt-out signals

Because **robots.txt** is emerging as a solution in this space, the discussion will be anchored on it as a starting point, but not limited to that mechanism. Proposals for alternative solutions may be made, but time will not be available for a detailed presentation or discussion.

Interested participants are invited to submit position papers on the workshop topics. Participants can choose their preferred format, including Internet-Drafts, text- or Word-based documents, or papers formatted similar as used by academic publication venues. Submission as PDF is preferred. Paper size is not limited, but brevity is encouraged. By default, submissions that are considered relevant will be published on the workshop website. If you wish for your submission to be anonymous or withheld from such publication, please indicate that clearly in the submission. The organizers will issue invitations based on the submissions received. Sessions will be organized according to the submissions received, and not every accepted submission or invited attendee will have an opportunity to present; the intent is to foster an active discussion and not simply to have a sequence of presentations.

Discussion at the workshop will be held under *Chatham House Rule*, and therefore will not be recorded or minuted. However, a workshop report will be published afterwards.

It is anticipated that the workshop report will include:

- A list of participants (unless they request to be withheld)
- Documentation of use cases and requirements discussed
- Recommendations for IETF standards work to be considered (if any)
- Recommendations for non-IETF standards work to be considered (if any)

The workshop will be by invitation only. Those wishing to attend should submit a position paper to ai-control-workshop-pc@iab.org. Position papers from those not planning to attend the workshop themselves are also encouraged. Feel free to contact the Program Committee with any further questions: ai-control-workshop-pc@iab.org.

Our Privacy Policy

The *General Data Protection Regulation* (GDPR) is a regulation for data protection and privacy for all individual citizens of the *European Union* (EU) and the *European Economic Area* (EEA). Its implementation in May 2018 led many organizations worldwide to post or update privacy statements regarding how they handle information collected in the course of business. Such statements tend to be long and include carefully crafted legal language. We realize that we may need to provide similar language on our website and in the printed edition, but until such a statement has been developed here is an explanation of how we use any information you have supplied relating to your subscription:

- The mailing list for *The Internet Protocol Journal* (IPJ) is entirely “opt in.” We never have and never will use mailing lists from other organizations for any purpose.
- You may unsubscribe at any time using our online subscription system or by contacting us via e-mail. We will honor any request to remove your name and contact information from our database.
- We will use your contact information only to communicate with you about your subscription; for example, to inform you that a new issue is available, that your subscription needs to be renewed, or that your printed copy has been returned to us as undeliverable by the postal authorities.
- We will never use your contact information for any other purpose or provide the subscription list to any third party other than for the purpose of distributing IPJ by post or by electronic means.
- If you make a donation in support of the journal, your name will be listed on our website and in print unless you tell us otherwise.

Thank You!

Publication of IPJ is made possible by organizations and individuals around the world dedicated to the design, growth, evolution, and operation of the global Internet and private networks built on the Internet Protocol. The following individuals have provided support to IPJ. You can join them by visiting <http://tinyurl.com/IPJ-donate>

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at **ole@protocoljournal.org** or **olejacobsen@me.com**

These days, it is common for Internet technology conferences to deploy a *temporary* network in convention centers or hotels to support Internet access for attendees and exhibitors. In some cases, these networks are used for special technology demonstrations. In this issue we will look at two examples of such networks.

The *TCP/IP Interoperability Conference*—later renamed *Interop*—began as a small workshop in August 1986. It quickly grew in scope to incorporate tutorials, and by 1988 an exhibition network connected 51 exhibitors to each other and to the global Internet. This network, or “Shownet,” was designed and deployed by a group of volunteers, and it became the proving ground for many emerging technologies. In 1994, Interop added Tokyo to its international venues, where 30 years later the conference and exhibition attracts more than 120,000 visitors. We will publish a separate article about the Japanese version of Shownet in a future edition. This time David Strom describes the history and evolution of the Interop Shownet. His article is dedicated to the memory of Daniel C. Lynch, the founder of Interop, who passed away earlier this year.

Work on the transition from IPv4 to IPv6 continues to be a major focus of several working groups in the *Internet Engineering Task Force* (IETF). As solutions are developed, technology events such as the *Asia Pacific Internet Conference on Operational Technologies* (APRICOT) provide end users an opportunity to experience IPv6 by simply selecting a designated Wi-Fi network on their devices. One such “IPv6 Mostly” experiment was conducted during APRICOT 2024 in Bangkok; Brian Candler describes it in our second article.

Ten years ago, *The Internet Protocol Journal* was relaunched with the help of numerous supporters, sponsors, and individual donors. Today we very much depend on this funding model, and once again we encourage you to make a donation or ask your organization to become a sponsor. We appreciate your feedback and suggestions. Please contact us via e-mail at: ipj@protocoljournal.org

The Interop Shownet

by David Strom

This is the story about how a group of very dedicated people came together at the dawn of the Internet era to build something special, something unique and memorable. It was called the *Interop Show 'n Tel-Net*, later known as *InteropNet*, or *Shownet*, and it was created in September 1988 at the third *TCP/IP Interoperability Conference* held in Santa Clara, California. This story tells how it evolved and specifically how the larger context of this network became a powerful tool that moved the Internet from a mostly government-sponsored research project to a network that would support commercial businesses and could be used by millions of ordinary people in their daily lives. But before we consider what happened then, we must turn back the clock a couple of years.

In August 1986, a few very motivated people decided to teach others how to implement the early Internet protocols. This first conference, called the *TCP/IP Vendors Workshop*, was held in Monterey, California, and was by invitation only (See Figure 1).

Figure 1: TCP/IP Vendors Workshop Agenda, August 1986.

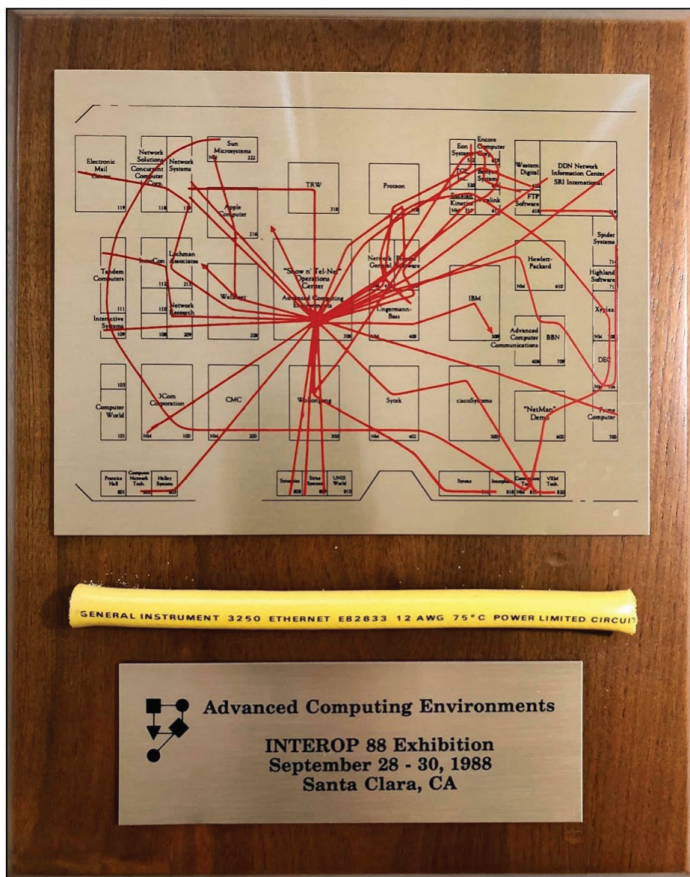

<p style="text-align: center;">TCP/IP Vendors Workshop Agenda Announcement</p> <p style="text-align: center;">25-27 August 1986 Doubletree Inn, Monterey, California</p> <p style="text-align: center;">Workshop Chair, Dan Lynch</p> <p>Sunday, August 24 5-7 PM -- Welcome Mixer at the Hotel</p> <p>Monday, August 25</p> <p>8:30 -- Coffee and Danish</p> <p>9:00 -- Welcome and Workshop Overview -- Dan Lynch, ACE</p> <p>9:10 -- DoD and ISO Protocol Coexistence Plan -- Mike Corrigan, OSD</p> <p>9:30 -- Future Directions for the Internet -- Jon Postel, USC-ISI</p> <p>9:45 -- NSFnet - Status and Plans -- Steve Wolff, NSF</p> <p>10:00 -- Certification Activity Status -- Bob Jones, SDC</p> <p>10:15 -- OSI Gateway Project -- John Heafner, NBS</p> <p>10:30 -- Break</p> <p>11:00 -- ULANA Specification -- Stan Ames, Mitre</p> <p>11:15 -- How to get information -- Elizabeth Feinler, SRI International</p> <p>11:30 -- Specification and Testing -- Dan Lynch (Testing and Certification, IMP (PSN) port availability)</p> <p>12:00 -- Lunch -- Find a place to eat nearby. -- Easy task.</p> <p>1:30 -- Network -- Vanilla Style -- Carl Sunshine, SDC (IP, ICMP, Net Management, Fragmentation, Security, Precedence (TOS))</p> <p>3:00 -- Break</p> <p>3:30 -- Network -- With Nuts -- Dave Mills, Linkabit (M/A-COM) Routing, ARP, RARP, BOOTP, Address Mapping Issues, Gateways (EGP, GGP, IGP), Subnetting, ISDN</p> <p>5:30 -- Break</p> <p>7:00 -- Meet at Monterey Bay Aquarium for a Private Viewing, Hors d'Oeuvre, Dinner, and a talk: Don't follow me, I'm a lost Internet Datagram -- Vint Cerf, NRI</p>	<p style="text-align: center;">TCP/IP Vendors Workshop Agenda Announcement</p> <p style="text-align: center;">Page 2</p> <p>Tuesday, August 26</p> <p>8:30 -- Coffee and Danish</p> <p>9:00 -- Files -- Jeff Mogul, Stanford (FTP, TFTP, Network File Servers (NFS, RFS, TOPS))</p> <p>10:15 -- Break</p> <p>10:45 -- Domain Name System Architecture -- Jon Postel</p> <p>11:15 -- Telnet -- Jon Postel (Telnet, Telnet Options, NACs)</p> <p>12:00 -- Lunch -- Find a place nearby.</p> <p>1:30 -- Mail -- Paul Mockapetris, USC-ISI (SMTP, User Mail Agents, Multi Media Mail, X.400)</p> <p>3:15 -- Break</p> <p>3:45 -- Transport -- Vint Cerf (TCP, Retransmission, UDP, Netbios on TCP)</p> <p>5:30 -- Done for the day...</p> <p>Wednesday, August 27</p> <p>8:30 -- Coffee and Danish</p> <p>9:00 -- Transactions -- Bob Braden, USC-ISI (Domain Names Implementation, Remote Procedure Calls, Transaction Services)</p> <p>10:30 -- Break</p> <p>11:00 -- Data Link and Physical-- Steve Holmgren, CMC (1822, X.25, Ethernet, Token Ring, Token Bus, Satellite, Packet Radio, Appletalk)</p> <p>12:00 -- Lunch -- As usual, find a spot on the wharf...</p> <p>1:30 -- Data Link and Physical, continued from morning</p> <p>3:00 -- Wrapup -- Dan Lynch (Identification of pressing issues for vendors, plans for follow on meetings.)</p>
--	--

Speakers included Vint Cerf, who was at MCI at the time, Jon Postel, *Request For Comments* (RFC) Editor and at ARPANET before playing a key role in Internet administration, and Paul Mockapetris and Bob Braden, both at the *University of Southern California's Information Sciences Institute* (USC-ISI).

Two subsequent conferences were held the following March in Monterey and then December in Crystal City, Virginia, and both were called the *TCP/IP Interoperability Conference*. All three were unusual events for several reasons: first, the presenters and instructors were the actual engineers that developed the earliest Internet protocols. They were also there to impart knowledge, rather than sell products—mainly because few commercial products were yet invented. One of the instructors, Douglas Comer of Purdue University, wrote the first and best-selling book on the topic: *Internetworking with TCP/IP, Volume 1, Principles, Protocols and Architecture*.

By September of 1988, the format of the conference changed, and expanded beyond lectures to a more practical proving ground. The event was renamed once again, and so *Interop*—and its show network—was born. The mission was still to teach Internet technologies and protocols, but for the first time the event was used to test and demonstrate various Internet communications devices on an active computer network. That show used a variety of Ethernet cables to connect 51 exhibitors together, with T1 links to the NASA Ames Research Center in Mountain View, California, and the NSFNet in Ann Arbor, Michigan (Figure 2).

Figure 2: Left: Interop 88 Exhibition show network. Right: NETWORLD+INTEROP 1996 advertisement.

THIS EVENT COULD REALLY GET ROUTY.

And the routing part is just for starters. After all, this is the world's top interoperability event.

At NetWorld+Interop® '96 Las Vegas, you'll get a chance to work with more than 50 hard-core networking experts like Wej, Doug, Robin and Steve. Together with other members of our Network Operations Center (NOC) team, they're in charge of operating our 6000 node, multi-vendor, multi-protocol network proving ground—the InteropNet™.

The NOC team designs and integrates classical networks with cutting-edge technologies.

So you get to see ATM running with existing networks. Or test 100baseT vs. 100VG, routing vs. switching, client/server interoperability, Internet applications and more.

The InteropNet also connects more than 550 vendors with the latest networking solutions, like LAN emulation, Fibre Channel, 155Mbps Wireless, FDDI, 100VG-AnyLAN, ATM, frame relay transports...the list goes on and on.

Call today to get a FREE VIP Exhibition Pass! Or access the Web at <http://www.interop.com> to register and get complete event information.

NETWORLD+INTEROP

Exhibition is April 2-4 • Conference is April 1-5 • Las Vegas Convention Center • 800-488-2883

InteropNet is a registered trademark of InteropNet, Inc. © 1996 InteropNet, Inc. All other names are the property of their respective holders.

The Interop conference quickly grew into a worldwide series of events^[1] with multiple shows held in different cities that were attended by tens of thousands of visitors with more than a thousand connected booths. In those early years, the largest shows were held in Tokyo, which began in 1994 and continued annually (with a pause because of the pandemic), with the latest show held in mid-2024. This year's show spanned over 500 vendors' booths and drew about 40,000 visitors each of its three days. The Tokyo Interop is also where the *ShowNet* (this is the chosen capitalization for the Tokyo show) not only has survived, but also has thrived, and continues to innovate and demonstrate Internet interoperability to this day. Many products had their world or Japanese debuts at various Tokyo Interop events, including Cisco's XDR and 8608 Router and NTT's Open APN.

My Own Interop Journey with Network Computing Magazine

Before I discuss the evolution of Interop and the role and history of its show network, I should first mention my own personal journey with Interop. In 1990, I was in the process of creating the first issue of *Network Computing* magazine for CMP Media. Our first issue was going to debut at the Interop show, the second time it was held that year in the San Jose, California, Convention Center.

The publisher and I both thought this place was the best one for our debut for several reasons. First, our magazine was designed for similar motivations—to demonstrate what worked in the new field of computer networking. We had designed our publication around a series of laboratories that had the same equipment found in a typical corporate office, including wide-area links and a mixture of PC MS-DOS, Apple Macintosh, and Unix devices and even a DEC minicomputer connected together. Second, we wanted to make a “big splash,” and our salespeople were already showing prototype issues ahead of the show to entice advertisers to sign up. Finally, *Network Computing's* booth would be connected to the Shownet and the greater Internet, just like many of the exhibitors who were trying out some product for the very first time.

One other feature about *Network Computing* that set us apart from other business trade magazines at the time: each bylined article would contain the email address of the author, so that readers could contact them with questions and comments. I wanted to use the domain **cmp.com** and set up an actual Internet presence, but alas I was overruled by management, so we ended up using a gateway maintained by one of the departments at UCLA where a couple of our editors were housed. While posting an author's email contact is now common, it was a radical notion at the time.

That 1990 Interop conference began my own personal journey of numerous shows around the world through the years, including speaking and teaching, as well as covering them for various business and networking publications that I would write for.

The Earliest Days of Interop

The Interop show in the late 1980s was a markedly different trade show from others of its era. At the time, trade shows with networked booths were non-existent. By way of perspective, up until that point in those early years, there were two kinds of conferences: one focused on the trade show with high-priced show floors and fancy exhibits. There, exhibitors were forced to “pay to play,” meaning if they bought booth space, they could secure a speaking slot at the associated conference. The other was a more staid affair that was a gathering of the engineers and actual implementers. Interop was a notable early example bridging the two: it looked like a trade show but was more of a conference, all in the guise of getting better commercial products out into the marketplace. It helped that it had its roots in those early TCP/IP conferences.

“You could see the Internet in a room, thanks to the Shownet, with hundreds of nodes talking to each other. That was unique for its time,” said Carl Malamud. “The Shownet was the most complex Internet installation you could do at any moment of time.”

Malamud would play several key roles in the development of various early Internet-based projects, including running the first Internet-based radio station, and he was a Shownet volunteer in 1991. In addition, Interop commissioned him to write the book *Exploring the Internet: A Technical Travelogue*.^[6]

That complexity has been true from the moment the Shownet was first conceived to the present day. Many of the Internet protocols—both in their earliest years and up to the present era—were debugged over the Shownet: volunteers recall testing NetBIOS over TCP/IP, 10BaseT Ethernet, SNA over TCP/IP, *Fiber Distributed Data Interface* (FDDI), *Simple Network Management Protocol* (SNMP), *Internet Protocol Version 6* (IPv6), various versions of segment routing, and numerous others. That extensive protocol catalog is a testament to the influence and effectiveness of the Shownet, and how enduring a concept it has been over the course of Internet history. Steve Hultquist, who was part of the early *Network Operations Center* (NOC) teams, remembers that the first version of 3Com’s 100BaseT switch—with “serial number 1”—was installed on the show network.

The force behind Interop was Dan Lynch, who passed away earlier this year. Lynch foresaw the commercial Internet and designed Interop to hasten its adoption. He based Interop on a series of efforts to bring together TCP/IP vendors, and the proto-Interop shows that were run in the middle 1980s that were more “Plugfests” or “Connectathons,” where vendors would try out their products. The main difference was those efforts deployed mostly proprietary protocols, whereas Interop ran on open source.

He told Sharon Fisher in November 1987: “There are millions of PCs out there and they’re starting to get networked in meaningful ways, not just in little printer-sharing networks.”

Part of his vision—and those that he recruited—was the notion of interoperability that could be used as a selling point and as an alternative to single-vendor proprietary networks from IBM, Digital Equipment Corporation, and others that were common in that era. Larry Lang, who worked for many years at Cisco, said, “The reassurance that it was okay to give up having ‘one throat to choke’ came from confidence that the equipment was interoperable. It is hard to remember a time when that was a worry, but it surely was.”

Part of Lynch’s vision was to ensure that proving interoperability was a very simple litmus test: did the product being exhibited work as advertised in a real-world situation? The answer to that question seems like common sense, but doing so in a trade show context was a relatively rare idea. And while it was a simple question, the answer was usually anything but simple, and sometimes the reasons why some product didn’t work—or didn’t work all the time—was what made the Shownet a powerful product improvement tool. That is just as true today as it was back then. The more realistic the Shownet, the more often it would expose these special circumstances that would bring out the bugs and other implementation problems.

It would prove to be a potent and enduring vision.

What Does Interoperability Mean?

The notion of interoperability seems so common sense now—and indeed it is the default position for most of the current networking world. However, in the early days of the Internet it was fraught with problems in terms of both larger-scale implementations and smaller issues that would prevent products from working reliably. One of Sharon Fisher’s articles in *Computerworld* in 1991^[2] speaks about TCP/IP this way: “The astounding thing is not how gracefully it performs but that it performs at all. TCP/IP is not for everyone.” Times certainly have changed in the 33 years since that was written. Today the notion of Internet connectivity, using TCP/IP protocols, is a given assumption in any computing product—from smart watches to the largest mainframe computers.

Those early implementation differences plagued both large and small vendors alike, and required a meeting of the minds where the protocol specifications weren’t exacting enough to ensure its success, or where bugs took time to resolve. Enter the Interop conference. As a reminder, in those early days the popular IP applications were based on the *File Transfer Protocol* (FTP), the *Simple Mail Transfer Protocol* (SMTP), and the *Simple Network Management Protocol* (SNMP). The web was still being invented and far away from being the de facto smash hit that it is today. Video conferencing and streaming didn’t exist. Telephones still ran on non-IP networks.

One of the early casualties was the *Open Systems Interconnection* (OSI) series of protocols promulgated by the *International Organization for Standardization* (ISO).

It was precisely because of the interoperability among TCP/IP products and “the failure of OSI to effectively demonstrate interoperability in the early 1990s that was the final nail in its coffin,” said Brian Lloyd, who worked at Telebit at the time. There are other stories of the defeat of OSI, such as this one in the *IEEE Spectrum*.^[3]

The Relationship Among the Shownet, the Conference Tutorials, and the NOC

To accomplish Lynch’s vision, Interop was not only the Shownet, but also its interaction with two other elements that became force multipliers in the quest for interoperability. These elements were the tutorials that were given before the opening of the show floor, and the NOC team that ran the network itself. All three had an important synergy to promote the actual practice of interoperability among different vendors’ products: not only in the demonstration of what worked with what but also in the discovery of protocol mismatches or programming errors so that new equipment could be made to interoperate.

Dave Crocker, who authored many RFCs and served on the Interop program committee that selected speakers in the 1990s, called out this tripartite structure of Shownet, NOC, and conference as a major strength of Interop. “Interop was able to contrast the technologies of the Internet with the interoperability of non-Internet technologies, such as IBM’s *Systems Network Architecture* (SNA). It had very pragmatic implications and wasn’t just promoting marketing speak.”

Many of the engineers who developed those early protocols and techniques and other pieces of Internet technology taught the tutorials (and as I mentioned, I taught a few of them during those early years, in addition to serving with Crocker on the program committee), so that others could learn how to best implement them. Here is where Interop contained its secret sauce: the people who taught the tutorials were the people who contributed to the underlying protocols and code, in some cases code so new it was changing over the duration of the show itself. “It was only after getting to Interop that we found out how few options were actually used by most implementations, and only then did we have access to the larger Internet and various versions of Unix computers,” said Brian Lloyd. “It was real bleeding edge stuff back then and the place to go for product testing and see how marketers and engineers would work together.”

And the NOC was a real one, like what could be found at large corporations, monitoring the network for anomalies and using it to debug various implementations leading up to the opening moments of the show. “It was unusual for its time,” said Fisher in another article in *Infoworld*.^[4] “The NOC team was infamous in the trade press for its tours and the time members took to explain things to us,” she said. Malamud recalls that the NOC had a strict “no suits” policy, meaning that its denizens were engineers that rolled up their sleeves and got stuff done.

All of this happened with very few paid staff: most of the people behind the Shownet and NOC were volunteers who came back, show after show, to work on setting things up and then taking them down after the show ended. That was, and to some extent still is, a very high-pressure environment: imagine wiring up a large convention center and connecting all of its conference rooms with a variety of network cabling. Several of the original Interop Shownet and NOC volunteers are continuing the tradition by helping to build and run the *Internet Engineering Task Force* (IETF) event networks at every IETF meeting around the world.

One of the more infamous moments of Interop was the *Internet Toaster*, created originally by John Romkey for the 1990 show^[5].

“I wanted to get people thinking of SNMP not just as getting variables, but for control applications, a wider vision. So we had an SNMP controlled toaster. If you put bread in the toaster, and set a variable in SNMP, the toaster would start toasting. A whole *Management Information Base* (MIB) was written for it, including how you wanted the toast, and whether it was a bagel or Wonder Bread. I ended up with lots and lots of bread in my garage. It got a lot of attention, but I don’t think that managing your kitchen through SNMP is very practical today.”

Dave Buerger, who was an early tech journalist at CMP, remembers Interop as having “a strange sense of awe unfolding for everyone as we glimpsed the possibilities of global connectivity. Exhibits on the show floor were more experiments in connecting their booths to the rest of the world.”

Construction of the Earliest Shownets (before 1993)

To say that Lynch was very persuasive is perhaps a big understatement. He convinced people who were quirky, unruly, or difficult to work with to spend lots of time pulling things together. “Dan allowed us to do stuff that the usual convention wouldn’t normally allow, and managed people that weren’t used to being managed,” said Malamud.

Peter de Vries was one of the earliest Shownet builders when he was working at Wollongong as one of the early Internet vendors. He ended up working for Interop for three years before opening the West Coast office for FTP Software. He remembers Lynch “dragging people kicking and screaming into using the Internet” back in the late 1980s and early 1990s. “But he was a fun guy to work for, and he had an unusual management style where he didn’t issue demands but convinced you to do something through more subtle suggestions, so by the time you did it you were convinced you had the original idea.”

These volunteers would essentially be working year-round, especially once the calendar was filled with multiple shows per year. Back in those early years, the convention centers didn’t care about cabling, and hadn’t yet figured out that having a more permanent physical networking plant could be used as an asset for attracting future meetings.

“We were often the first show to hang cables from the ceiling, and it wasn’t easy to do,” said Malamud, who chronicled the 1991 Shownet assembly^[6]. The first Interop shows used thick Ethernet cables that required a great deal of finesse to work with; de Vries recalls they had to pass wires through expansion joints and other existing holes in the walls and floors, wires that didn’t easily bend around corners.

“Each network tap took at least ten minutes of careful drilling to attach to this thick cable.” He has many fond memories of Lynch: “My goal was to try to get everyone to use TCP/IP, but Dan took it to the next step and showed that TCP could be a useful tool, something better than a fax. He was a real visionary.”

Ethernet—in all of its variations over the years, including early implementations of 10BaseT and 100-megabit speeds—wasn’t the only cabling choice for Interop; the show would expand to fiber and *Token Ring* cabling as part of its mission. Brian Chee was one of those volunteers who remembers having to re-terminate 150 different fiber strands across the high catwalks of the convention spaces. “We even had to terminate the fiber on the roof of the convention center to connect it to the Las Vegas Hilton across the street,” he said.

Getting all that cabling up in the air wasn’t an easy task either. Patrick Mahan worked on the San Francisco show in 1992 and recalls that he and other networking volunteers were paired with the union electrical workers on a series of scissor lifts. “We needed multiple lifts operating in tandem to raise them, and we had just started hanging a 100-foot length [cable] when a loud air-horn goes off and each lift immediately starts descending to the floor, because it was time for the mandatory union 15-minute break. It took about three minutes before the cable bundles started breaking apart and crashing to the cement floor. You could hear the glass in the fiber cables breaking!”

The Vegas climate made installations difficult, especially when its non-air-conditioned convention halls reached temperatures of 110 degrees Fahrenheit outside. “Many convention centers don’t turn on their air conditioning until the night before the show begins, so it was a particularly harsh environment,” said Glenn Evans, who worked as both a volunteer and an employee of Interop during the late 1990s and early 2000s. “Vegas in May is very dry, and static electricity is a big issue. We fried several switch ports inadvertently and spent long nights adding static filters to avoid it because some shows had more than 1,200 connections across their networks.” Evans emphasized that the install teams relied on “redneck engineering to come up with creative solutions, and it didn’t have to be perfect, [it] just had to work for five days.”

The cabling had to be laid out three times for each Shownet. The volunteers would have access to the convention center for a day months before any actual show. They would lay out the first cable segments and add connectors, then roll them up and store them in a warehouse. Then before the show there would be a “hot staging” event where the cables were connected to their equipment racks and tested.

Finally, several nights before the show began saw the real deployment at the convention center, which would span several 24-hour days before the actual opening. Those long nights were epic: de Vries recalls falling asleep in the middle of one night at the top of a 15-foot ladder, only to be gently awakened by the only other person in the convention center at the time. “Those installations nearly killed me!”

Many of the participants during those early years were motivated by a sense of common purpose, that their efforts were directly contributing to the Internet and its usefulness. “I loved that we could help the overall industry get stuff right,” said Hultquist. “They were some of the smartest people that I have ever worked with and were constantly pushing the envelope to try to deploy all sorts of emerging technologies.”

But the physical plant was just one issue; once the cabling was in place, the real world of getting equipment up and running across these networks was challenging. In those early Interops, equipment was often at the cutting edge, and engineers would make daily or even minute-by-minute changes to their protocol stacks and application code.

James van Bokkelen was the president of FTP Software then, and he recalls seeing the Shownet in 1988 crash while running BSD v4.3, thanks to a buggy version of one TCP/IP command. Turns out the bug was present in Cisco’s routers that were used on the Shownet. “It took a few minutes of scampering before everything was in place and we got Shownet back online,” he said. Scampering indeed: the volunteers had to compare notes, debug their code, and reboot equipment often located at different ends of the convention floor.

“We were getting alpha software releases during the show. This network created an environment where people had to fix things in real time in real production environments,” said Hultquist. “Wellfleet, 3Com, and Cisco were all sending us router firmware updates so their gear could interoperate with each other. I loved that we could help the overall industry get stuff right.”

At one of the 1991 Interop events, “FDDI completely melted down,” said Merike Kaeo, who at the time was working for Cisco in charge of their booth and volunteering in the NOC. “There was some obscure bug where a router reboot wasn’t enough, you had to reset the FDDI interface adapter separately. It didn’t take all that long to get things running, thankfully.”

Some of the problems were far more mundane, such as using equipment with NiCad batteries that had very short shelf life. Chee recalls that one Fluke engineering director got tired of trying to get these batteries replaced with Lithium-ion batteries. “He would send his team up to the rafters with network test equipment that had very short battery life; they were quickly replaced in their newer products.”

As more Shownets were brought up over the years, they had built-in redundant—and segregated—links. “We all played a part to make sure that after 1991, we would have a stable portion that would run reliably and put any untested equipment on another network that wouldn’t bring the working network down after the show started,” said Bill Kelly, who worked for Cisco in its early days.

de Vries said the first couple of Interop Shownets had less than 10 miles of cabling, which grew by 1991, according to Malamud, to having more than 35 miles of cabling, connecting a series of ribs, each one running down an aisle of the convention floor or some other well-defined geographic area. “Each rib had both Ethernet and Token Ring connected to an equipment rack with various routers,” said Malamud.

“There were two backbones that connected 50 different subnets, one based on FDDI and the other on Ethernet, which in turn were connected via T-1 lines to NASA Ames Research Center and Bay Area Internet points.”

Bill Kelly, who worked on the Shownet NOC while he was at Cisco, developed a three-stage model that covered a product lifecycle. “The first stage is using the IETF RFCs to try to make something work. Then the second stage is when a vendor is late to market and must figure out how to play nicely with the incumbents and the standards. The third stage is mostly commodity products, and everything works as advertised.”

The Middle Years (1994–1999)

The Internet—and Interop—were both growing quickly during this time. New Internet protocols and RFCs were being created frequently, and applications—and dot-com businesses—sprang up without any business plans, let alone initial paying customers. There were new venues each year in Europe, shows in Sydney, Australia, and Singapore, and Sao Paulo, Brazil. Some years had as many as seven or eight different shows, each with its own Shownet that needed to be customized for the exhibit halls in these cities.

Let’s return to 1986 for a moment. That year Novell began its own trade shows, called *NetWorld*, to explain its growing *Netware* community. By 1994, these shows had grown, and that is when Novell and Interop merged their shows, calling them *NetWorld+Interop*. This moniker held until 2004, when a series of technical media companies purchased Interop.

“Shownet didn’t change much after the Novell merger. We could accommodate their stuff at the edge, but it didn’t impact the core network,” said Hultquist. For the Shownet team, Netware was just another protocol to interoperate across. Despite Novell’s influence, during these years, TCP/IP became a networking standard. So did the cabling that made up the Shownet: “In the mid-1990s, a lot of the cable plant could be reused from show to show, with a standard set of 29-strand multimodal fiber with quick connectors and 48 strands of Category 5 copper cable for the ribs,” said Evans.

TCP/IP evolved too: by the end of the 1990s, the protocols and Ethernet hardware became commodities and were both factory-installed in millions of endpoint devices. “The Internet was becoming more standardized, and Interop became less of an experiment and more of a technology demonstration,” said Evans.

Nevertheless, vendors tried to differentiate themselves with quirky exhibits, pushing the envelope of connectivity. One stunt happened during the 1995 Interop at the Broadcom booth, which demonstrated Ethernet signals over barbed wire. “The wires were ugly and rusty and had nasty little barbs all over them,” according to one description written years later.^[6,11]

By 1999, the Shownet split into two separate parts: the live production network connecting the exhibit booths called *InteropNet*, and *InteropNet Labs* used for showcasing new technologies and products. Back then, these new technologies included VoIP, VPNs, and other “hot technologies,” according to a post by Tim Greene on CNN.^[7] Several market forces caused this situation. First, more and more conferences began promoting the idea of Internet connectivity for both attendees and vendor participants. “As that reality dawned on people, the Interop Shownet became an increasingly useless anachronism,” said Larry Lang, who was part of the team building Cisco’s support for FDDI at that time. “As our competition became Wellfleet rather than IBM, why would we want to participate in an expensive and time-consuming display that suggested complete equivalence among all the products?”

Hultquist was quoted in that CNN piece saying that attendees “won’t know whether a piece of equipment really worked because of the demands placed on them by more experimental or untested products.”

A second issue had to do with striking a balance between established vendors and newcomers. Kelly remembers the relationship between Cisco and Interop to be “complicated because we were the market leader and if we just donated equipment without any technical support, we ran the risk of outsiders misconfiguring the devices. Interop was also used to dealing with small engineering groups and not pesky marketing types that wanted to know the value of participating in the show.” Plus, long-running contributors to the original Shownets often got a jump on developing new gear and interacting with products that weren’t yet on the market.

By the end of the 1990s, the Shownet staging operation had also split into two. Prior to that moment, each Shownet would be staged in a Silicon Valley warehouse. But then the show runners for Tokyo decided to set up their own facilities to stage and constitute their own Shownet, and reformulated their NOC team from local talent, where they continue to build and demonstrate interoperability to the present day.

The New Millennium of Interop

Interop continued to grow in the new millennium. Two notable events affected the Shownet. The day the towers fell in New York in 2001 was also the day that the fall Interop show in Atlanta started. Many of the Shownet volunteers recall how quickly their network became the main delivery of news and video feeds to those attendees who were stuck in Atlanta, since all flights were grounded for the next several days. Brian Chee remembers that “within minutes of the disaster we maxed out the twin OC-12 WAN connections into the Shownet. We brought up streaming video of *CNN Headline News* over IP multicast, and that cut our wide-area traffic substantially, while at the same time it was an impressive demonstration of that technology.”

But then a few years later another event happened. “The day the Slammer virus hit, in 2003, we had just gone into production across the Shownet. That virus hurt our network throughput just enough that all our monitoring devices were useless,” said Chee. “But the NOC team was able to characterize the problem within a few minutes, and we were able to use air gapped consoles to reset routers and filter out the virus-infected packets.” That is as real world as it gets and is an example of how the Shownet proved its worth, time and time again.

But what is amazing is how enduring the legacy of Shownet continues to be. For example, during the 2019 Tokyo Interop, it played a critical role in demonstrating the interoperability among various segment routing vendors running over IPv6, resulting in a draft Internet document.^[8] I had an opportunity to review a draft report from the Tokyo team about the 2024 network that will be published in a future IPJ issue. “We faced varied challenges and considerations to achieve this while serving user traffic,” they wrote^[9].

Subsequent Tokyo shows—indeed the now sole survivors of the Interop legacy—would continue to draw on a huge talent pool of local talent. This year’s show had more than 650 volunteer engineers, including 30 alone to operate its NOC. “In 2024, we had 11 working groups leading the following fields: facilities, optical transport, external connectivity, backbone network, data center and cloud, wireless network, monitoring, security, testers, 5G, and media over IP,” said Takashi Tomine, who was part of the NOC team. The NOC occupies an impressive amount of show-floor real estate, where it continues to serve as a teaching and demonstration tool, as well as a working network nerve center.

It also is an opportunity for university students and junior staff to obtain hands-on experience in network operations and spend two weeks touching technology in ways that they might not have in their jobs or classrooms. The NOC team conducts walking tours, wherein guides describe what these teams have done in the many Interops held elsewhere down through the years. The 2024 show endures in another way, the “hot staging” model that was developed more than 30 years ago at the first Silicon Valley shows. The team has a total of eight days to assemble the network, and a few hours to take it apart after the show ends.

“First, we install every device in the right place on the racks, turn on the devices, and check their status. Checking device statuses is very important because some devices are transported directly from overseas to the venue, so it is necessary to ensure that they are not malfunctioning. We usually finish this process on the first day. On the second day, we start the network setup,” said Tomine.

His article will be published in a subsequent IPJ issue that goes into further details about the Tokyo show and how it grew over the years.

Figure 3: Interop Tokyo
2024 ShowNet Walking Tour

The 2024 Tokyo Interop showcased several new technologies, or technologies used in new and innovative ways. For example, the Shownet shared streaming video content with three geographically distributed TV broadcasting stations, all over IP networks. The team built a special media operations center to control these broadcasts and to demonstrate real-time video recording and editing of several conference sessions and demonstrations. In that respect, it was back to the future when the first multicast IP streams were broadcast years ago.

“The coolest thing we got out of working at Interop is that technology doesn’t happen without the people, and the people involved were some of the hardest-working and smartest people that you’ll ever meet. They checked their egos at the door, and solved problems jointly,” said Evans. “It was run like a democratic dictatorship, where everyone had a say.”

Acknowledgements

This article wouldn’t be possible without the help of numerous volunteers and staff at Interop events of the past, including Bill Alderson, Karl Auerbach, Dave Buerger, Brian Chee, Dave Crocker, Peter J.L. de Vries, Glenn Evans, Sharon Fisher, Connie Fleenor, Steve Hultquist, Merike Kaeo, Bill Kelly, Larry Lang, Brian Lloyd, Carl Malamud, Jim Martin, Naoki Matsuhira, Ryota Roy Motobayashi, Takashi Tomine, and James van Bokkelen.

Dedication

This article is dedicated to the memory of Daniel Courtney Lynch, August 16, 1941 – March 30, 2024, founder of the Interop events and whose vision gave us the Interop Shownet.

Experimental IPv6-only Network at APRICOT 2024

by Brian Candler, NSRC

The Asia Pacific Regional Internet Conference on Operational Technologies (APRICOT)^[0] is the Internet Network Operators Summit for the Asia Pacific region. Every year, a wireless network conference is deployed to provide connectivity for hundreds of delegates, with a separate “IPv6-only” SSID as an alternative for people to try. This year, we decided to experiment with a new approach, by using some of the recent mechanisms designed for “IPv6-mostly” networks to build a better “IPv6-only” network.

What Is IPv6-mostly?

“IPv6-mostly” is a way to gracefully sunset *Internet Protocol Version 4* (IPv4) on dual-stack access networks. The work in this area has been driven in part by Google’s enterprise network, which has become so large that they ran out of RFC 1918^[1] private addresses. Technically, there are two pieces to this plan:

- A new “IPv6-only preferred” option for *Dynamic Host Configuration Protocol Version 4* (DHCPv4) (option 108, RFC 8925)^[2]. By requesting this option, a client declares that it is willing to run in a single-stack, IPv6-only mode. And by returning this option, the DHCPv4 server confirms that the network is happy to work this way too. The client then doesn’t configure itself with any IPv4 address.
- A new “PREF64” *Neighbor Discovery Option for Router Advertisements* (RFC 8781)^[3]. This option tells the client that a *Network Address Translator 64* (NAT64) is available, and what prefix to use.

If both of these conditions are true, the client configures itself with a *Customer-Side NAT46 Translator* (CLAT), with a hidden private IPv4 address. Any IPv4 application traffic is routed through this translator and carried across the network as IPv6 until it reaches the *Provider-Side NAT64* (PLAT), where it is converted back to IPv4. This whole mechanism is called *464XLAT*.

The end result is that you can interact with IPv4 resources—even using IPv4 literals, like `ping 8.8.8.8`—when running on an IPv6-only network. In effect, your IPv6 network doubles as a large block of private addresses behind a NAT. A big advantage of this approach is that there is no need to use DNS64 to generate fake AAAA records for IPv4-only destinations.

“IPv6-mostly” is supported by modern versions of macOS (13+), iOS, and Android. Any other clients will simply continue with regular dual-stack operation, but overall the usage of your DHCPv4 address pools will decrease.

Using IPv6-mostly Features for IPv6-only

For APRICOT, we wanted to build a pure IPv6-only network, not dual-stack. But we also wanted to enable the CLAT in client devices that support it in order to get maximum compatibility with IPv4. Here is how we enabled it: the pieces were all built inside an Ubuntu 22.04 *Virtual Machine* (VM) running on a compact *Next Unit of Computing* (NUC) computer. The NUC is a line of small-form-factor barebone computer kits designed by Intel.

First, we needed a DHCPv4 server that would respond to clients that requested option 108, granting them permission to run IPv6-only. Regular DHCP servers like *ISC DHCP* and *Kea DHCP* are quite happy to do that. However, we also did *not* want to respond to clients who *didn't* support option 108; if we did, we'd have to offer them an IPv4 address, and we'd be back to a dual-stack network.

I couldn't find an off-the-shelf DHCPv4 server that was capable of working this way, so I found a modular DHCP server in Go called *coredhcp*^[4] and created a new plugin^[5] to implement the desired behavior. This plugin has now been merged into the main codebase.

Second, I needed to send router advertisements with the PREF64 option. The conference routers were Arista Layer 3 switches, and although they have this feature in very recent firmware, it wasn't available in the version we were using.

Therefore, I used Linux's *radvd*^[6] to perform the router advertisements. This feature was not available in the latest released version, only git HEAD, so I had to compile *radvd* from source. Since it's not possible for one router to send advertisements on behalf of another, it meant that the VM where *radvd* was running also had to act as the gateway for the IPv6-only network, turning the VM into a router for IPv6 traffic.

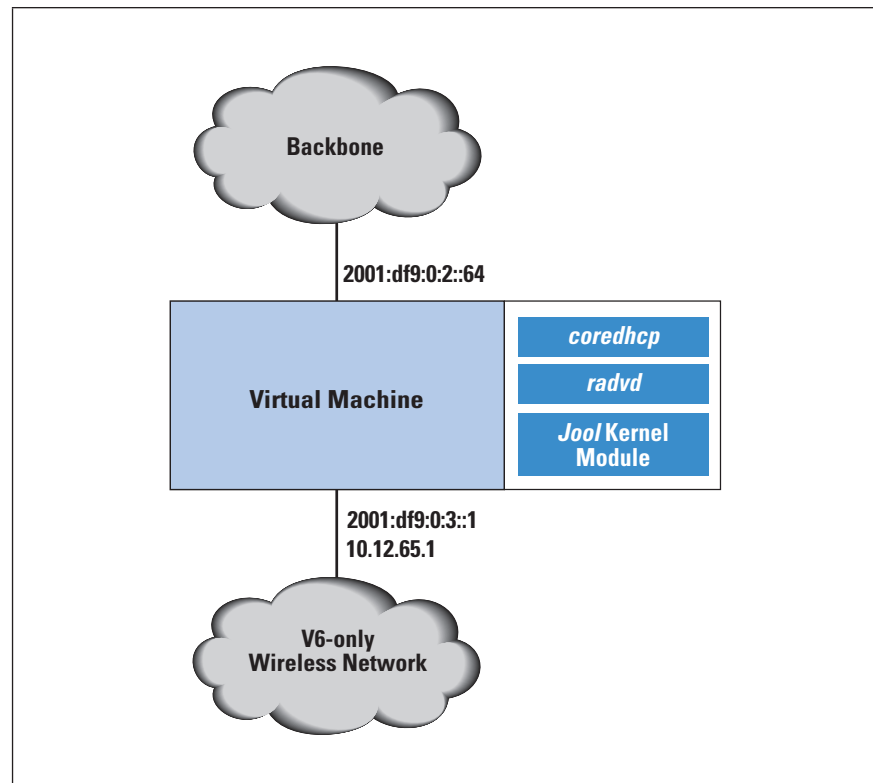

And finally, I needed a NAT64 translator somewhere on the network. This process could potentially have been done on a conference router, but since the IPv6 traffic had to pass through the VM anyway, I decided to implement NAT64 on the VM as well. I implemented it using *Jool*,^[7] a kernel module for NAT64 (refer to Figure 1 on the following page).

Configuration

We bundled all the components into a single VM running Ubuntu Linux 22.04. The VM acted as the router for the IPv6-only network, forwarding IPv6 packets in the kernel. It had an IPv6 address on the conference backbone, and an IPv6 address on a separate /64 subnet for the wireless network, with a static route on the upstream conference router.

We also configured the VM with an IPv4 address on the wireless-facing interface, but only so that the DHCPv4 server had an address to bind to. The VM offered no IPv4 addresses to clients, and enabled no IPv4 routing or NAT.

Figure 1: APRICOT 2024 Network Configuration for “IPv6 Mostly”

The other components running on the VM follow:

- The *Jool* kernel module, to perform the NAT64 translation;
- The *radvd* daemon, to announce the wireless prefix and the NAT64 prefix to clients; and
- The *coredhcp* server, to return DHCPv4 option 108 to those clients that requested it. It was also configured to act as a stateless DHCPv6 server, to give out DNS server addresses and domain search lists for any clients that didn’t support Router Advertisement options *Recursive DNS Server Option* (RDNSS) and *Domain Name System Search List* (DNSSL).

Problems

The basic reachability to the IPv4 Internet via NAT64 seemed to work well. However, we were plagued by clients being repeatedly removed from the IPv6-only network by the Cisco *Wireless LAN Controller* (WLC), at seemingly random intervals. Strangely, this didn’t seem to affect clients on the main conference SSID on the same access points. It turns out that several underlying issues were to blame.

First, the client private CLAT address **192.0.0.2** was leaking out as the source IP address on various multicast packets (such as multicast DNS, and Chrome doing service discovery on UDP port 1900). Logs showed that the wireless controller had a feature called “IP Theft or Reuse” that would add client MAC addresses to an exclusion list if it saw the same source IP address from multiple clients. We were able to turn that option off.

Second, some clients were being kicked off regularly every 10 minutes. The Cisco WLC had a setting where the wireless access points would perform dynamic channel reassignment every 10 minutes. We increased it to 24 hours.

Finally, when the conference was nearly over, we discovered another per-SSID setting, “IPv4 DHCP required,” which we also turned off. We believe that fixed the remaining problems.

There was one other major issue: clients would lose the ability to reach IPv4 destinations for a few minutes at a time, without being kicked off the wireless network—IPv6 connectivity continued to work. Using *tcpdump*, we saw that IPv6 neighbor discovery on the VM was forgetting about the IPv6 address of the CLAT. It turns out that the version of Jool in the Ubuntu 22.04 package repositories is old (v4.1.7), and this problem is known^[8]. It was straightforward to upgrade the package to the latest release, v4.1.11.

Apart from these problems, the CLAT/NAT64 mechanism worked very well for those devices that supported it. Remaining issues were minor: *traceroute* to an IPv4 destination showed only “*” for every hop, and the macOS ssh client didn’t work when given the “-4” flag (although it did work with an IPv4 literal address). Otherwise, it was just like being on a dual-stack network.

Conference Usage and Compatibility

From DHCP logs, I found that 142 unique devices had attempted to use the IPv6-only SSID, and of those, 115 (81%) supported DHCP option 108. That’s a surprisingly high proportion, representing a high usage of Apple laptops, iOS phones, and Android phones amongst delegates. Those devices should have gotten a good experience from the network, if it weren’t for the wireless disconnection issues.

The other 27 devices would have had a much worse experience. They got no DHCPv4 response, so they retried repeatedly, configured themselves with an IPv4 link-local address (**169.254.x.x**), and still would have been able to reach only Internet sites with IPv6 addresses.

We could have improved compatibility for these clients somewhat by providing a DNS64 service, which fakes AAAA records for DNS names that have only A records. However, these DNS settings would have applied to all hosts on the network, meaning that even those clients supporting option 108 would also have been exposed to fake DNS responses. I thought that the experiment was more useful without it, because the NAT64/DNS64 combination is already well-known and tested.

Post-conference Updates

Since the conference, I learned that it may no longer be necessary to provide any DHCPv4 server. Recent versions of MacOS will enable the CLAT even if the device has no IPv4 address at all.

However, an absent DHCPv4 server causes clients to keep sending DHCPDISCOVER messages, generating unnecessary load on both the clients and the network. Returning DHCPv4 option 108 stops the clients from doing this constant resending. There is also an older standard, “Auto-Config” DHCP option 116, in RFC 2563^[9], but DHCP logs from the IPv6-only conference network showed no clients using this option, so it appears to be obsolete.

I also discovered a problem about the choice of the NAT64 prefix. A *Well-Known Prefix* (WKP), **64:ff9b::/64**, is defined in RFC 6052^[10]. But if you use it, you will find that clients will be unable to connect via NAT64 to private addresses such as RFC 1918, because that is mandated by RFC 6052 section 3.1. If you want to use NAT64 on a typical home or enterprise network, and still be able to reach internal devices on private addresses, you will need to avoid the WKP. The conference network used a *Unique Local Address* (ULA) prefix (**fd64::/64**) instead.

Conclusion

IPv6-only using the IPv6-mostly mechanisms works surprisingly well, and is only going to improve over time as Windows^[11] and Linux add support for it.

Personally, I’d be quite happy to run this way at home, except that my Mikrotik router has no NAT64 capability. (RouterOS versions 7.8 and later do have the PREF64 router advertisement option though)^[12].

IAB Workshop on Barriers to Internet Access of Services (BIAS)

The *Internet Architecture Board* (IAB) organizes workshops about topics of interest to the community that bring diverse experts together, raise awareness, and possibly identify the next steps that can be explored by the community. The IAB held its *Barriers for Internet Access of Services* (BIAS) fully online workshop during the week of January 15, 2024.

The Internet is a crucial component of our critical infrastructure that wields a significant influence on various aspects of society. It serves as a vital tool for advancing the United Nations' *Sustainable Development Goals* (SDGs)^[1] and upholding human rights on a global scale. Thus the absence of meaningful access to digital infrastructure and services amounts to a form of disenfranchisement. The barriers to meaningful access to Internet-based services and applications are increasing, posing challenges that persist even when Internet connectivity is available, thereby resulting in unequal information and service access.

The workshop solicited position papers about barriers to accessing content and services on the Internet, for example, based on filtering, blocking as well as due to general inequality of technological capabilities, like device or protocol limitations. 19 position papers were submitted to the workshop of which 12 papers were selected for publication^[2]. Two invited talks were also presented based on published papers. There were 40 participants in the workshop over three days.

This marked my first IAB workshop since joining the board. I am delighted to have collaborated with Mirja Kühlewind, Mallory Knodel, Tommy Pauly, and Christopher A. Wood in organizing this event. The themes of censorship, circumvention techniques, and the digital divide have surfaced in various IAB discussions lately. Our goal for this workshop was to present reports, expert opinions, and ignite discussions on these topics. Through this experience, I gained valuable insights and strongly believe that the IETF community must remain mindful of these crucial issues when designing protocols. It is imperative to ensure that we create the most secure, user-friendly protocols for all Internet users.

This article provides a short overview of the workshop discussion. However, if you would like to learn more you can also check out the initial draft version of the IAB workshop report^[3], or watch the entire thing on YouTube^[4]. The workshop was organized into three main themes across three days based on the submitted papers.

Community Networks

Community Networks are self-organized networks which are wholly owned by the community and thus provide an alternative mechanism to bring connectivity and Internet services to those places that lack commercial interest. Discussion ranged from highlighting the need for measuring *Quality of Experience* (QoE) for Community Networks, to the potential role a *Content Delivery Network* (CDN) can play in Community Networks, to the role of satellite networks, and finally, to the vital role of the spectrum in this space.

Digital Divide

The digital divide refers to disparities in access to the Internet and services. It signifies the gap between those who have effective and meaningful access to digital technologies and those who do not. Discussion recognized three key aspects of the digital divide: differences between population demographics in the provision of online resources by governments, inequality in the use of multilingual domains and email addresses, and increased costs for end-user downloads of contemporary websites' sizes. There was a general recognition that there may be more technical aspects of the digital divide that were not presented.

Censorship

Censorship is the legal control or suppression of what can be accessed, published, or viewed on the Internet. This discussion focused on reports of censorship as observed during recent years in different parts of the world, as well as on the use of and expectation for censorship circumvention tools, mainly the use of secure VPN services. This included censorship reports from India and Russia, where censorship has changed significantly recently, highlighting the legal frameworks and court acts that put obligations on regional network providers to block traffic. Further, measurements to validate the blocking, as well as analyses of how blocking is implemented were also discussed.

Next Steps

The discussion highlighted the need for the technical community to address the management gaps and document best practices for Community Networks including listing of manageability considerations explicitly for Community Networks. Further, the need to build consensus on solutions that have the most significant impact in fostering digital inclusion and the need to further promote them was discussed. We need to continue to work towards enhancing our protocols ensuring user privacy, develop further protocols that enable more transparency on filtering and new VPN-like services. Further discussion of these topics could happen in the *Global Access to the Internet for All* (GAIA)^[5], *Human Rights Protocol Considerations* (HRPC)^[6], *Privacy Enhancements and Assessments* (PEARG)^[7], and *Measurement and Analysis for Protocols* (MAPRG)^[8] research groups, based on the relevance to each group.

IAB Statement on the Risks of Attestation on the Open Internet

While attestation of client software and hardware is a useful tool for preventing abuse or fraud on the Internet, the use of such attestation as a barrier to access otherwise open protocols and services would negatively impact the evolution of the Internet as a whole.

Openness and the empowerment of end users are core values of the IETF. RFC 3935^[1], Section 4.1, explains this as part of the IETF's mission statement:

“We want the Internet to be useful for communities that share our commitment to openness and fairness. We embrace technical concepts such as decentralized control, edge-user empowerment and sharing of resources, because those concepts resonate with the core values of the IETF community. These concepts have little to do with the technology that's possible, and much to do with the technology that we choose to create.”

The Internet is built upon the idea that anyone who implements the appropriate standards should be able to interoperate on the Internet. Many of the core services that run on the Internet, such as email and the web, are designed to be openly accessible in this way. Adding client attestation into otherwise open systems can significantly reduce openness for the Internet broadly. A recent “Web Environment Integrity”^[2] proposal has highlighted this risk, although such models pose a risk beyond just the web.

Attestation of client software and hardware is distinct from user authentication. User authentication verifies the identity of a user or a credential associated with a user, and is compatible with any implementation that supports the correct form of authentication. In contrast, attestation of client software and hardware places explicit restrictions on the implementations that are allowed to participate in the protocol. For services that have intentionally restricted access, such client attestation (as described in *Remote ATtestation procedureS* (RATS), RFC 9334^[3]) is a valuable security measure, particularly when used in conjunction with user authentication. However, this approach is not appropriate for openly accessible services.

Allowing clients to use a variety of software as long as it is protocol-compliant is an essential part of the IETF development process and the openness of the Internet. Although customized or open-source software can also be used to circumvent client-side security measures, the continuing viability of open software is required for continued innovation. Restricting access via attestation of software or hardware would limit the development of new protocols and extensions to existing protocols, lock users into a limited ecosystem of applications, and hamper the ability to audit implementations, conduct measurements, or perform essential security research.

If client attestation signals are used in open services to mitigate fraud or abuse, they should be designed to only signal the authenticity of a user or client without imposing strict software or hardware requirements. They should also be designed such that attestation is not required, but has a clear backup behavior when attestation is not possible. IETF-based protocols such as *Privacy Pass* [RFC 9576] attempt to provide a protocol that can be deployed in ways that promote user privacy without exposing detailed identifiers about the client systems that are being used. Fundamentally, attesting specific properties about a networking client (for example, there is some human user involved in this interaction) maintains the openness of the Internet, whereas attesting that a specific piece of software is in use does not and should be avoided.

The IAB invites those in the industry and standards community working on client attestation in open services to engage with the relevant IETF working groups (in particular, Privacy Pass^[4] and RATS^[5]), and encourages those groups to focus on defining safe deployment models for attestation and abuse prevention that will not put the openness of the Internet at risk.

Internet Community Encouraged to Submit Event Proposals for UA Day 2025

Event proposals are now being accepted for the third annual *Universal Acceptance (UA) Day*, to be held between 1 March and 30 May 2025. UA Day, held annually, is an opportunity to rally local, national, regional, and global communities and organizations to spread UA awareness and to promote UA adoption with key stakeholders.

UA is a technical best practice that ensures all valid domain names and email addresses, regardless of script, language or character length, can be equally used by all Internet-enabled applications, devices, and systems. Co-organized by the *Universal Acceptance Steering Group* (UASG) and the *Internet Corporation for Assigned Names and Numbers* (ICANN), UA Day 2025 will consist of various virtual and in-person events held by the UASG, ICANN, global partners, and regional and local organizations.

UA Day 2025 builds on the success of *UA Day 2024* and the inaugural *UA Day* in 2023. Together, the 2023 and 2024 events attracted approximately 15,000 participants worldwide across dozens of countries. These milestone events have helped mobilize technical and language communities, companies, governments and *Domain Name System* (DNS) industry stakeholders to champion UA on a global scale.

Those interested in organizing a UA Day event must complete the *UA Day Event Proposal Form*^[1] by 11 October 2024. ICANN will provide limited support for proposed UA Day events based on this group's recommendations. The following types of events are eligible for support:

- *UA Awareness*: Provide a high-level overview of UA and *Email Address Internationalization* (EAI), the benefits of being UA-ready, basic technical concepts related to UA and next steps for becoming UA-ready.
- *UA Technical Training*: Provide in-depth training on becoming EAI-ready for email system administrators and on becoming UA-ready for software developers.
- *UA Academic Curricula*: Work with academic faculty members and experts to integrate *Internationalized Domain Names* (IDNs) and UA-related topics into existing technical curricula and design a roadmap.
- *UA Adoption*: Conduct a UA adoption exercise and share challenges and solutions to becoming UA-ready, and document your experience. Please note that advance preparatory work and review are required in order to qualify for a UA Adoption event.
- *UA Regional Strategy*: Discuss appropriate mechanisms for promoting UA adoption at the local, regional, and national levels.

Proposals will be considered from all relevant organizations, including international, regional and local organizations, technology organizations and companies, open-source communities, standards bodies, email service providers, academia, industry groups, and language communities.

UA is considered a foundational requirement for the continued expansion of the Internet. Since 2009, the landscape for domain names has changed markedly—in overall number of *Top-Level Domain Names* (TLDs) available, TLD character length and scripts available. However, the checks used by many software applications to validate domain names and email addresses often use rules that do not fully support Universal Acceptance. Achieving UA ensures everybody has the ability to experience the full social and economic power of the Internet using their chosen domain name and email address that best aligns with their interests, business, culture, language, and script.

Questions can be directed to **UAProgram@icann.org**. A full UA Day event calendar will be published in due course. In the meantime, interact with the UASG on social media (X, Facebook and LinkedIn) using the hashtag **#Internet4All**.

The UASG is a community-led initiative that was formed in 2015 and funded by ICANN. It consists of volunteers from many companies, governments, and community groups. The UASG works to raise awareness of the importance of UA globally, provide free resources to organizations to help them become UA-ready, and measure the progress of UA adoption. To learn more, visit <https://uasg.tech/>

ICANN's mission is to help ensure a stable, secure, and unified global Internet. To reach another person on the Internet, you need to type an address—a name or a number—into your computer or other device. That address must be unique so computers know where to find each other. ICANN helps coordinate and support these unique identifiers across the world. ICANN was formed in 1998 as a nonprofit public benefit corporation with a community of participants from all over the world. To learn more, visit <https://icann.org>

Our Privacy Policy

The *General Data Protection Regulation* (GDPR) is a regulation for data protection and privacy for all individual citizens of the *European Union* (EU) and the *European Economic Area* (EEA). Its implementation in May 2018 led many organizations worldwide to post or update privacy statements regarding how they handle information collected in the course of business. Such statements tend to be long and include carefully crafted legal language. We realize that we may need to provide similar language on our website and in the printed edition, but until such a statement has been developed here is an explanation of how we use any information you have supplied relating to your subscription:

- The mailing list for *The Internet Protocol Journal* (IPJ) is entirely “opt in.” We never have and never will use mailing lists from other organizations for any purpose.
- You may unsubscribe at any time using our online subscription system or by contacting us via e-mail. We will honor any request to remove your name and contact information from our database.
- We will use your contact information only to communicate with you about your subscription; for example, to inform you that a new issue is available, that your subscription needs to be renewed, or that your printed copy has been returned to us as undeliverable by the postal authorities.
- We will never use your contact information for any other purpose or provide the subscription list to any third party other than for the purpose of distributing IPJ by post or by electronic means.
- If you make a donation in support of the journal, your name will be listed on our website and in print unless you tell us otherwise.

Thank You!

Publication of IPJ is made possible by organizations and individuals around the world dedicated to the design, growth, evolution, and operation of the global Internet and private networks built on the Internet Protocol. Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

The *TCP/IP Interoperability Conference*—later renamed *Interop*—began as a small workshop in August 1986. It quickly grew in scope to incorporate tutorials, and by 1988 an exhibition network connected 51 exhibitors to each other and to the global Internet. This network was designed and deployed by a group of volunteers, and it became the proving ground for many emerging technologies. In 1994, Interop added Tokyo to its international venues, where 30 years later the conference and exhibition attracts more than 120,000 visitors annually. Following an article by David Strom describing the history and evolution of the Interop show network in our previous issue, we now bring you the first installment of an article that describes how this network continues to evolve at the Tokyo Interop show. The article is by Takashi Tomine, Ryo Nakamura, and Ryota Motobayashi—all members of the team that designs and deploys their version called *ShowNet*. A second installment detailing the technologies demonstrated in the 2024 ShowNet will be published in a future issue.

Our previous issue also contained an article about the “IPv6 Mostly” experiment that was conducted during APRICOT 2024 in Bangkok. It is perhaps surprising that we are still very much living in an Internet that is heavily dependent on *IP Version 4* (IPv4) given the amount of time that has passed since the initial *IP Version 6* (IPv6) specifications were published. In our second article, Geoff Huston provides an in-depth analysis on the topic of IPv6 Transition and suggests that perhaps changes in Internet Architecture and technological developments will have us waiting a very long time before IPv4 addressing becomes obsolete.

Book reviews used to be a fairly regular feature in this journal, but it has been quite a long time since we have published any reviews. We asked Craig Partridge to review the book *The Real Internet Architecture: Past, Present, and Future Evolution*, and we hope this latest review will encourage you to send us suggestions for other books on networking and related topics. As always, you can contact us with your feedback by sending an e-mail to: ipj@protocoljournal.org

ShowNet at Interop Tokyo: A Continuously Evolving Demonstration Network

by Takashi Tomine, Ryo Nakamura, and Ryota Motobayashi

Interop Tokyo, which inherits the objectives of the Interop conference series, is the largest annual exhibition of Internet technologies in Japan. It is held yearly for three days in June. Over 500 exhibitors showcase their products and services at individual booths, and more than 120,000 people visit the venue during the exhibition, as shown in Figure 1. Moreover, a co-located conference offers several dozen sessions and keynote talks.

Figure 1: A view of the Interop exhibition in 2024.

An essential part of Interop Tokyo is *ShowNet*, the largest demonstration network built at Interop Tokyo exhibitions. ShowNet provides network connectivity for Interop exhibitors and attendees but is not limited to this service. Since Interop originates from the word “interoperability,” ShowNet conducts various interoperability tests, experiments, and demonstrations of new networking technologies. For example, in 2019, we deployed service function chaining using *Segment Routing over IPv6* (SRv6)^[1] with four SRv6-capable nodes and five SRv6 proxies^[2] from different vendors.

At that time, SRv6 was an emerging packet-forwarding paradigm, and we faced varied challenges and considerations to achieve this archetype while serving user traffic.

The knowledge we gained through the deployment was published as an Internet Draft^[3]. We have deployed and demonstrated not only routing techniques but also broader technologies, including facilities, optical transport, wireless, security, monitoring, testers, and emerging technologies, such as 5G and media over IP in recent years.

The 2024 ShowNet, featuring comprehensive technical demonstrations, consisted of more than 20 full-height racks, allowing attendees to see the devices running in production. Figure 2 shows a picture of such a ShowNet booth in 2024.

Figure 2: The ShowNet booth in 2024. Whiteboards were mounted on the side walls of each rack, where the NOC members wrote explanations about the devices, design, and technologies. Attendees could see the running devices with those explanations.

History

Interop Tokyo celebrated its 30th event in 2023. In other words, thirty years have passed since an IT trade show, *NetWorld+Interop*, landed in Japan with cutting-edge technologies such as Ethernet 10BASE-T, *Fiber Distributed Data Interface* (FDDI), *Asynchronous Transfer Mode* (ATM) with IP, *Xerox Internetwork Packet Exchange* (IPX), and Apple's *AppleTalk*. Because of a consolidation among other strong Informa sister brands, no Interop event has been held in the United States since 2023. However, Interop is still alive and well in Tokyo, and it maintains its original mission: establishment of multi-vendor interoperability.

In the early 1990s, fathers of the Internet in Japan who visited an Interop event in the US were impressed by its effectiveness—a practical display of interoperability among multi-vendor networking equipment. The groundwork to adapt the event to a Japanese audience began then, and in 1994 Tokyo became one of the host cities of *NetWorld+Interop*, with Las Vegas, Berlin, Atlanta, and Paris (Interop was merged with Novell's *NetWorld*, a similar event that occurred from 1994 to 2004).

As an essential part of the event, Interop ordinarily deploys a temporary show-floor network *InteropNet*—or *ShowNet*, varied by years or venues—to provide Internet connectivity for each exhibitor. This concept was naturally introduced for the Tokyo show too. Until 1997, the design and equipment of InteropNet was basically shared through every show during the annual world tour. Actually, for the first Tokyo show, the construction and verification work of InteropNet (for Tokyo) was held not in Japan but at the Ziff-Davis's *Hot Stage Test Facility* in Sunnyvale, California. The persons of talent for the latest network construction and operation—the *Network Operations Center* (NOC) team—were also invited globally during the initial Tokyo era.

In 1998, following the event organizer's business operations review, Tokyo decided to set up a show-floor network with a local focus. The Tokyo NOC team has focused solely on the Japanese events since that time.

After making that decision in 1998, Tokyo has refrained from using the original *InteropNet* name, and now calls its own network *ShowNet*. ShowNet has since run every year except 2020, when the COVID-19 pandemic prohibited such public gatherings. In addition to Japan's Internet technology community, diverse members from industry and academia now gather every year to continue building and demonstrating ShowNet.

Volunteers are indispensable to achieving such complex networking. Initially named *InteropNet Team Members* (ITMs), volunteers are currently called *ShowNet Team Members* (STMs) in Tokyo. This program, which includes an educational aspect for young students and engineers, continues to be an essential component of ShowNet.

Who Makes ShowNet?

Building ShowNet at the Interop Tokyo exhibition is not an easy feat, so more than 650 engineers with diverse backgrounds are now involved in the project. The NOC team includes the core members, who design the ShowNet network and conduct broad experiments and demonstrations. In recent years, the NOC team has consisted of around 30 expert volunteers from academia, carriers, vendors, etc. They use their areas of expertise and skills to manage the project. Two leaders supervise the ShowNet project; they choose the NOC team members yearly. Teams are either selected by invitation from personal and professional connections or transitioned from STMs or Contributor Members.

The STM program offers a unique opportunity for university students and junior staff from companies to obtain hands-on experience in network operations. Participants in the STM program, who are relatively young and novice network engineers, engage in building ShowNet at the venue as volunteers, and they have the opportunity to touch, configure, operate, and debug various devices and cutting-edge technologies.

This valuable experience is difficult to gain in universities or in their regular workplace. The program also allows young engineers to build and foster relationships and learn from each other by spending two weeks building ShowNet together. In recent years, around 30 slots have been available for participants in this program, but we receive more than twice as many applications each year, so the NOC team members are responsible for the selection process. Figure 3 shows the 2024 STMs.

Figure 3:
The participants in the STM program in 2024.

ShowNet Team Members engaged in building ShowNet.

The third category of engineers involved in ShowNet is the *Contributor Members* who showcase products at Interop Tokyo each year. The contributor vendors make their products and services available to ShowNet and demonstrate them on the live network during the exhibition. These members are skilled engineers from those vendors, and they help build ShowNet with their expertise in the products. The presence of the contributor members is also indispensable for building ShowNet.

A Timeline in a Year

This section briefly introduces a timeline of ShowNet in a year. We, the people involved in ShowNet, put a long-term effort into accomplishing the ShowNet project every year.

Planning

ShowNet covers broad aspects of today's networking technologies. To manage this complexity, we organize the project into working groups, each focusing on a specific field. In 2024, we had 11 working groups leading the following fields: facilities, optical transport, external connectivity, backbone network, data center and cloud, wireless network, monitoring, security, testers, 5G, and media over IP. The NOC team consisted of approximately 30 members, with each working group led by two to four NOC team members who have expertise in that group's area of interest.

Preparation for ShowNet starts in October, the year before the Interop exhibition in June. First, the two leaders gather and organize the NOC team members and begin to discuss topics and technologies that ShowNet will address in the next Interop Tokyo. Then the leaders meet monthly with all NOC team members to share and discuss the overall structure and design of demonstrations. Additionally, each working group holds meetings at least once a month, as needed.

The Contributor Members—vendors providing their products to ShowNet—join the discussion in December. The NOC team members introduce the concept for the next ShowNet and the technologies they want to adopt to the contributor members per working group. Also, the contributors propose their products and use cases they wish to showcase. The NOC team members receive these requests and integrate them into demonstrations. From then until the end of May, the demonstration contents are continuously refined, and the NOC team members consolidate everything into a concrete network design.

Hot Stage

Two weeks before the Interop Tokyo exhibition, we start building ShowNet at the Makuhari Messe exhibition hall. Building ShowNet has two phases: *Hot Stage* and *Deployment*. During hot stage, we build and test all the designs and conduct planned interoperability tests and experiments. In recent years, we have allotted eight days for the hot stage, and we hold two all-hands meetings every day, one in the morning and one in the evening, to share progress as we continue the construction of ShowNet.

When the hot stage begins, all members of the NOC team, the STM, and the contributor members gather at the venue and start building the network. First, we install every device in the right place on the racks, turn on the devices, and check their status. Checking device status is very important because some devices are transported directly from overseas to the venue, so it is necessary to ensure that they are not malfunctioning. We usually finish this process on the first day.

On the second day, we start the network setup: connect appropriate links between devices with patch cables as designed. After the physical network connections are completed, NOC members in charge of the backbone network start configuring the backbone routers with the help of the ShowNet team members. In the early days, ShowNet backbone was a simple Layer-3 network with a single *Interior Gateway Protocol* (IGP) instance. But now, ShowNet adopts several overlay technologies such as *Multiprotocol Label Switching* (MPLS), SRv6, and *Virtual eXtensible Local Area Network* (VXLAN), so we have to configure more overlays after the Layer-3 routing configuration.

The working groups other than the backbone network group prepare their demonstrations in parallel. Every part of ShowNet is built with multi-vendor equipment, so we have to check interoperability everywhere. The working groups also conduct several interoperability tests during the hot stage. These interoperability tests are beneficial for finding bugs or slight differences in implementation.

Sometimes, these bugs or differences are critical to building ShowNet, so contributor members from vendors try to fix them with their development teams.

Testing the network is always essential, even in an event network. In ShowNet, we conduct failover tests in the latter part of the hot stage—stop and resume each backbone router sequentially and confirm that routing redundancy works as expected. If troubles arise during the test, the backbone network group of the NOC team and the ShowNet team members troubleshoot and debug the problems together. This collaborative troubleshooting process is also a good hands-on experience for the junior network engineers of STM. Figure 4 shows a snapshot of a failover test.

Figure 4: A snapshot of the failover test in 2024. Red lines in the display indicate that some user segments have unexpectedly lost the connectivity, and the NOC team and ShowNet team members start to troubleshoot. The software used here is deadman^[5], which was designed and implemented for ShowNet.

Deployment

In 2024, after we finished the hot stage, we started to deploy the ShowNet network in the whole Makuhari Messe venue four days before the Interop Tokyo exhibition began. Interop Tokyo used five halls in Makuhari Messe. The ShowNet network spread to each hall with optical transport from the ShowNet booth. Every hall had a small booth on which access switches were installed for ShowNet to extend the network to all the exhibitors' booths. Electrical construction members deployed optical fibers from the ShowNet booth to the small booths in each hall and copper cables from the switches on the booths to the exhibitors' booths. After spreading the cables, the ShowNet team members connected these cables to the access switches of the ShowNet backbone and checked the correctness of Layer-1 to Layer-7 connectivity. Figure 5 shows a snapshot of such a scene.

Figure 5: Three ShowNet Team members and a NOC team member are checking deployed cables for exhibitor booths in an exhibition hall.

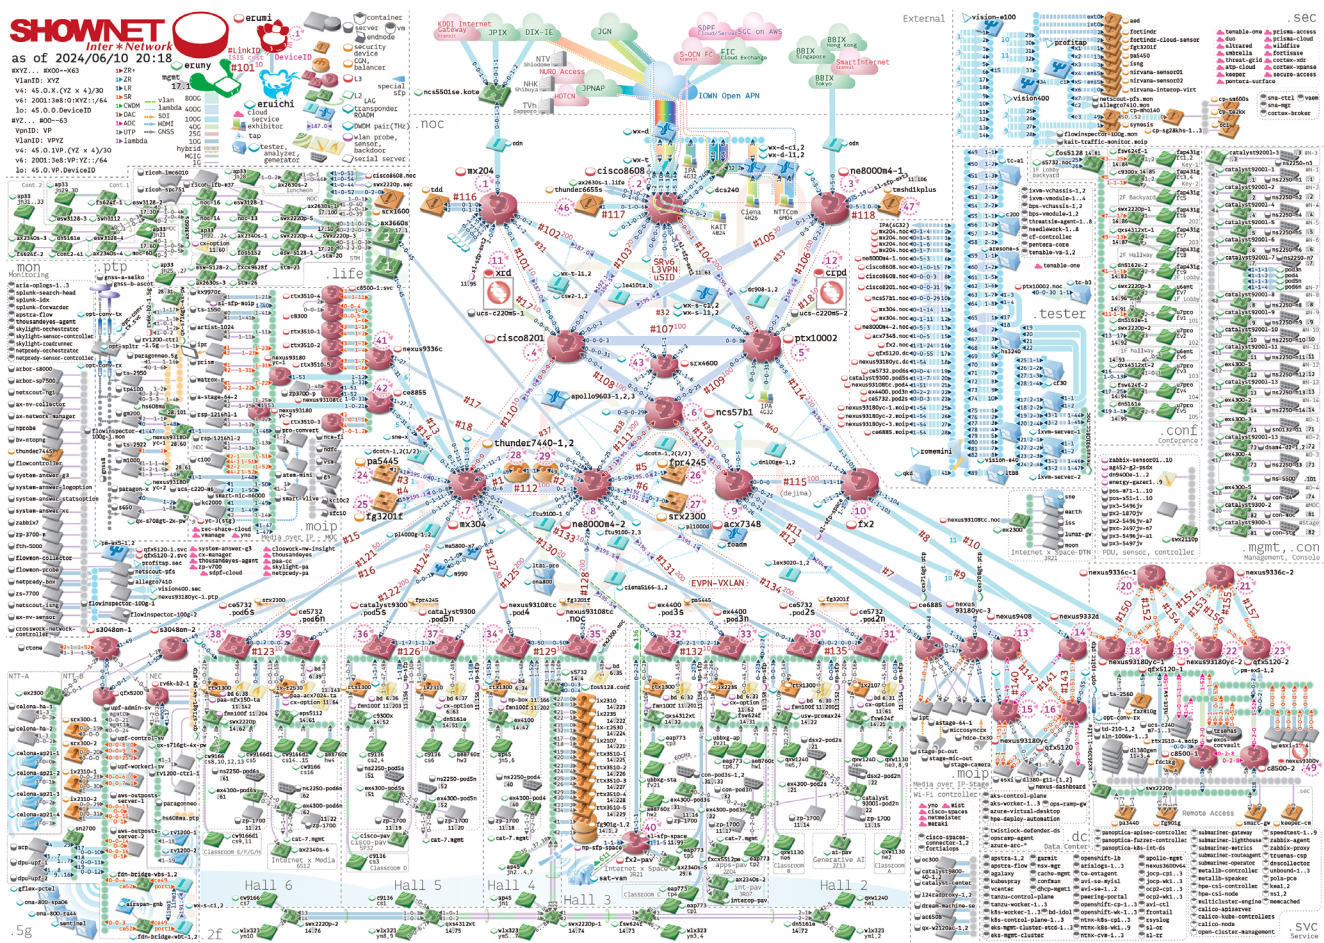

As the deployment phase begins, exhibitors of Interop Tokyo also arrive at the venue and start preparing their booths. ShowNet provides Internet connectivity for the demonstrations held in their booths. If they have any problems on the ShowNet network, they go to the *ShowNet Service Counter* and describe their problem, and we start to identify and resolve it. Usually, problems in this phase are caused by physical things like a cut cable or mis-connection of cables or access switches, but sometimes some logical bugs cause critical challenges. Such bugs are sometimes difficult to solve because we must fix them before the exhibition starts.

It is also crucial to ensure the visibility and presentation of the equipment and services contributed to ShowNet. After the whole ShowNet network is built, we tidy up the ShowNet booth. We try to ensure that every piece of equipment inside the racks is presented well, because it is not only a device but also an exhibit. We also post captions for all equipment and prepare description slides for attendees.

After we finish all the processes for building the ShowNet, we complete the network diagram. Figure 6 shows the network diagram of ShowNet 2024. You can see all the devices, links, services, and designs of ShowNet 2024 on this diagram. One of the NOC members creates the diagram. From the hot stage onward, the same member continuously monitors all the design and configuration changes and keeps the diagram up-to-date. Eventually, the diagram captures all of the ShowNet network on a single sheet. This diagram is an essential tool for ShowNet: engineers use it to grasp the overall network design, communicate and share changes, and troubleshoot problems. The diagram is practical and functional, especially when building the network and troubleshooting.

Figure 6: Diagram of the ShowNet network at Interop Tokyo 2024. The full-size version is available^[6]. Green icons indicate Layer-2 devices, red icons are Layer-3, and yellow icons are Layer-4 and above devices. The icons in the diagram are also available under the Creative Commons license^[7].

Exhibition

The Interop Tokyo exhibition usually starts on a Wednesday in mid-June and lasts three days. When it starts, we begin operating the ShowNet network and also offer some presentations for attendees. ShowNet is one of the main parts of Interop Tokyo, so many attendees come to the ShowNet booth. Attendees can see the demonstrations, learn about the technologies, observe the devices running in the racks, and see and feel the functions that run on ShowNet.

During the exhibition, ShowNet members, especially the NOC team members, work on showcasing the ShowNet network. The NOC room inside the ShowNet booth is equipped with large screens that show several tools monitoring the network status and security, as shown in Figure 7. The NOC team members operate ShowNet from there, and attendees can observe them; actually, the NOC room is also a part of the show. In addition, the NOC team members conduct tours, called *ShowNet Walking Tours*, during the exhibition. Participants on the tours can walk around each ShowNet rack with a NOC member and observe the running devices, and the NOC member will answer any questions. Figure 8 captures a scene from one of the tours. The NOC team members also give several presentations at the ShowNet booth and in session rooms at the exhibition.

Figure 7: The NOC room on the exhibition floor, visible to attendees.

Tear-Down

After the 2024 exhibition ended at 5 p.m. on Friday, we started to tear down the ShowNet network. Our contract required that we vacate the halls by midnight. First, the NOC team and contributor members shut down devices, a requirement before they could be powered off. Next, we shut off all power supplies, unplugged the patch cables, unmounted the devices, and returned them to the contributors. After that, the NOC and ShowNet team members wound up all cables and cleaned up all racks for use next year. Figure 9 shows the racks during tear-down.

Conclusion

The ShowNet network is a unique environment. It not only provides Internet connectivity for exhibitors and attendees, it also displays a large-scale ephemeral event network that will demonstrate emerging and cutting-edge technologies. ShowNet conducts various interoperability tests, experiments, and demonstrations with numerous devices contributed by multiple vendors. Furthermore, ShowNet offers an invaluable opportunity for engineers to collaborate with diverse engineers from different fields. We believe that the connections and relationships among them established through ShowNet have contributed to revitalizing network communities. In addition, it has more than 30 years of experience and adds to our knowledge to handle these cutting-edge trials. Interop Tokyo will continue this work inherited from US Interop.

Acknowledgments

We would like to express our gratitude to everyone around the world who has been involved in all Interop events, from the past to the present.

Figure 8: ShowNet Walking Tour: NOC team members explain the network to attendees in front of each rack.

Figure 9: A scene of the tear-down process in 2024. All devices were unmounted from the racks.

TAKASHI TOMINE received a Master’s degree from Keio University, Japan, and finished his Ph.D. program without a dissertation at Keio University. He is now an Associate Senior Research Engineer at the National Astronomical Observatory of Japan. He has been an Interop Tokyo ShowNet NOC team generalist since 2013. His research interests include network operation, international research educational networks, and cybersecurity. He can be reached at: **tomine@interop-tokyo.net**

RYO NAKAMURA received his Ph.D. degree in Information Science and Technology from the University of Tokyo, Tokyo, Japan, in 2017. He is currently an Associate Professor at the Information Technology Center, the University of Tokyo, where he operates the university’s campus network. His research interests include networking in operating systems, network virtualization, and network operations. Since 2009, he has been involved in Interop Tokyo ShowNet, as a ShowNet team member until 2011, and as a member of the NOC team from 2012 to the present. He has been primarily responsible for the backbone network of ShowNet, and led demonstrations of SDN-related technologies from 2013 to 2017. He can be reached at: **ryo@interop-tokyo.net**

RYOTA “ROY” MOTOBAYASHI holds a Bachelor of Engineering from Shinshu University and is qualified as CISSP, Japan’s Registered Information Security Specialist and Information Technology Engineer (Class I and Network Specialist). He went through various networking-related projects, from hardware design to corporate strategy planning for NEC Corporation 1988-2023. Since 2024, he has worked for Telecom Engineering Center, a certification body in Japan. His long-term contributions to Interop Tokyo are NOC 1994–1996, NOC Advisory 2006–2017, and Program Committee 2004–2023. He can be reached at: **jj1wt1@jar1.com**

The IPv6 Transition

by Geoff Huston

The state of the transition to IPv6 within the public Internet continues to confound us. RFC 2460^[1], the first complete effort at a specification of the IPv6 protocol, was published in December 1998, more than 25 years ago. The entire point of IPv6 was to specify a successor protocol to IPv4 because of the prospect of running out of IPv4 addresses. Yet while the public Internet ran out of IPv4 addresses more than a decade ago, the contrary observation is that this network platform is still largely sustained through its use of IPv4. The transition of the public Internet to the IPv6 protocol has been going on for 25 years now, and if there were any urgency to be instilled in the transition effort by the prospect, and then the reality, of IPv4 address exhaustion, then we’ve been living with exhaustion a very long time now, and we’re largely inured to it. It’s probably time to ask the question again: How much longer will this transition to IPv6 take?

At APNIC Labs^[0] we’ve been measuring the uptake of IPv6 for more than a decade now. We use a measurement approach that looks at the network from the perspective of the Internet user base. What we measure is the proportion of users who can reach a published service when the only means to do so is by using IPv6. The data is gathered using a measurement script embedded in an online ad, and the ad placements are configured to sample a diverse collection of end users continually.

Figure 1 displays the IPv6 adoption report showing our measurements of IPv6 adoption across the Internet user base from 2014 to 2024.

Figure 1: IPv6 Adoption – 2014 to 2024. (APNIC Labs Data)

On the one hand, Figure 1 is one of those classic “up and to the right” Internet curves that shows continues growth in the adoption of IPv6. The problem is in the values in the scale of the Y-axis. The issue here is that in 2024 we were at a level where only a little more than one-third of the Internet user base could access an IPv6-only service. Everyone else, now in 2025, is still in an IPv4-only Internet.

This situation appears to be completely anomalous. It's been more than a decade since the supply of "new" IPv4 addresses was exhausted, and the Internet has not only been running on empty, but also is now tasked to span an ever-increasing collection of connected devices—and it has achieved this feat without collapsing. In late 2024 it is variously estimated (or guessed!) that some 20 billion devices used the Internet, yet the Internet IPv4 routing table encompasses only some 3.03 billion unique IPv4 addresses. The original "end-to-end" architecture of the Internet assumed that every device was uniquely addressed with its own IP address, yet the Internet is now sharing each individual IPv4 address across an average of 6 devices, and apparently it all seems to be working! If "end-to-end" was the sustaining principle of the Internet architecture in the 1980's, then as far as the current users of IPv4-based access and services across the public Internet are concerned, it's all over!

IPv6 was meant to address these issues, and the 128-bit wide address fields in the protocol have sufficient address space to allow every connected device to use its own unique address. The design of IPv6 was intentionally very conservative. To a first level of approximation IPv6 is simply "IPv4 with bigger addresses." There are also some changes to fragmentation controls, the address acquisition protocols [*Address Resolution Protocol* (ARP) vs. *Neighbour Discovery*], and the *IP Options* fields, but the upper-level transport protocols are unchanged. IPv6 was intended to be a largely invisible change to a single level in the protocol stack, and definitely not intended to be a massive shift to an entirely novel networking paradigm.

In the sense of representing a very modest incremental change to IPv4, the IPv6 design achieved its objective, but in so doing it necessarily provided little in the way of any marginal improvement in protocol use and performance. IPv6 was no faster, no more versatile, no more secure than IPv4. The major benefit of IPv6 was to mitigate the future risk of IPv4 address exhaustion. In terms of conventional market operations, many markets, including that of the Internet, apply a hefty discount factor to future risk. The result is that the level of motivation to undertake this transition is highly variable given that the expenditure to deploy this second protocol does not immediately realize tangible benefits in terms of lower cost, greater revenue, or greater market share. In a networking context where market-based coordination of individual actions is essential, a level of diversity of views of the net value of running a dual-stack network often leads to reluctance on the part of individual actors and sluggish progress of the common outcome of the transition. As a result, there is no common sense of urgency.

To illustrate this fact, we can look at the time series shown in Figure 1 and ask the question: "If the growth trend of IPv6 adoption continues at its current rate, how long will it take for every device to be IPv6-capable?"

Asking this question is the same as looking at a linear trend line placed over the data series used in Figure 1 for the date when this trend line reaches 100%. Using a least-squares best fit for this data set from January 2020 to the present day, and using a linear trend line, we can come up with Figure 2.

This exercise predicts that we'll see completion of this transition in late 2045, or some 20 years into the future. It must be noted that there is no deep modelling of the actions of various service providers, consumers, and network entities behind this prediction. The only assumption that drives this prediction is that the forces that shaped the immediate recent past are unaltered when looking into the future. In other words, this exercise simply assumes that "tomorrow is going to be a lot like today."

Figure 2: IPv6 Adoption – Projection.

The projected date in Figure 2 is less of a concern than the observation that this model predicts a continuation of this transition for a further two decades. If the entire concept of IPv6 was to restore a coherent address plan across the collection of Internet-connected devices, then placing this model of coherent unique device addressing in abeyance for some 30 years, from around 2015 through to 2045, leads to questioning the role and value of such a unique device addressing framework in the first place! If we can operate a fully functional Internet without such a coherent end-device address architecture for three decades, why would we feel the need to restore address coherence at some point in the future? What's the point of IPv6 if it's not address coherence?

Something has gone very wrong with this IPv6 transition, and that's what I will examine in this article.

A Little Bit of History

By 1990 it was clear that IP had a problem. The Internet was still tiny at the time, but the growth patterns were exponential, doubling in size every 12 months. We were stressing out the pool of Class B IPv4 addresses, and in the absence of any corrective measures this address pool would be fully depleted in 1994 (Figure 3).

Frank Solensky presented predictions at the 18th meeting of the *Internet Engineering Task Force (IETF)*^[10].

Figure 3: IPv4 Depletion Predictions, Frank Solensky.

We were also placing pressure on the routing system at the time. The deployed routers in 1992 had only enough memory to support a further 12 to 18 months of routing growth. The combination of these routing and addressing pressures was collectively addressed in the IETF at the time under the umbrella of the ROAD effort, as described in RFC 1380^[2].

There was a collection of short-, medium- and longer-term responses that were adopted in the IETF to address the problem. In the short term, the IETF dispensed with the class-based IPv4 address plan and instead adopted a variably sized address prefix model. Routing protocols, including the *Border Gateway Protocol (BGP)*, were quickly modified to support these classless address prefixes. Variably sized address prefixes added additional burdens to the address-allocation process, and in the medium term the Internet community adopted the organisational measure of the *Regional Internet Registry (RIR)* structure to allow each region to resource the increasingly detailed operation of address-allocation and registry functions for their region. These measures increased the specificity of address allocations and provided the allocation process with a more exact alignment to determine adequate resource allocations that permitted a more diligent application of relatively conservative address-allocation practices. These measures realized a significant increase in address usage efficiency. The concept of "address sharing" using *Network Address Translation (NAT)*^[3] also gained some traction in the *Internet Service Provider (ISP)* world. Not only did NATs dramatically simplify the address administration processes in ISPs, they also played a major role in reducing the pressures on overall address consumption.

The adoption of these measures across the early 1990's pushed a 2-year imminent crisis into a more manageable decade-long scenario of depletion. However, they were not considered to be a stable long-term response. It was thought at the time that an effective long-term response really needed to extend the 32-bit address field used in IPv4. Then the transition from mainframe to laptop was well underway in the computing work, and the prospect of further reductions in size and expansion of deployment in smaller embedded devices was clear. An address space of 4 billion was just not large enough for what was likely to occur in the coming years in the computing world.

But in looking at a new network protocol with a vastly increased address space, the IETF realized that any such change would not be backward-compatible with the installed base of IPv4 systems. As a result, there were a few divergent schools of thought as to what to do. One approach was to jump streams and switch over to use the Connectionless Transport profile of the *Open Systems Interconnection* (OSI) Protocol Suite and adopt *OSI Network Service Access Point Address* (NSAP) addresses along the way. Another was to change as little as possible in IP except the size of the address fields. And numerous ideas were thrown about in the area of proposing significant changes to the IP model.

By 1994 the IETF had managed to settle on the minimal change approach, which was IPv6. The address field was expanded to 128 bits, a *Flow ID* field was introduced, fragmentation behaviour was altered and pushed into an optional header, and ARP was replaced with *multicast*.

The main thing to note was that IPv6 did not offer any new functionality that was not already present in IPv4. It did not introduce any significant changes to the operation of IP. It was just IP with larger addresses.

Transition

While the design of IPv6 consumed a lot of attention at the time, the concept of transition of the network from IPv4 to IPv6 did not.

Given the runaway adoption of IPv4, there was a naive expectation at that time that IPv6 would similarly just take off, and there was no need to give the transition much thought. In the first phase, we would expect to see applications, hosts, and networks adding support for IPv6 in addition to IPv4, transforming the Internet into a dual-stack environment. In the second phase we could then phase out support for IPv4. The expectation was that the process would take a few years.

This plan had numerous problems. Perhaps the most serious one was a resource-allocation problem. The Internet was growing extremely quickly, and most of our effort was devoted to keeping pace with demand. More users, more capacity, larger servers, more content and services, more responsive services, more security, better defence. All of these factors shared a common theme: *scale*.

We could either concentrate our resources on meeting the incessant demands of scaling, or we could work on IPv6 deployment. The short- and medium-term measures that we had already taken had addressed the immediacy of the problems of address depletion, so in terms of priority, scaling was a far more important priority for the industry than IPv6 transition. Through the decade from 1995 to 2005 the case for IPv6 quietly slumbered in terms of mainstream industry attention.

IPv4 addresses were still available, and the use of *Classless Inter-Domain Routing* (CIDR) and far more conservative address-allocation practices had pushed the prospect of IPv4 address depletion out by more than a couple of decades. Many more pressing operational and policy issues for the Internet absorbed the industry's collective attention in those days.

However, this period of respite was brief. The scaling problem accelerated by a whole new order of magnitude in the mid 2000's with the introduction of the iPhone and its brethren^[4]. Suddenly this scale problem was not just of the order of tens or even hundreds of millions of households and enterprises, it transformed into a problem of billions of individuals and their personal devices, and it added mobility into the mix. As a taste of a near-term future, the production scale of these "smart" devices quickly ramped up into annual volumes of hundreds of millions of units. The entire reason why IPv6 was a necessity was coming into fruition, but at this stage we were just not ready to deploy IPv6 in response. Instead, we rapidly increased our consumption of the remaining pools of IPv4 addresses and we supported the first wave of large-scale mobile services with IPv4. Dual stack was not even an option in the mobile world at the time. The rather bizarre economics of financing 3G infrastructure meant that dual-stack infrastructure in a 3G platform was impractical, so IPv4 was used to support the first wave of mobile services. This situation quickly turned to IPv4 and NATs as the uptake of mobile services gathered momentum.

At the same time the decentralised nature of the Internet was hampering IPv6 transition efforts. What point was there in developing application support for IPv6 services if no host had integrated IPv6 into its network stack? What point was there in adding IPv6 to a host networking stack if no ISP was providing IPv6 support? And what point was there for an ISP to deploy IPv6 if no hosts and no applications would use it? In terms of IPv6 at this time, nothing happened.

The operating-system sector made the first efforts to try to break this impasse of mutual dependence, and fully functional IPv6 stacks were added to the various flavours of Linux, Windows, and MacOS, as well as in the mobile host stacks of iOS and Android.

But even these implementations were not enough to allow a transition to achieve critical momentum. It could be argued that this situation made the IPv6 situation worse and set back the transition by some years.

The problem was that with IPv6-enabled hosts there was some desire to use IPv6, but these hosts were isolated “islands” of IPv6 sitting in an ocean of IPv4. The concentration of the transition effort then fixated on various tunnelling methods to tunnel IPv6 packets through the IPv4 networks (Figure 4). While you can perform this tunnelling manually when you have control over both tunnel endpoints, this approach was not that useful. What we wanted was an automated tunnelling mechanism that took care of all these details.

Figure 4: Phase 1 of the IPv6 Transition.

The first such approach that gathered some momentum was 6to4^[5]. The first problem with 6to4 was that it required public IPv4 addresses, so it could not provide services to IPv6 hosts that were behind a NAT. The more critical problem was that firewalls had no idea how to handle these 6to4 packets, and the default action when in doubt is to deny access. So 6to4 connections encountered an average of a 20 to 30% failure rate in the public Internet, making it all but unusable as a mainstream service. The NAT traversal issue was also a problem, so a second auto-tunnel mechanism was devised that performed NAT sensing and traversal. This mechanism, *Teredo*^[6], was even worse in terms of failure rates, and some 40% of Teredo connection attempts were observed to fail^[7].

Not only were these Phase 1 IPv6 transition tools extremely poor performers, as they were so unreliable, but even when they worked the connection was both fragile and slower than IPv4. The result was perhaps predictable, even if unfair. It was not just the transition mechanisms that were viewed with disfavour, but IPv6 itself also attracted some opprobrium.

Up until around 2011 IPv6 was largely ignored as a result in the mainstream of the public Internet. A small number of service providers tried to deploy IPv6, but in each case they found themselves with a unique set of challenges that they and their vendors had to solve, and without a rich set of content and services on IPv6, the value of the entire exercise was highly dubious! So, nothing much happened.

Movement at Last!

It wasn't until the central IPv4 address pool that the *Internet Assigned Numbers Authority* (IANA) managed was depleted at the start of 2011, and the first RIR, APNIC, ran down on its general allocation pool in April of that year, that the ISP industry started to pay more focussed attention to this IPv6 transition.

At around the same time, the mobile industry commenced its transition into 4G services. The essential difference between 3G and 4G was the removal of the *Point-to-Point Protocol* (PPP) tunnel through the radio access network from the gateway to the device and its replacement by an IP environment. This solution allowed a 4G mobile operator to support a dual-stack environment without an additional cost component, and it was a major enabler for IPv6. Mapping IPv4 into IPv6 (or the reverse) is fragile and inefficient for service providers as compared to native dual stack. In the 6-year period from 2012 to the start of 2018, the level of IPv6 deployment rose from 0.5 to 17.4%. At this stage IPv6 was no longer predominately tunnelled, as many networks supported IPv6 in native mode (Figure 5).

Figure 5: Phase 2 of the IPv6 Transition.

The problem here was that we were late with this phase of the transition. The intention of this transition was to complete the work and equip every network and host with IPv6 before we ran out of IPv4 addresses (Figure 6).

The position we had arrived at by 2012 was far more challenging. The pools of available IPv4 address space were rapidly depleting, and the regional address policy communities were introducing highly conservative address-allocation practices to eke out the remaining address pools. At the same time the amount of IPv6 uptake was minimal. The transition plan for IPv6 was largely broken (Figure 7).

Figure 6: The IPv6 Transition Plan.

Figure 7: The IPv6 Transition Plan in 2012.

NATs and Address Scarcity Pressures

At this point there was no choice for the Internet, and to sustain growth in the IPv4 network while we were waiting for IPv6 to gather momentum we turned to NATs. NATs were a challenging subject for the IETF. The entire concept of coherent end-to-end communications was to eschew active middleware such as NATs in the network. NATs created a point of disruption in this model, thereby causing a critical dependency upon network elements. They removed elements of network flexibility from the network and at the same time reduced the set of transport options to the *Transmission Control Protocol* (TCP) and *User Datagram Protocol* (UDP).

The IETF resisted any efforts to standardise the behaviour of NATs, fearing perhaps that standard specifications of NAT behaviour would bestow a legitimacy on the use of NATs, an outcome that many IETF participants were very keen to avoid.

This aversion did not reduce the level of impetus behind NAT deployment. We had run out of IPv4 addresses and IPv6 was still a distant prospect, so NATs were the most convenient solution. What this action did achieve was to create a large variance of NAT behaviours^[15] in various implementations, particularly with respect to UDP behaviours. This situation has exacted a cost in software complexity where an application needs to dynamically discover the type of NAT (or NATs) in the network path if it wants to perform anything more complex than a simple two-party TCP connection.

Despite these issues NATs were a low-friction response to IPv4 address depletion, where individual deployment could be undertaken without incurring external dependencies. On the other hand, deployment of IPv6 was dependant on other networks and servers also deploying IPv6. NATs made highly efficient use of address space for clients, as not only could a NAT use the 16-bit source port field, but by time-sharing the NAT binding, NATs achieved an even greater level of address efficiency. A major reason why we've been able to sustain an Internet with tens of billions of connected devices is through the widespread use of NATs.

Server architectures were also changing. The introduction of *Transport Layer Security* (TLS)^[8] into the web-server world included a point in TLS session establishment where the client informs the server platform the name of the service that it intends to connect to. Not only did this information allow TLS to validate the authenticity of the service point, but it also allowed a server platform to host an extremely large collection of services from a single platform (and a single platform IP address) and perform individual service selection via this *TLS Server Name Indication* (SNI). The result is that server platforms perform service selection by name-based distinguishers [*Domain Name System* (DNS) names] in the session handshake, allowing a single server platform to serve large numbers of individual servers. The implications of the widespread use of NATs and the use of server sharing in service platforms has taken the pressure off the entire IPv4 address environment.

One of the best ways to illustrate the changing picture of address scarcity pressure in IPv4 is to look at the market price of address transfers over the past decade. Scarcity pressure is reflected in the market price. Figure 8 shows a time series of the price of traded IPv4 addresses.

The period of the COVID outbreak coincided with a rapid price escalation over 2021, but the price has since declined to between \$30 and \$40 per address, and this price, admittedly over a \$16 range from \$26 to \$42 per address, was stable across 2024. This price data indicates that IPv4 addresses were still in demand in 2024, but the level of demand appears to have equilibrated against available levels of supply, implying that there was no scarcity premium in evidence in the address market in 2024. This data points to the combination of the efficacy of NATs in extending the efficiency of IPv4 addresses by using the 16 bits of port address space plus the additional benefits of using shared address pools.

Figure 8: Market Prices of IPv4 Address Transfers. (Data from Hilco Streambank)

However, it's not just IPv4 that has alleviated the scarcity pressure for IPv4 addresses. Figure 1 indicates that over the past decade the level of IPv6 adoption has risen to encompass some 40% of the user base of the Internet. Most applications, including browsers, support *Happy Eyeballs*^[9], which is a shorthand notation for preferring to use IPv6 over IPv4 if both protocols are available for use in support of a service transaction. As network providers roll out IPv6 support, the pressure on their IPv4 address pools for NAT use is relieved because the applications prefer to use IPv6 where available.

How Much Longer?

Now that we are somewhere in the middle of this transition, the question is: How much longer is this transition going to take?

This question seems simple, but it does need a little more elucidation. What is the “end point” when we can declare the transition to be over? When will this transition be “complete”? Is it the time when the Internet has no more IPv4-based traffic? Or is it the time when the Internet no longer requires IPv4 in public services? Or do we mean the point when IPv6-only services are viable? Or perhaps we should look at the market for IPv4 addresses and define the endpoint of this transition at the time when the price of IPv4 addresses completely collapses? Perhaps we can take a more pragmatic position here and rather than looking for completion as the point when the Internet is completely bereft of all use of IPv4 addresses and their use, we could define “completion” as the point when use of IPv4 is no longer necessary. The implication would be that when a service provider can operate a viable Internet service using only IPv6 and having no supported IPv4 access mechanisms at all, then we would have completed this transition.

What is the implication? Certainly, the ISP needs to provide IPv6. But all the connected edge networks and the hosts in these networks need to support IPv6 as well. After all, the ISP has no IPv4 services at this point of completion of the transition. It also implies that all the services the clients of this ISP use must be accessible over IPv6. Yes, this accessibility includes all the popular cloud services and cloud platforms, all the content streamers, and all the content-distribution platforms. It also includes specialised platforms such as Slack, Xero, Atlassian, and similar platforms. The data published at the Internet Society's *Pulse* page^[11] reports that only some 47% of the top 1000 web sites are reachable over IPv6, so clearly a lot of service platforms have work to do, and this work will take more time.

When we look at the IPv6 adoption data for the United States, another somewhat curious anomaly is evident (Figure 9).

Figure 9: IPv6 Adoption in the US - 2014 to 2024. (APNIC Labs Data)

The data shows that the level of IPv6 use in the US has remained constant since mid-2019. Why is there no further momentum to continue with the transition to IPv6 in this part of the Internet? I would offer the explanation that the root cause is a fundamental change in the architecture of the Internet.

Changes to the Internet Architecture

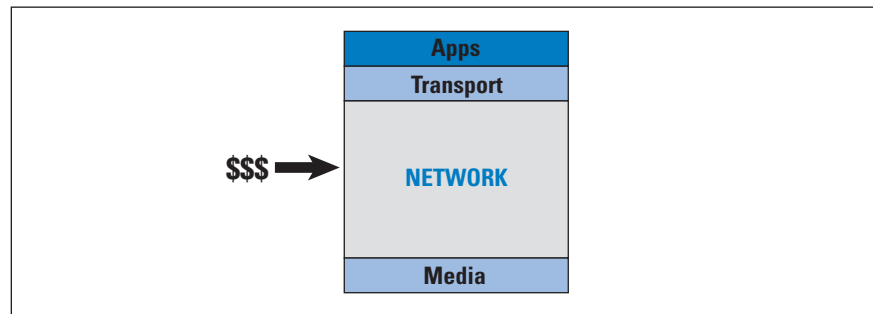

The major change to the Internet architecture is a shift away from a strict address-based architecture. Clients no longer need to use a persistent unique public IP address to communicate with servers and services. And servers no longer need to use a persistent unique public IP address to provide clients with access to the service or content. Address scarcity takes on an entirely different dimension when unique public addresses are not required to number every client and every distinct service.

Some of the clues that show the implications of this architectural shift are evident when you look at the changes in the internal economy of the Internet. The original model of IP was a network protocol that allowed attached devices to communicate with each other.

The network providers supplied the critical resource to allow clients to consume content and access services. At the time the costs of the network service dominated the entire cost of the operation of the Internet, and in the network domain distance was the dominant cost factor.

Network providers who offered distance services (so-called “transit providers”) were the dominant ones. Little wonder that we spent a lot of our time working through the issues of interconnection of network service providers, customer/provider relationships, and various forms of peering and exchanges. The ISPs were in effect brokers in the rationing of the scarce resource of distance capacity. This economy was a classic network economy (Figure 10).

Figure 10: The Classic Network Economy.

For many years the demand for communications services outstripped available inventory, and price was used as a distribution function to moderate demand against available capacity. However, everything changed because of the effects of *Moore's Law* consistently changing the cost of computing and communications.

The most obvious change has been in the count of transistors in a single integrated circuit. Figure 11 shows the transistor count over time since 1970.

The latest production chips at the end of 2024 were the Apple M3, a 3nm chip with up to 92 billion transistors. With perhaps the possible exception of powering AI infrastructure, these days processing capability is an abundant and cheap resource.

This continual refinement of integrated-circuit production techniques affects the size and unit cost of storage (Figure 12). While the speed of memory has been relatively constant for more than a decade, the unit cost of storage has been dropping exponentially for many decades. Storage is also an abundant resource.

These changes in the capabilities of processing have also profoundly affected communications costs and capacities. The constraining factor in fibre communications systems is the capabilities of the digital signal processors and the modulators. As silicon capabilities improve, it's possible to improve the signal-processing capabilities of transmitters and receivers, which allows for a greater capacity per wavelength on a fibre circuit (Figure 13).

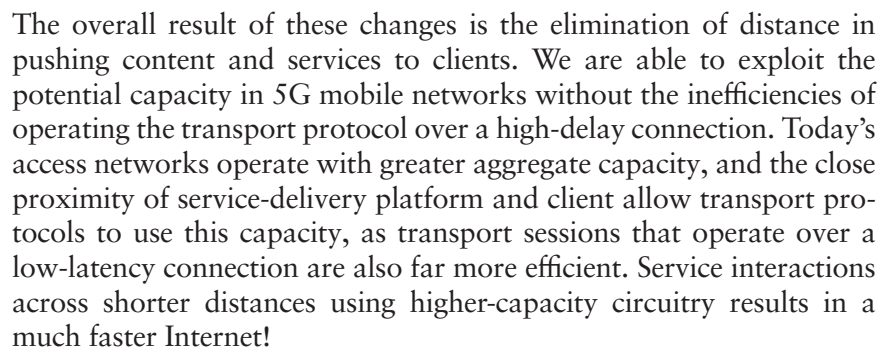

Figure 12: Computer Memory and Storage Unit Costs over Time^[13].

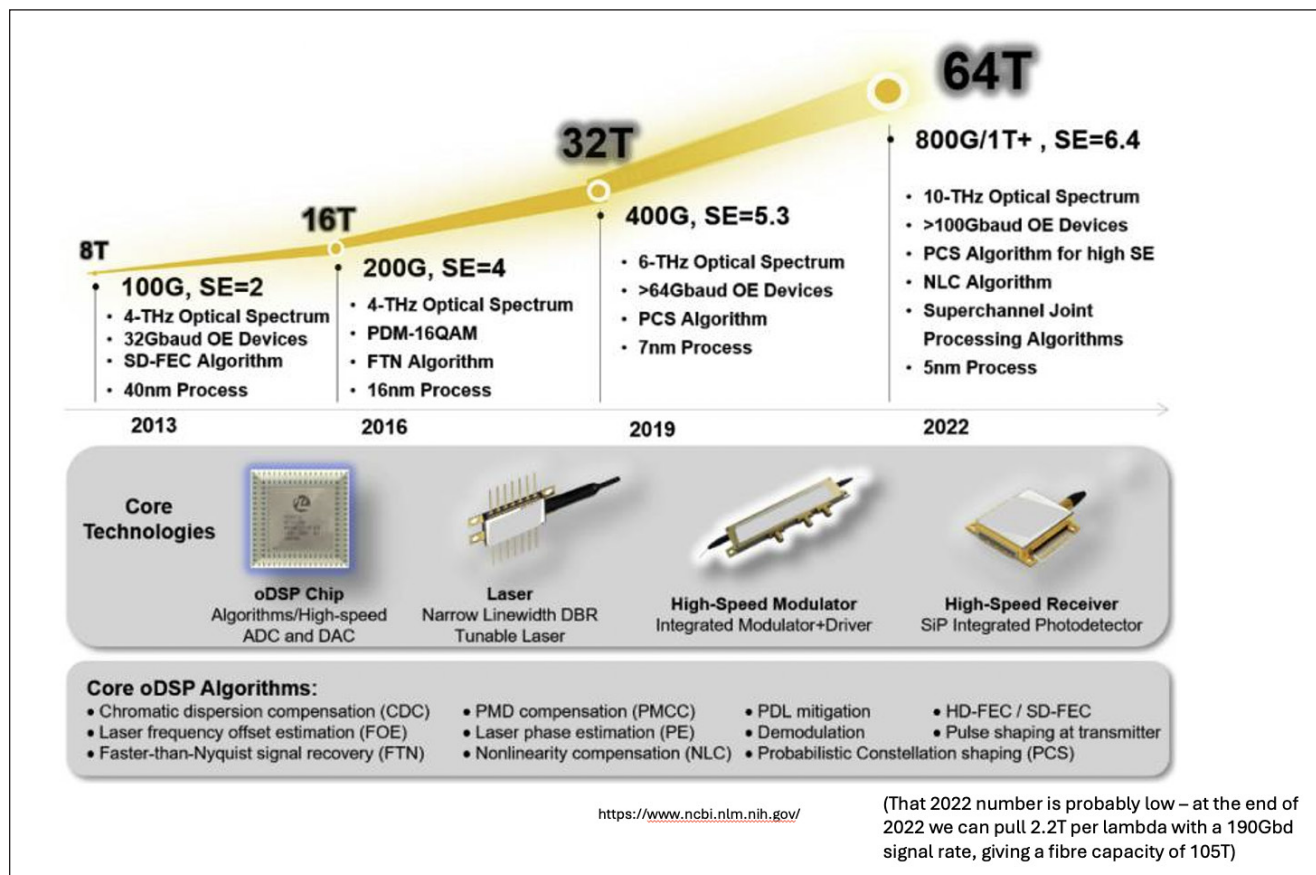

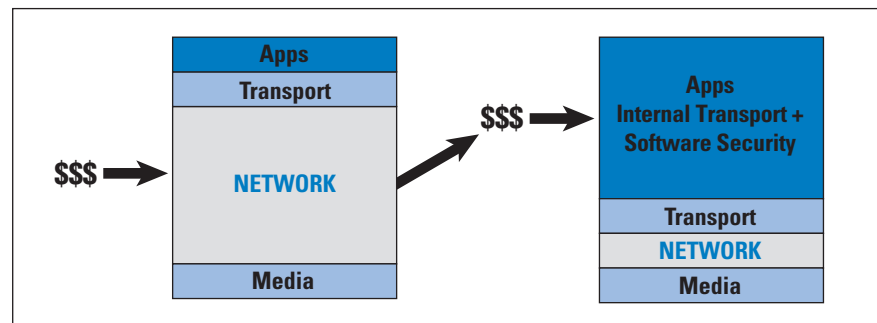

Figure 13: Fibre Capacity over Time^[14].

In addition to being bigger and faster, this environment of abundant communications, processing, and storage capacity is operating in an industry that enjoys significant economies of scale. And much of this environment is funded by capitalising a collective asset that is infeasible to capitalise individually, namely the advertisement market. The result of these changes is that a former luxury service accessible to just a few has been transformed into an affordable mass-market commodity service available to all.

However, it's more than just bigger, faster, and cheaper. This shift into abundance of basic inputs for the digital environment has changed the economics of the Internet as well. The role of the network as the arbiter of the scarce resource of communication capability has dissipated. In response, the economic focus of the Internet economy has shifted up the protocol stack to the level of applications and services (Figure 14).

Figure 14: The Transformation of the Network Economy.

Now let's return to the situation of the transition to IPv6. It is left to networks and network operators to make the investments to switch to a dual-stack platform initially (and then ultimately to remove support for IPv4). But this change is really not visible, or even crucial, to the content or service world. If IPv4 and NATs perform the carriage function adequately, then there is no motivation for the content and service operators to pay a network a premium to have a dual-stack platform.

It's domain names that operate as service identifiers, it's domain names that underpin the users' tests of authenticity of the online service, and it's the DNS that increasingly is used to steer users to the "best" service-delivery point for content or service. From this perspective addresses, IPv4 or IPv6, are not the critical resource for a service and its users. The "currency" of this form of CDN networking is *names*.

So where are we in 2025? Today's public Internet is largely a service-delivery network using CDNs to push content and service as close to the user as possible. The multiplexing of multiple services onto underlying service platforms is an application-level function tied largely to TLS and service selection using the SNI field of the TLS handshake. We use the DNS to perform "closest match" service platform selection. It's the objective of a CDN to directly attach to the access networks where its users are located, and the result is a BGP routing table inside the CDN with an average *Autonomous System (AS) Path Length* that is intended to converge to 1!

From this respect the DNS has supplanted the role of routing! We may not route “names” in today’s Internet, but it is certainly operating in a way that is largely isomorphic to such a named data network.

This architectural change has a few additional implications for the Internet. TLS, like it or not (and there is much to criticise about the robustness of TLS), is the sole underpinning of authenticity in the Internet. *Domain Name System Security Extensions* (DNSSEC) has not gathered much momentum to date. The protocol is too complex, too fragile, and just too slow to use for most services and their users. Some value its benefits highly enough that they are prepared to live with its shortcomings, but that’s not the case for most name holders and most users, and no amount of passionate exhortations about DNSSEC will change this situation! It supports the view that it’s not the mapping of a name to an IP address that’s critical. What is critical is that the named service can demonstrate that it operated by the owner of the name. Secondly, *Resource Public Key Infrastructure* (RPKI), the framework for securing information being passed in the BGP routing protocol, is really not all that useful in a service network where there is no routing!

The implication of these observations is that the transition to IPv6 is progressing very slowly not because this industry is chronically stupid or short-sighted—something else is going on here. IPv6 alone is not critical to a large set of end-user service-delivery environments. We’ve been able to take a 1980’s address-based architecture and scale it more than a billion-fold by altering the core reliance on distinguisher tokens from addresses to names. There was no real lasting benefit in trying to leap across to just another 1980’s address-based architecture (with only a few annoyingly stupid differences, apart from longer addresses!).

Where are we heading in the longer term? We are pushing everything, including value itself, out of the network and over to applications. Transmission infrastructure is becoming an abundant commodity. Network-sharing technology (multiplexing) is decreasingly relevant. We have so much network and computing resources available to us that we no longer have to take consumers to service-delivery points. Instead, we are taking services towards consumers and using the content frameworks to replicate servers and services. With so much computing and storage, the application is becoming the service, rather than just a window to a remotely operated service.

If that’s the case, then will networks matter anymore? The last couple of decades have seen us stripping out network-centric functionality and replacing it with an undistinguished commodity packet-transport medium. It’s fast and cheap, but it’s up to applications to overlay this common basic service with their own requirements. As we push these additional functions out to the edge and ultimately off the network altogether, we are left with simple dumb packet pipes!

You could argue that this situation is nothing new, and it's a continuation of the disruption that the Internet itself brought to bear on the predecessor telephone network infrastructure. The Internet architecture shifted functionality out of the core of the network and replaced synchronous real-time end-to-end virtual circuits with an extremely basic data packet-delivery service where networks were permitted to drop, duplicate, reorder, and re-time these packets in flight across the network.

It was left to the control functions that were embedded in the attached devices (such as the TCP protocol, for example) to create a functional, reliable, end-to-end communications service model. Internet hosts valued a network only to the level of a basic (and imperfect) packet-delivery service. Clients of a network were unwilling to pay a price premium for network-level services that were already being provided by the edge devices.

The result is a diminished network, dramatically reduced in both role and value. This diminished role impairs network operators to raise additional revenue through augmented services, whether it's through variable service responses through *Quality of Service* (QoS) responses or even as basic as IPv6 protocol support.

At this point it's useful to ask: What "defines" the Internet? Is the classic response, namely: "A common shared transmission fabric, a common suite of protocols, and a common protocol address pool" still relevant these days? Or is today's network more like: "A disparate collection of services that share common referential mechanisms using a common name space?"

When we think about what's important to the Internet these days, is the choice of endpoint protocol addressing really important? Is universal unique endpoint addressing a 1980's concept whose time has come and gone? If network transactions are localised, then what is the residual role of unique global endpoint addressing for clients or services? And if we cannot find a role for unique endpoint addressing, then why should we bother? Who decides when to drop this concept? Is this a market function, so that a network that uses local addressing can operate from an even lower cost base to gain a competitive market edge? Or are carriage services so cheap already that the relative benefits in discarding the last vestiges of unique global addresses are so small that it's just not worth bothering about?

And while we ponder such questions, what is the role of referential frameworks in networks? Without a common referential space, how do we usefully communicate? What do we mean by "common" when we think about referential frameworks? How can we join the "fuzzy" human language spaces with the tightly constrained deterministic computer-based symbol spaces?

Certainly, there is much to think about here!

And where does this situation leave the transition to IPv6?

I suspect that the dual-stack world we're in is a world we will be stuck in for quite some time. There seems to be no appetite to resolve this situation by completing the transition any time soon, and absolutely no desire to back out and revert to a IPv4-only network. We are here now, caught in a partial state of transition to IPv6 that is taking on an unfortunate air of permanence! And as the preponderance of value in this environment continues to move up the protocol stack into service, content, and today generative content in the guise of AI, there is little continued capacity to place collective attention on questions that have been left unresolved for decades.

It may well be that the question of when this IPv6 transition will end is a question that engenders decreasing levels of interest and attention in line with the larger picture of the decreasing relative economic value of the answer! Silicon abundance has enabled a few select content and service operators to privatise much of the former public communications platform, and in so doing they have managed to shrink the public Internet to a set of margins at the edges. That reality implies that the answer to the IPv6 transition question may soon be: "Who cares anyway?"

Book Review

The Real Internet Architecture: Past, Present, and Future Evolution, by Pamela Zave and Jennifer Rexford, Princeton University Press, ISBN 9780691255804, June 2024.

The goal of this book is to present a better way to describe the architecture of various networks, most notably the Internet. The initial portions of the book observe several deficiencies in how we both teach and talk about *networks* today. Most networking courses teach the bits and packets of the Internet, without a unifying framework. Networking papers suffer from “the lack of precise and consistent terminology.”

The authors present an alternative architectural model, in the hopes it will help with these issues. The core building block of the model is a network, where a network is defined as having members (hardware and software dedicated to participating in the network), names for members and groups of members, links, topology, a single administrator, and the capacity to route sessions of information. Networks offer users a simple service, namely the ability to send and receive information.

Networks can be connected three different ways:

- *Bridged Networks* are peers. Obviously IEEE 802 Ethernet networks are bridged. In this model, so too are IP networks run by different administrators. The Internet is a bridged (versus routed) network.
- *Layered Networks* put one network on top of another. A *Virtual Private Network* (VPN) is its own network and is placed on top of a set of bridged IP networks. IP networks are layered on bridged link-layer networks. As the examples illustrate, a network may be layered across multiple underlying (bridged) networks.
- Finally, there's the case where a member in a VPN is engaged in a session with a member on a bridged IP network at the layer below the VPN. For that case, the authors repurpose the term *subduction* to describe interactions that cross layers.

This brief description summarizes a much richer conceptual framework in the book, but one can see that a large set of complex network interactions are simplified by putting a box around large chunks, declaring those chunks individual networks (a VPN, an Ethernet, etc.), and then using bridging, layering, and subduction to put them together.

In most cases, the simplification is a relief. The complex interactions among a 5G network, VPNs, and the larger Internet to serve a web-request on my phone become conceptually simpler. Similarly, tenant networks in data centers feel more tractable.

But sometimes the model falters. Treating a *Hypertext Transfer Protocol* (HTTP) session as its own network, as the book does, with a single point-to-point link as its topology, feels simplistic. It is also not at all clear who the single administrator of the HTTP session is (also an issue for some other networks described).

There are also some missed opportunities. I would suggest, in the authors' model, that there are subductive control protocols, of which the *Address Resolution Protocol* (ARP) is probably the most notable, and that these protocols present distinct challenges not encountered by protocols that stay within their network box.

The book is a thought-provoking read. I would be surprised if it managed to persuade many instructors to teach using its paradigms. I think a full textbook would be required to make that happen. At the same time, I think the notion of subduction as a way to reference the challenge of cross-boundary protocols may well catch on.

JPNIC RPKI Guidelines Released

The *Japan Network Information Center* (JPNIC) has released a set of guidelines^[1] aimed at mitigating unauthorized routing incidents on the Internet using *Resource Public Key Infrastructure* (RPKI) *Route Origin Authorizations* (ROA). These guidelines provide technical and operational recommendations to enhance the security and reliability of Internet routing. The objective of these guidelines is to promote the adoption of RPKI-based security measures. Targeting a broad audience that includes both managerial and engineering professionals in the ISP and network operations sectors, the document offers a structured approach to implementing and maintaining RPKI.

Developed with inputs from the *Japanese Network Operators Group* (JANOG), research from the Ministry of Internal Affairs and Communications cybersecurity initiatives, and expert consultations, the guidelines offer practical insights based on real-world deployment experiences.

The guidelines cover both organizational and technical aspects of RPKI implementation. They explain the business risks associated with unauthorized routes and highlight the importance of adopting RPKI to mitigate these threats. By understanding these risks, decision-makers can justify investment in RPKI and align their security strategies with industry best practices. For network operators, the guidelines offer step-by-step instructions on creating ROAs and deploying *Route Origin Validation* (ROV). These measures ensure that only legitimate route announcements are propagated, reducing the risk of route hijacking and improving overall network security.

The guidelines also outline role-based measures for different types of network operators. IP holders are required to create ROAs and maintain consistency between their ROA records and routing information to prevent discrepancies. *Autonomous System* (AS) operators are encouraged to implement ROV to filter out invalid routes, strengthening the security of the global routing system. The guidelines include real-world configuration examples for routers and outline security measures for BGP beyond RPKI, ensuring that operators have practical resources to facilitate implementation.

Version 1 of the guidelines is available now in Japanese (translatable) in web and PDF formats and is supplemented with practical configuration examples for ROV deployment on routers. JPNIC plans to update the guidelines regularly in collaboration with experts to incorporate evolving best practices and emerging threats and has also developed an online tool, *rov-check*^[2], which allows network operators to verify whether their networks are effectively protected by ROV.

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

The *TCP/IP Interoperability Conference*—later renamed *Interop*—began as a small workshop in August 1986. It quickly grew in scope to incorporate tutorials, and by 1988 an exhibition network connected 51 exhibitors to each other and to the global Internet. This network was designed and deployed by a group of volunteers, and it became the proving ground for many emerging technologies. In 1994, Interop added Tokyo to its international venues, where 30 years later the conference and exhibition attracts more than 120,000 visitors annually. Following an article in our October 2024 issue describing the history and evolution of the Interop show network, and a second article detailing the Tokyo *ShowNet* in our previous issue, we now bring you the final installment in this series with an article that highlights some of the technology demonstrations performed during the 2024 Interop Tokyo event. The article is by Ryo Nakamura, Haruki Nakamura, Kazuya Okada, and Ryosuke Kato.

The *Domain Name System* (DNS) is one of the core components of the Internet. We have covered many aspects of the DNS over the years, but we have not discussed the *root server system* since an article in Volume 20, No. 2, June 2017. In this issue, Geoff Huston returns to the topic with a detailed tutorial and analysis of today's DNS root server operations.

We always welcome feedback and suggestions on any aspect of this journal. Included in this issue are two Letters to the Editor in response to the IPv6 Transition article in our May 2025 edition. If you'd like to get in touch, send your comments to: ipj@protocoljournal.org.

In late June, I attended the *Internet Governance Forum* (IGF) meeting in Lillestrøm, Norway. Lillestrøm happens to be the place where I attended high school. During my summer breaks, I worked at the nearby *Norwegian Defence Research Establishment* (NDRE), which had one of the first connections to the ARPANET starting in 1973. The IGF exhibition area had a series of posters highlighting the evolution of the Internet in Norway. I was pleased to see that the first poster featured Internet Hall of Fame Inductees Pål Spilling and Yngvar Lundh, my former managers at NDRE. See page 39.

Technology Highlights of ShowNet 2024

by Ryo Nakamura, Haruki Nakamura, Kazuya Okada, and Ryosuke Kato

Interop Tokyo 2024 was held from June 12 to 14 in the *Makuhari Messe* exhibition halls. With 542 organizations exhibiting and 124,482 visitors attending the exhibition, Interop Tokyo is one of the largest IT shows in Japan. *ShowNet*^[0], the large demonstration network for Interop Tokyo, was also built at the venue. In 2024, the ShowNet comprised approximately 2,300 products and services in more than 20 full-height racks built and operated by 650 engineers including 31 *Network Operations Center* (NOC) team members, 38 volunteer members, and 581 engineers from vendors who contributed their products to ShowNet. These engineers gathered at Makuhari Messe on May 31 and built the network in two weeks. Figure 1 is a picture of the second day of the ShowNet construction in 2024.

Figure 1: A snapshot of ShowNet under construction at Makuhari Messe on June 1, 2024.

The fundamental role of ShowNet is to provide network connectivity to Interop exhibitors and visitors. Furthermore, ShowNet conducts various experiments and demonstrations of new protocols, technologies, and products while serving user traffic.

In 2024, ShowNet featured the following technical topics in each field:

- *Facility*: A high-density *Main Distribution Frame* (MDF) with SN connector-based patch panels^[1].
- *Optical Transport*: Multi-vendor optical transport network with emerging optics such as 400GBASE-ZR+ and XR Optics.
- *Backbone Network*: An SRv6 uSID-based backbone network and *Ethernet VPN* (EVPN) and *Virtual eXtensible Local Area Network* (VXLAN) for access.
- *Data Center and Cloud*: Distributed container clusters and testing lossless networks for *Remote Direct Memory Access* (RDMA) over *Converged Ethernet* (RoCE) traffic.
- *Wireless Network*: Multi-band Wi-Fi access with Wi-Fi6E- and Wi-Fi7-capable Access Points, and multi-vendor *OpenRoaming*^[2].
- *Monitoring*: Integrated monitoring systems with various sensors and user interfaces, and experimentation of how to exploit AI for future monitoring.
- *Security*: Incorporating multiple aspects of protection and hardening such as SASE, ZTNA, EASM, and NGFW.
- *Tester*: Testing upper layers with protocol emulation for routing and penetration tests for security, and demonstrating automating test processes.
- *5G*: Multiple private 5G systems of RAN and cores with multiple vendors, and demonstration of live streaming over the 5G networks.
- *Media-over-IP*: Professional audio and media are now migrating from SDI to IP: demonstrating real-time broadcasting over IP networks.

In this article, we describe four of these topics, namely: *The Backbone Network*, *Optical Transport*, *5G*, and *Media-over-IP*.

The Backbone Network

The backbone network of ShowNet is the core of all the experiments and demonstrations. In 2024, the backbone network was composed of ten routers of nine products listed in Table 1. In addition, two containerized routers, XRd from Cisco Systems and cRPD from Juniper Networks, performed route reflectors for *Border Gateway Protocol* (BGP). With those routers, we built the backbone network based on Segment Routing while conducting SRv6 uSID interoperability tests.

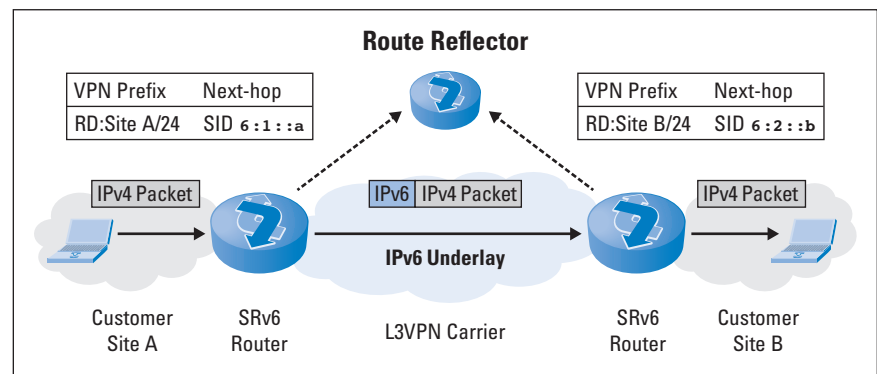

Table 1: Routers composing the backbone network of ShowNet in 2024.

Vendor	Product
Cisco Systems	Cisco 8201-32FH, Cisco 8608, NCS-57B1
Furukawa Electric	FX2
Huawei Technologies	NE8000-M4
Juniper Networks	ACX7348, MX204, MX304, PTX10002-36QDD

Segment Routing (SR)^[3] is a recent routing and forwarding paradigm that enables source routing. In SR, topological entities are represented by segments; for example, nodes, links, and adjacency. SR nodes control where packets should flow and how packets are processed by embedding a series of segments into a packet. SR has two concrete data-plane implementations: SR-MPLS leveraging *Multi-Protocol Label Switching (MPLS)* labels as *Segment Identifiers (SIDs)* and SRv6 leveraging IPv6 addresses as SIDs. An MPLS label stack encapsulating a packet indicates a SID list in SR-MPLS and IPv6 addresses in a *Segment Routing Header*^[4]—which is a new IPv6 extension header—it also indicates a SID list in the SRv6 data plane.

A major use case of SR is *Layer-3 VPN (L3VPN)*. Figure 2 illustrates a simple example of SRv6-based L3VPN. Two SRv6 routers perform Provider Edge functions for two customer sites, and exchange VPN prefixes via *Multi-Protocol BGP (MP-BGP)*. Note that the next-hops for those VPN prefixes are SRv6 SIDs: the ingress SRv6 router encapsulates packets from the customer site A to site B with IPv6 headers whose destination address is the SID (`6:2::b`) of the egress SRv6 router.

Figure 2: A simple example of SRv6-based L3VPN.

For ShowNet at Interop Tokyo, we have worked on Segment Routing continuously since 2018. In 2018 we conducted a simple and small interoperability test of the SR-MPLS and SRv6 data planes, and in 2019 we demonstrated service chaining over SRv6 with multiple vendors' products. Since 2021, we have deployed SR on the ShowNet backbone networks. The backbone network of ShowNet 2021 was composed of SR-MPLS, and we further conducted a measurement experiment on Internet latency using SR-MPLS-based *Egress Peer Engineering*, which enables steering specific egress traffic to given *External BGP (eBGP)* peers. The results of the experiment were published in a paper^[5] and in an APNIC blog post^[6]. In 2022 and 2023, the ShowNet backbone was fully SRv6-enabled, and IPv4 addresses were eliminated—interfaces of backbone links had no IP addresses configured thanks to IPv6 link-local addresses. Our chronicle with SR was summarized in a presentation at the *Asia Pacific Regional Internet Conference on Operational Technologies (APRICOT) 2024*^[7].

In 2024, a main topic in the backbone network was SRv6 micro SIDs (uSID). uSID, also known as the NEXT-C-SID flavor in^[8], is a mechanism for compressing SID lists in SRv6. A SID in the original SRv6 is a 128-bit IPv6 address, encapsulating packets with multiple SIDs. For example, traffic engineering, involves significant overhead on MTU sizes. uSID encodes multiple SIDs into a 128-bit IPv6 address format to avoid the overhead. Figure 3 illustrates a uSID structure with F3216 format^[9], which implementations must support at present.

The first 32-bit is a uSID block that all routers in an SRv6 domain share. The 16-bit blocks shown in Figure 3 are uSIDs. When an SRv6 node processes the first uSID (**fcbb:ccbb:0001:...**), the node shifts the 80 bits from the second to the last uSID 16 bits to the left and overwrites the first uSID. In other words, the new destination address of the packet is **fcbb:ccbb:0002:0003:0004:0005::**, and the packet is forwarded to the next SRv6 node that has the uSID **0002**. This new packet forwarding mechanism is currently being implemented in router products of multiple vendors, and we confirmed that uSID interoperability between the devices listed in Table 1 was successfully achieved in ShowNet 2024.

Figure 3: A uSID structure with the F3216 format.

The second topic is a demonstration for campus and enterprise networks. The “customers” of ShowNet are exhibitors connecting equipment in their booths to the network. This means that the last hop to the booths consists of several hundred UTP cables spread over the exhibition halls. Accommodating those access circuits becomes a technical demonstration of campus and enterprise networks. This year we built those access networks as L2 and L3VPN with *Ethernet VPN* (EVPN) and *Virtual eXtensible Local Area Network* (VXLAN)^[10] with campus switches from multiple vendors.

VXLAN is an Ethernet-over-IP tunneling protocol, and EVPN is a BGP-based control plane that can construct overlay fabrics using VXLAN as its data plane^[11]. EVPN-VXLAN was originally designed and introduced for data-center use; therefore, switches and routers that were intended primarily for use in data centers supported these protocols in the early days.

Over the years, recent switches for campus and enterprise networks, which are different product lines from those for data centers, have begun to support EVPN-VXLAN for campus use. Adopting Ethernet overlays for campus networks will eliminate (often fragile) spanning-tree protocols and provide scalability and resiliency by using underlying dynamic routing protocols.

The access network in ShowNet 2024 was composed of three routers and eight switches of seven models listed in Table 2. All devices exchanged EVPN routes via route reflectors, constructed a VXLAN fabric, and forwarded user traffic over the fabric. User VLANs could be extended between the switches over the IP underlay. In addition, EVPN can construct L3VPNs using EVPN Type-5 routes^[12]. We also confirmed that the EVPN Type-5 route interoperability works well with these devices.

Table 2: Routers and switches composing the access network with EVPN-VXLAN.

Vendor	Product
Cisco Systems	Catalyst 9300, Nexus 93108TC-FX
Huawei Technologies	CloudEngine S5732, NE8000 M4
Juniper Networks	EX4400, MX304, SRX4600

While SRv6 uSID and EVPN-VXLAN for access were major topics, the demonstrations were not limited to just these two. Other demonstrations and technical challenges were also conducted at the ShowNet backbone network; for example, an experiment of SRv6 over a satellite for disaster recovery, testing *Path Computation Element Protocol* (PCEP), and a total of 2 Tbps external circuits including a capacity of 1.8 Tbps provided by Open APN.

Optical Transport

The optical transport network in ShowNet multiplexes waves on fibers to optimize fiber use while showcasing products in this area. Furthermore, the optical transport network in 2024 faced challenges, including interoperability tests, and tests with other layers above Layer 2. The topics in 2024 were as follows:

- Using multi-band connections of C-band and L-band.
- Interoperability between 400GBASE-ZR+ transceivers based on OpenZR+.
- 1:N point-to-multipoint connections as defined by the *Open XR Optics Forum*.

The optical transport network in ShowNet 2024 consisted of multiple *Wavelength Division Multiplexing* (WDM) networks. One of the WDM networks used a *Reconfigurable Optical Add-Drop Multiplexer* (ROADM) with C-band and L-band wavelengths, connecting transponders and muxponders with capacities ranging from 400 to 800 Gbps.

This WDM network also provided connections of 100GBASE-LR4 and 400GBASE-FR4 to the backbone routers. In addition, we conducted an interoperability test of 400GBASE-ZR+ transceivers at ShowNet. 400GBASE-ZR+^[13] employs coherent optics that enable configuring and transmitting multiple wavelengths so that they can remove transponders. Different manufacturers provide coherent optics equipped with *Digital Signal Processing* (DSP), and we confirmed that they operated correctly in various combinations. Using this infrastructure, we also tried to transfer wavelengths directly from a carrier through the optical transport network built at ShowNet in collaboration with the carrier.

Another WDM network conducted a test of coherent 100GBASE-ZR in the QSFP28 form factor, which was developed after 400GBASE-ZR+ emerged, with ROADMs using C-band wavelengths, in addition to the interoperability of 400GBASE-ZR+ transceivers. Further, we deployed XR Optics^[14], which enables point-to-multipoint optical connections. Deploying Open XR Optics with a ROADM was the first challenge, and it was successfully completed by strong cooperation with each vendor of the transceiver, transponder, ROADM, and *Erbium-Doped Fiber Amplifier* (EDFA) at ShowNet.

5G

Private 5G networks are wholly owned and operated 5G networks that enable individual companies to possess some radio spectrum for their purposes. In Japan, private 5G networks are recognized as Local 5G. This type of private 5G and local 5G is defined as a *Standalone Non-Public Network* (SNPN) in the 3GPP standards. We have been conducting private 5G experiments in a part of ShowNet with 5G-related vendors and integrators since 2022. This year, we deployed three different private 5G networks with multiple vendors and conducted two demonstrations: live streaming in *Network Operations Center* (NOC) guided tours in the exhibition using the 5G networks to improve participants' experience and provided Internet connectivity to several exhibition booths. In addition, we designed a stable and redundant *Precision Time Protocol* (PTP)^[15] network for the 5G networks. In this demonstration, we constructed three private 5G networks that use licensed n79 spectrums in Japan. The demonstration highlighted the advantages of private 5G networks over mobile carriers' 5G services, including low latency and guaranteed access in licensed areas.

NOC guided tours in the exhibition adopted real-time video streaming with the private 5G systems for this year. On the tours, called the *ShowNet Walking Tours*, a NOC team member gives a talk about design concepts and underlying technologies for every rack. However, the areas around the racks were crowded and noisy during the exhibition, so it was difficult for tour participants to see the equipment that NOC members were describing. Furthermore, technologies and devices introduced during the tour were extensive; therefore, conveying this information clearly to the tour participants through only verbal explanations was also challenging.

To address the uncomfortable situation in the tours, we streamed the voice and live movie of the tour guide describing the racks to attendees' 5G-capable tablets and smartphones. Encoded movies and audio were transported to a decode server located in a ShowNet rack via a 5G system. Then, the decoded movie was mixed with supplemental slides and was presented on the attendees' tablets at the right time. An on-premises streaming server delivered the edited movie and audio to attendees' 5G tablets and smartphones via two different 5G networks. Figures 4 and 5 show a camera recording a tour guide describing a ShowNet rack, and the video is mixed with slides. Tour attendees watch the mixed stream, as shown in Figure 6.

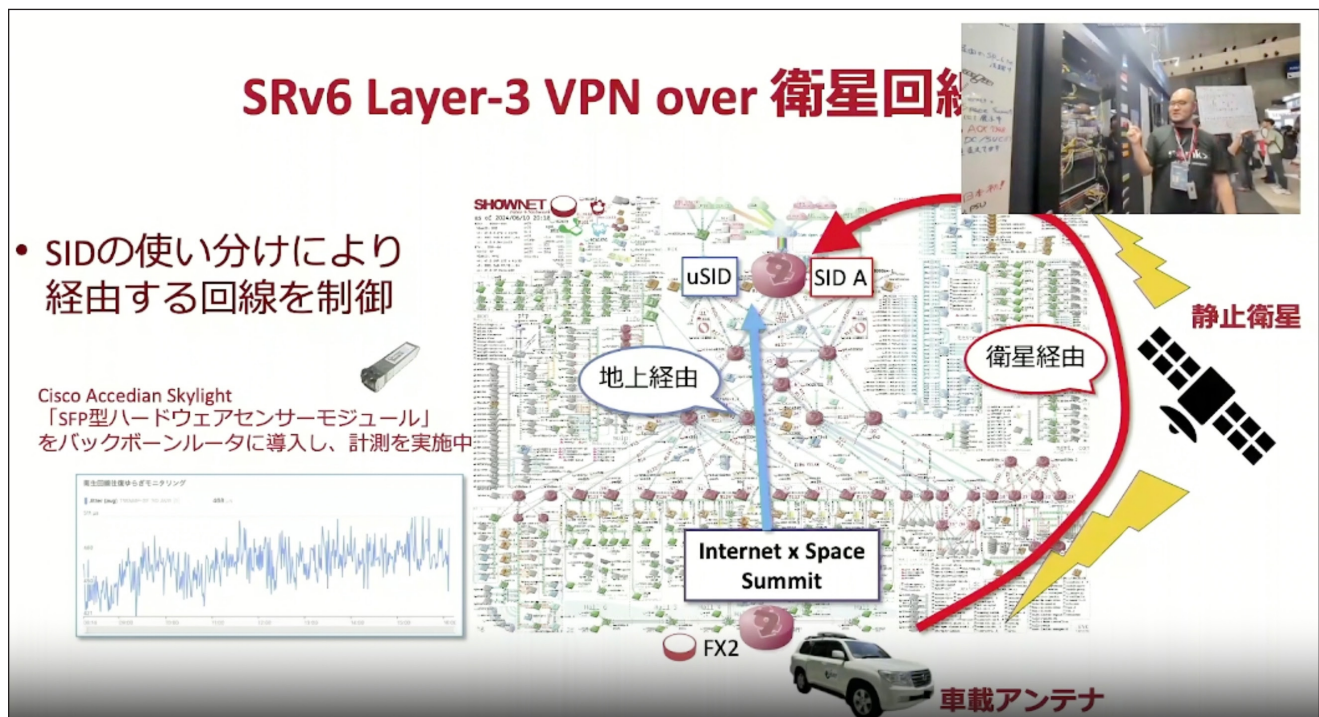

Figure 4: Live broadcasting with private 5G-enabled smartphone cameras.

Figure 5: Mixing the received video image with a slide related to what the NOC member is describing.

Figure 6: Video images delivered to tour attendees' tablets and smartphones.

This demonstration using the 5G systems provided very stable live streaming in the exhibition halls, in contrast to using Wi-Fi. Wi-Fi access was also available, but the Wi-Fi public bands of 2.4 and 5 GHz were already experiencing congestion due to massive numbers of visitors' mobile Wi-Fi devices. Therefore, latency and available network bandwidth were unstable, and it was not easy to provide guaranteed streaming. Wi-Fi 6E, which uses 6-GHz channels, still has not been congested because of the small number of capable devices. However, it is anticipated that this situation will change next year.

Media-over-IP

Professional audio and media are now migrating from *Serial Digital Interface* (SDI) cables, which have low transfer rates and high costs, to Ethernet/IP-based systems for higher transfer rates and lower costs because of the availability of commodity equipment. ShowNet has featured these media-over-IP solutions as one of the main topics since 2022. In 2024, we collaborated with broadcasters pursuing the transition to IP in broadcasting to explore the possibilities of media-over-IP networks and services for broadcasting industries; we attempted to connect and exchange media between the ShowNet booth and three geographically distributed broadcast stations over IP networks.

In the ShowNet booth, we built the *Media Operation Center* (MOC), a broadcast control room for media production and remote operation with IP-based systems. Using this MOC (Figure 7), we demonstrated real-time recording, editing, and broadcasting of a stage (Figure 8) where many sessions were held during the exhibition. This facility also supported live mixing and streaming on the tours with the 5G demonstration described previously.

Media-over-IP technologies are standardized by the *Society of Motion Picture and Television Engineers* (SMPTE)^[16], and its standards are prefixed with SMPTE. For example, the SMPTE ST 2110 series^[17] defines protocols and parameters for professional video, audio, and data-over-IP transport.

From the network viewpoint, that media traffic is *Real-time Transport Protocol* (RTP) streams over IP multicast, and media endpoints speaking the protocols require *Precision Time Protocol* (PTP) to synchronize clocks. Thus, in ShowNet 2024, we built a Layer-3 multicast network with *Open Shortest Path First Version 2* (OSPFv2) and *Protocol Independent Multicast – Sparse Mode* (PIM-SM) for the control room by using Cisco Nexus series and Huawei Cloud Engine switches. These switches are capable of PTP for broadcast profiles (SMPTE ST 2059-2). Furthermore, we configured Layer-2 VPN and Layer-3 VPN connections using VPN devices for media transmission and control between two broadcast stations in Tokyo (30 km away from the venue) and a station in Sapporo (830 km away from the venue) over the Internet. These connections established a remote production environment between the broadcast stations and the MOC booth at ShowNet.

Figure 7: The Media Operation Center at the ShowNet booth.

Figure 8: A stage presentation broadcasted by the media-over-IP systems deployed on ShowNet.

We demonstrated media production with the remote broadcast stations over IP networks during the three-day exhibition. Traffic transferred through the networks included bidirectional uncompressed video streams (SMPTE ST 2110-20, 1080i with 59.94 Hz, up to 1.3 Gbps per stream) and compressed video streams by JPEG-XS (SMPTE ST 2110-22, 1080i with 59.94 Hz, up to 200 Mbps per stream). Additionally, sensors embedded in *Small Form-factor Pluggable* (SFP) modules from Accedian were placed at a ShowNet rack and the broadcast stations to enable active monitoring by *Two-Way Active Measurement Protocol* (TWAMP) measurements. This setup allowed us to observe real-time network performance impacts on media traffic.

During the event, we collaborated with broadcasting industry members to conduct live broadcast and video production of sessions at the exhibition. Eventually, all media transport and equipment operations between the broadcast stations and the Media Operation Center at the ShowNet booth were conducted entirely over IP.

Conclusion

In this article, we introduced technology highlights from ShowNet in 2024. ShowNet covers broader aspects of networking technologies and conducts demonstrations from Layer 1 to Layer 7. Unfortunately, explanations of all the topics discussed in this article are not possible because of the amount of material it would necessitate. So, in this article we covered only four topics: the backbone network, optical transport, 5G, and media-over-IP, and briefly described these technical overviews.

ShowNet is a show in the Interop exhibition; different from ordinary networks, it is an ephemeral network built and operated for just three days. However, we do not let the show network end as just a show. Through conducting various experiments and demonstrations, as described in this article, we aim to encourage network communities in Japan, foster relationships between engineers, and contribute the knowledge and insights gained at ShowNet to society.

Acknowledgments

The design, construction, and demonstration of the ShowNet network were made possible through the collaboration of NOC team members, contributing vendors and their teams, and ShowNet Team members. We want to thank all the people involved in the ShowNet at Interop Tokyo 2024.

RYO NAKAMURA received his Ph.D. degree in Information Science and Technology from the University of Tokyo, Tokyo, Japan, in 2017. He is currently an Associate Professor at the Information Technology Center, the University of Tokyo, where he operates the university’s campus network. His research interests include networking in operating systems, network virtualization, and network operations. Since 2009, he has been involved in Interop Tokyo ShowNet as a ShowNet team member until 2011, and as a member of the NOC team from 2012 to the present. He has been primarily responsible for the backbone network of ShowNet, and he led demonstrations of SDN-related technologies from 2013 to 2017. He can be reached at:
ryo@interop-tokyo.net

HARUKI NAKAMURA received a Master’s degree from Keio University Graduate School of Media Design in 2019. He started his career as a Solutions Engineer at Cisco Systems G.K., focusing on data-center networking and computing technologies. Since 2022, he has expanded his responsibilities to include IP Media Networking and joined Interop Tokyo ShowNet as a contributor. In 2024, he served as a ShowNet NOC member in the Media-over-IP Working Group, where he led initiatives to collaborate with contributors and broadcasting companies on proof-of-concept projects for the next-generation Media-over-IP system. He can be reached at:
hanakamu@interop-tokyo.net

KAZUYA OKADA received a PhD degree in computer science from the Nara Institute of Science and Technology (NAIST), Japan, in 2014. He is currently a Principal Researcher at the InfoTech (Research Division of Information Technology), Toyota Motor Corporation, Japan. His research interests include cyber resilience and cybersecurity for connected vehicles. He has been a NOC team member of ShowNet since 2011. He can be reached at: **okada@interop-tokyo.net**

RYOSUKE KATO has been employed by BroadBand Tower, a Japanese data-center company, since 2013. His role involves the investigation of essential network technologies for data centers, with a focus on IP closed network services between data centers and optical transmission technologies. Additionally, he has been an active member of the NOC team for ShowNet since 2017. He contributed to the demonstration of data-center network interconnection technologies from 2017 to 2019 and was involved in optical transmission technology from 2021 to 2024. He can be reached at: **kato@interop-tokyo.net**

The Root of the DNS

by Geoff Huston, APNIC

The *Domain Name System* (DNS) of the Internet is a remarkably simple system. You send queries into this system via a call to the name resolution library of your local host, and you get answers back. If you peek into the DNS system you'll see exactly the same simplicity: The DNS resolver that receives your query may not know the answer, so it, in turn, will send queries deeper into the system and collect the answers. This query/response process is the same, applied recursively. Simple.

However, the DNS is simple in the same way that Chess or Go are simple. They are all constrained environments governed by a small set of rigid rules, but they all generate surprising complexity in their operation.

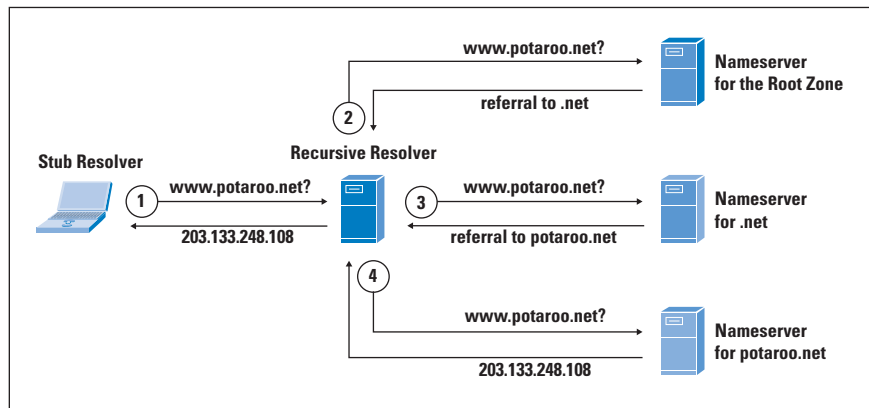

The Root Zone

The DNS is not a dictionary of any natural language, although these days when we use DNS names in our written and spoken communications we might be excused from getting the two concepts confused! The DNS is a hierarchical namespace. Individual domain names are constructed using an ordered sequence of labels. This ordered sequence of labels serves numerous functions, but perhaps most usefully it can be used as an implicit procedure to translate a domain name into an associated attribute value through the DNS name resolution protocol.

For example, I operate a web server that is accessed using the DNS name **www.potaroo.net**. If you direct your browser to load the contents of this DNS name, your system first needs to resolve this DNS name to an IP address, so that your browser knows where to send the IP packets to perform a transaction with my server. But how does the system know which nameserver is authoritative for the zone that includes the name **www.potaroo.net**?

This point is where the structure of the namespace is used to discover the nameserver. In this case, the DNS resolver will query a *root server* to resolve the name. As this name is not defined within the *Root Zone* (the zone that is served by the root servers), the response from any root server to such a query will be a *referral* response. In this example, this response is a redirection that lists the set of nameservers that are authoritative for the **.net** zone. Ask any of these **.net** nameservers for this same DNS name and again you will get back a redirection response, consisting of the list of nameservers that are authoritative for the **potaroo.net** zone. Ask any of these **potaroo.net** nameservers for the same name, **www.potaroo.net**, and you will receive the IP address you are looking for (Figure 1).

Figure 1: Name Resolution in the DNS.

Every DNS name is resolved in the same way. The name itself defines the order of name resolution processing, and it defines the path to be followed through the distributed database that leads to the answer you seek.

In this entire process, there is one starting point for every DNS resolution operation: the *Root Zone*.

Some criticize any exceptional consideration given to the root zone of the DNS; they think it is just another DNS zone, like any other. It is a set of authoritative servers that receive queries and answer them, like any other zone. There is no magic in the root zone, and all this attention on the root zone as *special* in some way is entirely unwarranted.

However, I think this view understates the criticality of the root zone in the DNS. The DNS is a massive, distributed database. Indeed, it is so massive that there is no single static map that identifies every authoritative source of information and the collection of data points about which it is authoritative. Instead, we use a process of dynamic discovery, where the resolution of a DNS name is first directed to locating the authoritative server that has the data relating to the name we want resolved, and then querying this server for the data. The beauty of this system is that these discovery queries and the ultimate query are precisely the same query in every case.

But everyone has to start somewhere. A DNS recursive resolver does not know all the DNS authoritative servers in advance, and it never will. But it does know one thing: It knows the IP address of at least one of the root servers in its provided configuration. From this starting point everything can be constructed in real time. The resolver can ask a root server for the names and IP addresses of all other root servers (the so-called *priming query*), and it can store that answer in a local cache. When the resolver is given a name to resolve, it can then start with a query to a root server to find the next point in the name delegation hierarchy and go on from there in a recursive manner.

If this description illustrates how the DNS actually works, then it is pretty obvious that the entire DNS system would have melted down years ago. What makes this approach viable is *local caching*. A DNS resolver stores the answers in a local cache and uses this locally held information to answer subsequent queries for the life of the cached entry. So perhaps a more refined statement of the role of the root servers is that every DNS resolution operation starts with a query to the cached state of the root zone. If the local cache cannot answer the query, then a root server must be queried.

However, behind this statement lurks an uncomfortable observation: If all of the root servers are inaccessible, then the entire DNS ceases to function. This is perhaps a dramatic overstatement in some respects, as there would be no sudden collapse of the DNS and the Internet along with it. In the hypothetical situation where all the instances of the root servers were inaccessible, then DNS resolvers would continue to work using locally cached information. However, as these cached entries time out, they would be discarded from these local resolvers (as they could not be refreshed by re-querying the root servers). The light of the DNS would slowly fade to black bit by bit as these cached entries time out and are removed. The DNS root zone is the master lookup for every other zone. That's why it deserves particular attention. For that reason, the DNS root zone is uniquely different from every other zone.

Root zone servers are not used for every DNS lookup because of local caching. The theory is that the root servers will only see queries as a result of cache misses in resolvers. With a relatively small root zone and a relatively small set of DNS recursive resolvers, the root zone query load should be small. Even as the Internet expands its user base the query load at the root servers does not necessarily rise in direct proportion. It is the number of DNS resolvers that supposedly determines root server query load if we believe in this model of the function of the root in the DNS.

However, the model does not appear to hold up under operational experience. Figure 2 shows the total volume of queries per day recorded by the root servers since January 2016.

Over the period from 2016 to 2020, the volume of queries seen by the collection of root servers tripled. The query volume decreased in 2021 and stabilised over 2022. It is likely that changes to the behaviour of the Chrome browser may explain this abrupt change. Chrome used to probe the local DNS environment by making a sequence of queries to non-existent names (so-called *Chromeoids*) upon startup, and because the query names referred to undelegated top-level domains, these queries were a significant component of the queries seen at the root servers. Changing this behaviour in Chrome at the end of 2020 appears to have resulted in a dramatic change to the DNS query profile as seen by the root servers. However, over 2023 and 2024 the aggregate volume of queries seen by the root servers resumed its upward trend, rising by 40% from some 90 billion queries per day at the start of 2023 to more than 130 billion queries per day at the start of 2025.

Figure 2: Root Service Queries per Day – from ^[1].

What are we doing in response to this trend in the growth of queries to the root zone? How are we ensuring that the root zone service can continue to grow in capacity in response to this resumption in the growth of query rates?

Digression – The Economics of the DNS

In conventional markets, when a good is consumed, the consumer pays the producer a fee for the consumption of that good. As long as the fee covers the cost of production of the good, increasing consumption generates increasing revenue that can cover the costs associated with expanding the means of production of the good. Obviously, that's a very simplistic view of the operation of markets, but the key assumption is that greater consumption generates more revenue for producers, which, in turn, allows producers to produce greater volumes of the good. The essential assumption is that there is an underlying market-based discipline associated with the production and consumption of the good.

This assumption breaks down in the DNS, and in the root zone servers in particular. DNS queries are essentially unfunded. Like many Internet users, I have an *Internet Service Provider* (ISP), and I pay an access fee for its service.

Typically, an ISP operates a DNS recursive resolver for its clients, and my access fee contributes to my ISP's costs in running this resolver service. However, it's a fixed access fee, not a metered fee, so I contribute the same sum to the running of this shared resolver whether I submit one DNS query per day or one million!

As well as the costs in operating this resolver service, does the ISP incur any other cost in operating a DNS service to resolve my queries? No! All of the authoritative nameservers that are queried by my ISP's resolver are not funded by my ISP. More generally, all DNS queries in the public Internet are not directly funded by the querier!

Obviously, there are costs associated with operation of authoritative nameservers, and, for the most part, these costs are met by the "owners" of the zones that are served by these nameservers. There are various funding models for authoritative nameservers, ranging from metered costs per answered query, flat-rate costs, and even free services in some circumstances. But the essential aspect of this service is that authoritative nameservers do not derive revenue from the entities that query them. If there is a revenue stream, it comes from the DNS zone administrators who are paying for the nameservers to serve their zone.

I did note that this fact holds "for the most part," and there is one very notable exception here, namely the root zone. The twelve entities who provide the nameservers for the root zone do so as a collection of independent, largely autonomous volunteers who meet their own costs.

This situation is in many ways a curious relic of an earlier Internet that had a spirit of cooperative enterprise in many of its endeavours, but at the scale where each *Root Service Operator* is operating a service platform capable of responding to an average query load of some 10 billion queries per day, then it is no slight donation of effort and resources to a common-good outcome. Such a core of altruism in the centre of a market-driven frenzy of activity that operates today's digital world is unusual to see.

Given the criticality of the role that these operators collectively undertake, and the observation that directly or indirectly we are all beholden to the outcomes of these efforts to maintain a functional namespace for the Internet, then perhaps, odd as it may be, this situation is better than many of the alternatives.

In a market economy, a monopoly supplier of a critical resource is able to extract a monopoly rental from all others, while customers cannot seek relief through competitive offerings because of the very nature of the monopoly. Today's world looks to market regulators and the associated public regulatory frameworks to protect markets from such forms of abuse. But in the Root Service function we find a service that is both universal across the entire collection of individual public regimes and a collective monopoly.

A self-imposition by these operators of a freely offered service is perhaps not the only possible response to counter such risks of potential abuse of role. So far, however, the ethos of these twelve root service operators has proved to be an adequate and sufficient measure.

But perhaps it's now time to consider the outstanding question, namely "How are we ensuring that the root-zone service can continue to grow in capacity in response to this resumption in the growth of query rates?", and now factor in the apparent need to escalate the level of resources that are in effect donated to this service by this small collection of operators.

Root Zone Scaling

The original model of authoritative servers in the DNS was based on the concept of *unicast* routing. A server name had a single IP address, and this single server was located at a single point in the network. Augmenting server capacity entailed using a larger server and adding network capacity. However, such a model does not address the issues of a single point of vulnerability, nor does it provide an optimal service for distant clients.

More Servers

The DNS approach to this problem is to use multiple nameserver records. A DNS resolver was expected to retry its query with a different server if its original query did not elicit a response. That way, a collection of servers could provide a framework of mutual backup. To address the concept of optimal choice, DNS resolvers were expected to maintain a record of the query/response delay for each of the root servers and prefer to direct the majority of their queries to the fastest server.

Why not use multiple address records for a single common server name? The two approaches (multiple server names and multiple address records for a name) look similar. Once a resolver has assembled a collection of IP addresses that represent the nameservers for a domain, then it seems to me that a resolver could be justified for treating the list of IP addresses consistently, irrespective of whether the list was assembled from multiple IP addresses associated with a single name, or from multiple names. The use of multiple names allows for the use of multiple paths through the DNS to resolve these names of the nameservers that can remove a potential single point of failure, although I wonder as to the true benefit of using a set of nameserver names within a common single DNS zone as compared to using a single name with multiple IPv4 and IPv6 *Resource Records*, particularly when the bulk of DNS zones are provisioned with 2 or 4 nameservers, so there are typically 2 or 4 IPv4 and IPv6 addresses. I suspect that the use of multiple names is a policy compliance outcome rather than a true effort to provision nameservers with resilience through diversity.

If we want to increase the capacity of the root zone, then why not just add more nameserver names to the root zone?

What's so special about this zone's use of 13 named nameservers and a total of 26 IP addresses? For the root zone, the scaling issue with multiple nameservers is the question of completeness and the size of the nameserver response to the *priming query*. The question here is: If a resolver asks for the nameservers of the root zone, should the resolver necessarily be informed of all such servers in the response? The size of the response will increase with the number of servers, and the size of the response may exceed the default maximal DNS over a *User Datagram Protocol* (UDP) payload size of 512 bytes.

The choice of the number of server names for the root zone, 13, was based on the calculation that this was the largest list of a server list that could fit into a DNS response that was under 512 bytes in size. This choice assumed that only the IPv4 address records were being used in the response. With the addition of the IPv6 AAAA records, the response size has expanded. The size of the priming response for the root zone with 13 dual-stack authoritative servers is 823 bytes, or 1,097 bytes if the *Domain Name System Security Extensions* (DNSSEC) signature is included, and slightly larger if DNS cookies are added.

In today's DNS environment, if the query does not include an *Extension Mechanisms for DNS* (EDNS)(0)^[2] indication that they can accept a DNS response over UDP larger than 512 bytes, then the root servers will provide a partial response in any case, usually listing all 13 names, but truncating the list of addresses of these services in the *Additional Section* of the response to fit with a 512-byte payload.

Past experiments have been conducted with more than 13 nameservers at the apex of a DNS-like name system (such as the *Yeti*^[3] project, of some 5–8 years ago), and while it is technically feasible to do so, some vexing questions remain, such as how to select new root service operators, what is a safe ceiling of the number of such services, and how would it impact the stability and coherence of the name system.

Until we have much broader levels of adoption of query name minimisation than we appear to have today, root servers are privy to the myriad of domain names that users are querying. Such data is effectively a real-time view into the activity in the Internet through this meta-data query stream. If we opened up the root service to a broader set of operators, would a temptation to monetise this unique and highly valuable data stream prove overwhelming? In this space is it even possible to enforce constraints that would preclude any such activity?

So far, we appear to have avoided such difficult questions by leaving the number of root nameservers constant and scaling the root service in other ways.

If we can't, or don't want, to just keep on adding more root servers to the nameserver set in the root zone, then what are the other scaling options for serving the root zone?

More Service Platforms

The first set of responses to these scaling issues was in building root servers that have greater network capacity and greater processing throughput. But with just 13 servers to work with, this capacity was never going to scale at the pace of the Internet. We needed something more.

The next scaling step was the conversion from unicast to *anycast*^[32–37] services. There may be 26 unique IP addresses for root servers (13 in IPv4 and 13 in IPv6), but each of these service operators now uses anycast to replicate the root service in different locations. The current number of root server sites is described at root-servers.org (Table 1). Now the routing system is used to optimise the choice of the “closest” location for each root server.

Table 1: Anycast Site Counts for Root Servers, March 2025 ^[4].

Root	A	B	C	D	E	F	G	H	I	J	K	L	M	Total
Sites	59	6	13	220	328	359	6	12	85	148	131	123	23	1,513

The root server system has embraced anycast, some parts more enthusiastically than others. Currently a total of 1,513 sites have one or more instances of root servers. Some 24 months earlier, in January 2023, the root server site count was 1,396, so that’s an 8% increase in the number of sites in a little over two years.

The number of authoritative server instances is larger than the number of sites, as it is common these days to use multiple server engines within a site and use some form of query distribution at the front end to distribute the incoming query load across multiple back-end engines at each site. Today, the total of root server system instances is 1,907.

Even this form of expanding the distributed service may not be enough in the longer term. We are seeing the resumption of the growth profile last seen in 2016–2020. With a 25% compound annual query growth rate, in four years we may need double the root service capacity from the current levels, and in a further four years we’ll need to double it again. Exponential growth is a very harsh master.

Can this anycast model of replicated root servers expand indefinitely? Or should we look elsewhere for scaling solutions?

Query Deflection for Negative Responses

There have been many studies of the root service and the behaviour of the DNS over the past few decades. If the root servers were meant simply to respond to the cache misses of DNS resolvers, then whatever is happening at the root is not entirely consistent with such a model of behaviour. Indeed, it’s not clear what is going on at the root!

It has been reported that the majority of queries to the root servers result in NXDOMAIN (“non-existent domain”) error responses. In looking at the published response code data, it appears that some 50% of root zone queries result in NXDOMAIN responses (Figure 3). The NXDOMAIN response rate was as high as 75% in 2020, and dropped presumably when the default behaviour of the Chrome browser in using Chromeoids changed. In theory these queries are all cache misses at the recursive resolver level, so the problem is that the DNS is not all that effective in handling cases where the name itself does not exist.

Figure 3: Proportion of Root Zone NXDOMAIN Responses per Day ^[1].

If we want to reduce the query pressure on the root servers, one possible approach is to alter the way DNS resolvers handle queries for non-existent names, and in particular names where the top-level label in the queried name is not delegated in the root zone. How else can we deflect these queries away from the root server system?

One such approach is described in RFC 8198^[5], “Aggressive NSEC Caching.” When a top-level label does not exist in a DNSSEC-signed zone and the query has the EDNS(0) DNSSEC “OK” flag enabled, the NXDOMAIN response from a root server includes a signed NSEC record that gives the two labels that exist in the root zone that “surrounds” the non-existent label.

NSEC records say more than “this label is not in this zone.” It says that no label that is lexicographically between these two labels exists. If the recursive resolver caches this NSEC record, then it can use this same cached record to respond to all subsequent queries for names in this label range, in the same way that it conventionally uses “positive” cached records.

If a recursive resolver cached both the 1,443 top-level delegated labels and the 1,444 NSEC records in the root zone, then the resolver would not need to pass any queries to a root server for the lifetime of the cached entries. If all recursive resolvers performed this form of NSEC caching of the root zone, then the query volumes seen at the root from recursive resolvers would fall significantly for non-existent labels.

How Many TLDs Are in the Root Zone?

There were 1,443 *Top-Level Domains* (TLDs) in the root zone of the DNS in March 2025. It has not always been this size. The root zone started with a small set of generic labels, and in the late 1980’s expanded to include the set of two-letter country codes. There were some tentative steps to augment the number of generic top-level domain names, and then in the 2010s *The Internet Corporation for Assigned Names and Numbers* (ICANN) embarked on a larger program of generic TLD expansion. Figure 4 shows the daily count of TLDs in the root zone since 2014.

Figure 4: Daily Count of Root Zone TLDs.

What was surprising to me was that TLDs are not necessarily permanent. The largest TLD count occurred in August 2017, with 1,547 TLDs, and since then the number of TLDs has been declining.

Aggressive use of NSEC caching in recursive resolvers appears to play a contributory role in helping us scale the root zone. *Bind* supports this function as of release 9.12, *Unbound* supports it as of release 1.7.0, and *Knot* resolver supports it as of version 2.0.0. But the queries at the root zone keep growing despite the declining proportion of queries, resulting in an NXDOMAIN response. While this measure may have dampened the relative growth of queries for non-existent names seen at the root servers, to some extent it has not significantly affected the overall problem of the growth of queries directed to the root servers; other factors appear to be causing it.

I'd characterise the situation as aggressive NSEC caching representing a tactical response to root zone scaling concerns, as distinct from a strategic response. The technique is still dependent on the root server infrastructure, and it uses a query-based method of promulgating the contents of the root zone. Nothing really changes in the root service model. What NSEC caching does is allow the resolver to make full use of the information in the NSEC response.

Root Zone Mirroring

Another scaling option is to jump completely out of the query/response model where recursive resolvers incrementally learn the contents of the root zone query-by-query and simply load the entire root zone into their local cache and refresh this local copy with a period of several hours or even a day or so. The idea here is that if a recursive resolver is loaded with a copy of the root zone, then it can operate autonomously with respect to the root servers for the period of validity of the local copy of the root zone contents. It will send no further queries to the root servers.

The procedures to follow to load a local root zone are well documented in RFC 8806^[6], and I should also note here the existence of the *LocalRoot*^[7] service that apparently offers DNS NOTIFY messages when the root zone changes. The root zone is not a big data set. A signed, uncompressed plaintext copy of the root zone as of March 14, 2025, is 2.2 MB in size.

However, this approach has its potential drawbacks. How do you know that the zone you might have received via some form of zone transfer or other is the current genuine root zone? Yes, the zone is signed, but not every element in the zone is signed (NS records for delegated zones are unsigned). The client is left with the task of performing a validation of every digital signature in the zone, and at present there are some 1,444 *Resource Record Digital Signature* (RRSIG) records in the root zone. Even then the client cannot confirm that its local copy of the root zone is complete and authentic because of the unsigned NS delegation records in the root zone.

The IETF published RFC 8976^[8], the specification of a message-digest record for DNS zones, in February 2021. This RFC defines the *Message Digest for DNS Zones* (ZONEMD) record.

What's a Message Digest?

A *Message Digest* is a form of a condensed digital signature of a digital artefact. If the digital artefact has changed in any way, the digest will necessarily change in value as well. If a receiver of this artefact is given the data object and its digest value, then the receiver can be assured, to some extent, that the contents of the file have been unaltered since the digest was generated.

These digital signatures are typically generated using a *Cryptographic Hash Function*. These functions have several useful properties. They are normally a fixed-length output function, so that the resulting value is a fixed size, irrespective of the size of the data for which the hash has been generated.

They constitute a *unidirectional* function, in that knowledge of the hash function value will not provide any assistance in trying to recreate the original data. They are *deterministic*, in that the same hash function applied to the same data will always produce the same hash value. Any form of change to the data should generate a different hash value. Hash functions do not necessarily produce a unique value for each possible data collection, but it should be exhaustively challenging (unfeasible) to synthesise or discover a data set that produces a given hash value (*preimage resistance*), and equally challenging to find or generate two different data sets that have the same hash function value (*collision resistance*).

In other words, an adversary, malicious or otherwise, cannot replace or modify the data set without changing its digest value. Thus, if two data sets have the same digest, one can be relatively confident that they are identical. Second pre-image resistance prevents an attacker from crafting a data set with the same hash as a document the attacker cannot control. Collision resistance prevents an attacker from creating two distinct documents with the same hash.

The root zone includes a ZONEMD record, signed with the *Zone Signing Key* of the root zone. When a client receives the root zone it should look for this record, validate the *Resource Record Digital Signature* (RRSIG) of the ZONEMD record in the same way that it DNSSEC-validates any other RRSIG entry in the root zone, and then compare the value of this record with a locally calculated message digest value of the local copy of the root zone. If the digest values match, then the client has a high level of assurance that this copy of the root zone is authentic and has not been altered in any way.

The dates in the DNSSEC signatures can indicate some level of currency of the data, but further assurance at a finer level of granularity than the built-in key validity dates that the local copy of the root zone data is indeed the current value of the root zone is a little more challenging in this context. DNSSEC does not provide any explicit concept of revocation of prior versions of data, so all “snapshots” of the root zone within the DNSSEC key validity times are equally valid for a client.

The root zone uses a two-week signature validity period (Figure 5).

Figure 5: Root Zone Start of Authority (SOA) Signature.

```

This approach of a whole-of-zone signature has some real utility in terms of the distribution of the root zone to DNS resolvers and thereby reduces the dependency on the continuous availability and responsiveness of the root zone servers. The use of the ZONEMD record allows any client to use a local copy of the root zone irrespective of the way in which the zone file was obtained. Within the limits of the authenticated currency of the zone file, as already noted, any party can redistribute a copy of the root zone, and clients of such a redistributed zone can answer queries using this data with some level of confidence that the responses so generated are authentic. It would be useful to augment the existing in-band root zone retrieval using *Authoritative Transfer* (AXFR) with a simple memorable web-retrieval object, such as https://1.2.3.4/root_zone.txt, for example, to allow the zone distribution function to be undertaken by *Content Distribution Networks* (CDNs) as well as by DNS servers.

Resolvers that elect to use a locally managed copy of the root zone can use the ZONEMD record to verify the authenticity of a received root zone. Resolver implementations that perform this verification using ZONEMD include *Unbound* (from v1.13.23) and *PowerDNS Recursor* (from v4.7.04) and *Bind* (v9.17.13).

Notification mechanisms that could prompt a resolver to work from a new copy of the root zone are not addressed in this ZONEMD framework. To me that's the last piece of the framework that could promote every recursive resolver into a peer root server. We've tried numerous approaches to scalable distribution mechanisms over the years. There is the structured *push* mechanism, where clients sign up to a distributor and the distributor pushes updated copies of the data to them. Routing protocols use this mechanism. There also is the *pull* approach, where the client probes its feed point to see if the data has changed and pulls a new copy if it has changed. This mechanism has some scaling issues in that aggressive probing by clients may overwhelm the distributor. We've also seen hybrid approaches where a change indication signal is pushed to the client, and it is up to the client to determine when to pull the new data.

This model of local root zone distribution has the potential to change the nature of the DNS root service, unlike NSEC caching. If there is one thing that we've learned to do astonishingly well in recent times it is distribution of content.

Indeed, we've concentrated on this activity to such an extent that it appears that the entire Internet is nothing more than a small set of CDNs. If the root zone is signed in its entirety with zone signatures that allow a recursive resolver to confirm its validity and currency and is submitted into these distribution systems as just another digital object, then the CDN infrastructure is perfectly capable of feeding this zone to the entire collection of recursive resolvers with ease. Perhaps if we changed the management regime of the root zone to generate a new zone file every 24 hours according to a strict schedule, we could eliminate the entire notification superstructure. Each iteration of the root zone contents would be published 2 hours in advance and it would be valid for a period of precisely 48 hours, for example. At that point the root zone could be served by the existing millions of recursive resolvers rather than the twelve operators and some 2,000 server instances we use today. That's a thousand-fold increase in the capacity of the root system, and at the same time it eliminates the general reliance on a narrow neck of incremental queries being directed to the 12 root server operators that underpin today's DNS.

Futures

We operate the root service in its current framework because it represents a set of compromises that have been functionally adequate so far. That is to say the predominate query-based approach to root zone distribution hasn't visibly collapsed in a screaming heap of broken DNS yet! And it will probably continue to operate in a robust manner for many years to come.

But we don't have to continue relying on this query-based approach just because it hasn't broken so far. Our need to further scale this function is ongoing, and it makes a lot of sense to take a broader view of available options and the just-in-time delivery process used by the DNS incremental query name-resolution algorithm.

We have some choices as to how the root service can evolve and scale.

With Aggressive NSEC Caching we can have recursive resolvers make better use of signed NSEC records and we appear to have staved off some of the more pressing immediate issues about further scaling of the root system. But that's probably not enough.

We can either wait for the DNS system to collapse and then try to salvage the DNS from the broken mess, or perhaps we could explore some alternatives now. For example, we could look at how we can break out of a query-based incremental root content promulgation model and view the root zone as just another content "blob" in the larger ecosystem of content distribution. If we can cost-efficiently load every recursive resolver with a current copy of the root zone, and these days that's not even a remotely challenging target, then perhaps we can put aside the issues of how to scale the root server system to serve ever greater volumes of queries to ever more demanding clients, and perhaps also provide an alternate answer to the continual questions about the politics and finances relating to root servers and their operation.

The reason why content distribution networks have revolutionised the Internet in recent years is that pre-provisioning at the edge makes for a faster, cheaper, and more scalable network in the current context of abundant computing and storage capabilities. If we are prepared to allow this same thinking to intrude into the way we provision the DNS, I suspect we could realise similar benefits for the DNS as well.

GEOFF HUSTON AM, B.Sc., M.Sc., is the Chief Scientist at APNIC, the Regional Internet Registry serving the Asia Pacific region. He has been closely involved with the development of the Internet for many years, particularly within Australia, where he was responsible for building the Internet within the Australian academic and research sector in the early 1990s. He is author of numerous Internet-related books, and was a member of the Internet Architecture Board from 1999 until 2005. He served on the Board of Trustees of the Internet Society from 1992 until 2001. At various times Geoff has worked as an Internet researcher, an ISP systems architect, and a network operator. E-mail: gih@apnic.net

Our Privacy Policy

The *General Data Protection Regulation* (GDPR) is a regulation for data protection and privacy for all individual citizens of the *European Union* (EU) and the *European Economic Area* (EEA). Its implementation in May 2018 led many organizations worldwide to post or update privacy statements regarding how they handle information collected in the course of business. Such statements tend to be long and include carefully crafted legal language. We realize that we may need to provide similar language on our website and in the printed edition, but until such a statement has been developed here is an explanation of how we use any information you have supplied relating to your subscription:

- The mailing list for *The Internet Protocol Journal* (IPJ) is entirely “opt in.” We never have and never will use mailing lists from other organizations for any purpose.
- You may unsubscribe at any time using our online subscription system or by contacting us via e-mail. We will honor any request to remove your name and contact information from our database.
- We will use your contact information only to communicate with you about your subscription; for example, to inform you that a new issue is available, that your subscription needs to be renewed, or that your printed copy has been returned to us as undeliverable by the postal authorities.
- We will never use your contact information for any other purpose or provide the subscription list to any third party other than for the purpose of distributing IPJ by post or by electronic means.
- If you make a donation in support of the journal, your name will be listed on our website and in print unless you tell us otherwise.

Letters to the Editor

As a long-time subscriber to the *Internet Protocol Journal*, I have always found the articles to be timely, extensively researched, and presented with clarity. Because of these qualities I've often used IPJ articles as reading assignments to my students in several of the courses that I teach. They give students a depth that is not too technical but yet contains enough of the necessary technical details that help them better understand the technology while also grasping the impact of the technology in the context of how it is being used today while looking ahead to the future.

I especially enjoy reading and sometimes sharing articles by Geoff Huston. Geoff has a real knack for presenting technical details within the larger scope of “how we got here and where we are going” that always makes his articles a pleasure to read.

However, Geoff's article on “The IPv6 Transition” in Volume 28, No. 1, May 2025 was especially beneficial. Students often ask me why, after all these years, IPv6 still plays “second fiddle” to IPv4 and is not more widely adopted. Geoff's article does a superb job of explaining the numerous reasons behind the slow transition to IPv6. And his analysis of how today's Internet is moving away from a strict address-based architecture offers an excellent assessment as to what lies ahead in the future for IPv6.

And the timeliness of Geoff's article could not have been better: after arriving in my email inbox that afternoon I had enough time to add some of his observations to my class discussion the very next morning!

Thanks, Geoff, and keep up the good work!

Regards,

—Dr. Mark Ciampa
Professor, Western Kentucky University
Bowling Green, KY
mark.ciampa@wku.edu

The Author responds:

Thank you Mark for your kind words. The Internet has not followed a path driven as much by market pressures as it is by technical evolution, and the outcomes are often surprising. This topic was the main theme of my article. One thing is sure, however, that the pressures to innovate will continue, and tomorrow will be as surprising as today!

Kind regards,

—Geoff Huston
gih@apnic.net

Hi Ole,

As always, I enjoy reading Geoff's articles in IPJ and I appreciate Geoff's continuing to write and your willingness to publish his material. What I so appreciate, Ole and Geoff, about IPJ is the *context* which you provide that gives me the larger frame/larger picture into which to place much of what I do. And even when I don't specifically need the context—I don't do anything with cellular networks for example—I find the articles fun reading regardless.

My “two bits” on Geoff's “IPv6 Transition” article: I logged into my first network-attached computer in 1981, as a student. I configured my first IP router in 1991, and I have spent my career to date supporting IT infrastructure (compute/network/storage) for academic or other non-profit research institutes, mostly in the life sciences. My perspective over the years, as I have sat in seminars at Interop or read news or attended internal meetings about IPv4 address exhaustion and the need for IPv6:

- Adding IPv6 support to our network would take money, staff hours, and training time, not only from network engineers but also from desktop, server, and storage system engineers; smells like a lot of effort to me.
- I find it difficult to prioritize distant risks over immediate priorities.
- Our user base has yet to ask for access to an IPv6-only resource (such a request would affect how we prioritize, but I have not seen even one).
- I suspect that any institution that wants to make a resource broadly available will invest significant effort into making it available via IPv4 because there are so many IPv4 users out there.

As a result, I have yet to configure any device to support IPv6. I am not opposed to IPv6 ... but since I still get up at 2am when my [pager](#) phone buzzes, in response to our network malfunctioning, I have—reasonably I propose—allocated my time to other priorities.

—Stuart Kendrick

Allen Institute, Seattle, WA USA
stuartk@alleninstitute.org

The Author responds:

Hi Stuart. We share a similar vintage, as I first logged into a computer as a student in 1976 (A Sperry Rand Univac mainframe), although building a network connection to the Internet for all Australian Universities would take a further 13 years, when the project that I was leading, AARNet, had managed to complete its initial mission.

In the early 1990's when the IETF was debating the approach to be used for the "next generation" IP protocol, there were many general approaches. One approach, originally called "SIP" was intended to change the IPv4 design as little as possible. It lengthened the address fields to 128 bits, but not much else changed. Other approaches described a more radical set of design changes. SIP won the day, and IPv6 is, to all intents and purposes, just IPv4 with bigger address fields.

In other words, IPv6 was not intrinsically "better" than IPv4 for any particular use case. It wasn't intrinsically faster, nor more secure, nor more agile. It just had bigger address fields. The result was that deploying IPv6 did not provide a network operator with a compelling competitive product. If a network operator already had secured ample pools of IPv4 addresses, then it was not necessarily impacted by IPv4 address scarcity, and the case for incurring the cost of deploying IPv6 in a dual-stack network scenario was extremely challenging to make. A direct result of this situation is the protracted transition to IPv6 for many parts of the Internet, an issue I explored in this article.

Frankly, it does not really make much sense to comment on the IPv6 design as "right" or "wrong." It represented the common wisdom of the IETF at that time. However, we did fail to predict just how long the dual-stack transition was going to take, or even if this transition would ever come to an end. Some 30 years after we started down this path I suspect we are no closer to answering these two very fundamental questions.

Regards,

—*Geoff Huston*

In Memoriam

Dave Täht

Dave Täht, formerly known as Michael David Täht (August 11, 1965 – April 1, 2025) was our friend, colleague, and mentor at LibreQoS. To the rest of the world, Dave was an American network engineer, musician, lecturer, asteroid exploration advocate, Internet activist, and much more^[1].

The fruits of Dave’s work are everywhere. Most people will never notice—a testament to his engineering. Dave’s work on creating algorithms like *Flow Queueing with Controlled Delay*^[2] and *Common Applications Kept Enhanced* (CAKE)^[3] was instrumental, and now it’s part of Linux, OpenWrt, and Starlink; mainstream networking equipment vendors like MikroTik use it as well.

Dave and Jim Gettys spearheaded the networking industry’s effort to eliminate bufferbloat, latency, and jitter on today’s interactive Internet, where bandwidth matters less^[4]. Around 2010, Dave was semi-retired in Nicaragua—and Jim in the USA. They independently came to the realization that Voice over IP and videoconferencing were suffering from the same issues: *lag* and *jitter*, caused by the proverbial time difference between Dave speaking on one continent and Jim hearing his voice on another. Jim coined the term “bufferbloat” to describe the culprit: the extensive and ever-increasing size of buffering on network devices. They started **Bufferbloat.net** and began solving the problem.

Besides his work on solving bufferbloat, Dave also spent years in Nicaragua trying to find ways to bring the Internet (and power, lighting, food, medicine, and books) as an outgrowth of Nicholas Negroponte’s *One Laptop Per Child Project*^[5].

Dave was also known for his little ditties, songs he liked to play while presenting at conferences or podcasts. He wrote “One First Landing,” for example, to cheer up people at SpaceX when they were not doing well with landing their rocket, and he was forced to rewrite it when they started to land their rockets successfully^[6]. And he was happy to do it!

For the last couple of years Dave lived on a boat in Half Moon Bay, a small city on the California coast, south of San Francisco; Dave always liked to sail.

Ad astra per aspera, Dave, you are an astronaut now!

—Robert, Herbert, and Frank - LibreQoS

LibreQoS is an Open Source project founded by Robert Chacón (and quickly joined by Dave Täht). LibreQoS provides a drop-in middlebox for *Internet Service Providers* (ISPs), applying CAKE to all of the ISP’s users, as well as an array of network monitoring tools.

—Karl Auerbach

Frederick Juergens Baker

The Internet has lost a generous long-time contributor. Frederick Juergens Baker (February 28, 1952 – June 18, 2025)^[1] was one of the original members of the *Internet Systems Corporation* (ISC) Board of Directors, appointed at ISC’s incorporation in 1994.

Fred had a long career in the communications industry, working for Control Data Corporation, Vitalink Communications, Advanced Computer Communications, and for 22 years, at Cisco Systems.

After retiring from Cisco, Fred worked as a contractor, notably for the Internet Society and ISC. In addition to serving on the ISC BOD, in 2017 he joined the *Root Server System Advisory Committee* (RSSAC) of the *Internet Corporation for Assigned Names and Numbers* (ICANN), representing ISC. He served as co-chair of RSSAC from October 2018 to December 2019, and as chair from January 2020 through December 2022.

Fred volunteered a lot of his time to working with the *Internet Engineering Task Force* (IETF), the body that develops standards for the Internet. He chaired numerous IETF working groups, including several that specified the *Management Information Bases* (MIB) used to manage network bridges and popular telecommunications links, and the IPv6 Operations working group.

He served as IETF chair from 1996 to 2001, and he served on the Internet Architecture Board from 1996 through 2002. Fred co-authored or edited at least 60 *Request for Comments* (RFC) documents ^[2,3] on Internet protocols, and contributed to others. The subjects covered include network management, *Open Shortest Path First* (OSPF) and *Routing Information Protocol* (RIPv2) routing, *Quality of Service* (using both the *Integrated Services* and *Differentiated Services* models), *Lawful Interception*, precedence-based services on the Internet, and others.

In addition, Fred served as a member of the Board of Trustees of the Internet Society from 2002 through 2008, and as its chair from 2002 through 2006. He was a member of the *Technical Advisory Council* of the US *Federal Communications Commission* in 2004. He worked as a liaison to other standards organizations such as the ITU-T. In 2009–2010, he served as chair of the *RFC Series Oversight Committee*.

He represented IETF on the *National Institute of Standards and Technology Smart Grid Interoperability Panel* and the *Architecture Committee* from 2008 through 2013, and was Cisco's representative to the *Broadband Internet Technical Advisory Group* (BITAG). He also holds several patents.

Fred was committed to the collaborative, consensus-driven process of creating open standards for the Internet, and he demonstrated his commitment throughout his long career with years of active volunteering. Besides his leadership roles, he also welcomed and mentored new participants in the IETF.

Fred was a wonderful guy, an Internet luminary, and a great friend to ISC over the course of decades of board membership, as well as representing ISC at RSSAC as chair and in many other roles in the IETF, ICANN, and ISOC worlds. We all will dearly miss him.

We extend our deepest condolences to Fred's family.

—Jeff Osborn, ISC
jsosborn@isc.org

IETF-developed MLS set to be used on 100s of Millions of Mobile Devices

Less than two years after *Messaging Layer Security* (MLS) was published as an RFC^[0], it is poised to be deployed on Android phones and Apple iPhones and other devices, thanks to newly updated RCS specifications, enabling interoperable encryption between different platform providers for the first time.

The GSM Association^[1] announced that the latest *Rich Communications Services* (RCS) standard includes end-to-end encryption based on the MLS protocol. RCS enhances traditional SMS messaging by offering a suite of service capabilities, including group chat, file transfers, typing notifications, and more. Key stakeholders for RCS implementation include device manufacturers, telecommunications operators, and business service providers.

MLS, developed by the IETF *Messaging Layer Security Working Group*^[2], provides unsurpassed security and privacy for users of group communications applications. Using MLS, participants always know which other members of a group will receive the messages they send, and the validity of new participants joining a group is verified by all the other participants. During its development^[3] in the IETF, MLS underwent formal security analysis and industry review. It currently supports multiple cipher suites, and makes it straightforward to add quantum attack resistant cipher suites in the future^[4].

The open processes and “running code” that are hallmarks of the IETF, mean that MLS is already proven to be efficient at Internet scale, working efficiently with groups that have thousands of participants. MLS is already available from, and implemented and deployed by a wide range of companies and organizations^[5]. This includes real-time platforms such as Webex, Wire, and Discord, as well as in devices such as drones.

MLS is also extensible, meaning it can be easily updated in a number of ways. Work is continuing in the MLS Working Group in a number of areas and the IETF *More Instant Messaging Interoperability* (mimi)^[6] working group is looking to build on MLS as they aim to specify the minimal set of mechanisms required to make Internet messaging services interoperable.

ICANN and ISOC Joint Report on 20 Years of IGF

The *Internet Corporation for Assigned Names and Numbers* (ICANN) and the *Internet Society* (ISOC) recently released a report that offers a substantive look at the global impact of the *Internet Governance Forum* (IGF). It demonstrates how coordination—rather than control—has driven tangible progress in the Internet’s resilience, reach, and trust. Structured not as a retrospective but as a practical record of outcomes, the report draws from two decades of work across infrastructure, access, security, and policy. It offers grounded evidence of what coordination has made possible and what could be lost if support for multistakeholder cooperation erodes. The key insights of the report are as follows:

- *Infrastructure and Access*: In Africa, *Internet Exchange Points* (IXPs) more than doubled in over a decade. In countries like Kenya and Nigeria, this growth helped localize traffic, cutting the delay in data travel (latency) from around 200–600 milliseconds to 2–10 milliseconds, and saving millions annually in international connectivity costs. The IGF enabled the sharing of best practices that directly contributed to this expansion.
- *Multilingual Access*: Nearly 4.4 million domain names are now registered in non-Latin scripts. Through IGF-hosted sessions and stakeholder coalitions, *Internationalized Domain Names* (IDNs) and *Universal Acceptance* (UA) have gained critical momentum. In 2025, more than 50 global events marked *UA Day*, promoting linguistic access across the Internet ecosystem.
- *Security and Resilience*: Today, 93% of top-level domains are secured using *Domain Name System Security Extensions* (DNSSEC), which protect against forged DNS responses. In parallel, over 1,000 networks have adopted the *Mutually Agreed Norms for Routing Security* (MANRS), a global initiative to reduce routing attacks. The IGF has catalyzed awareness, collaboration, and implementation of these safeguards.
- *Local Engagement and Policy Influence*: More than 180 *National and Regional IGFs* (NRI) now form a decentralized backbone of year-round Internet governance dialogue. Initiatives like *Youth IGFs* and the *IGF Parliamentary Track* are shaping national and international policy—including formal declarations on digital trust, user rights, and multistakeholder governance.

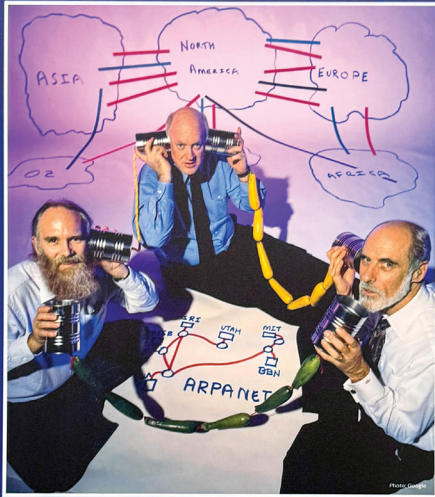

- *Community-Centric Innovation*: From the Arctic to the Andes, community networks have grown through IGF platforms and the *Dynamic Coalition on Community Connectivity* (DC3). These grass-roots efforts now inform regulatory change, including *International Telecommunication Union* (ITU) resolutions and national endorsements, and have helped close connectivity gaps in underserved regions.
- *Global Coordination Platform*: The IGF has evolved from an annual convening into a living ecosystem. It bridges technical and policy domains, connects local with global perspectives, and enables distributed but aligned Internet governance. That structure is now both a model and a necessity.

The report launches ahead of the 20-year review of the *World Summit on the Information Society* (WSIS+20)—a pivotal moment that will shape the next phase of global digital cooperation. It serves as both a record of achievement and a warning: coordination works but is not self-sustaining. The Internet's openness, security, and interoperability depend on it. If that cooperation falters, the conditions that have made the Internet thrive may not hold. The full report is available here:

https://www.internetsociety.org/wp-content/uploads/2025/06/20-Years-of-IGF_EN.pdf

Poster featuring Internet Pioneers Pål Spilling and Yngvar Lundh displayed at IGF 2025 in Lillestrøm, Norway.

1973

Pål Spilling, Yngvar Lundh and Dag Belsnes took part in the development of the TCP/IP protocol and established with Vint Cerf and his team the first connection to the Internet (Arpanet) at Kjeller – visit us on Tuesday and Thursday.

Thank You!

Publication of IPJ is made possible by organizations and individuals around the world dedicated to the design, growth, evolution, and operation of the global Internet and private networks built on the Internet Protocol. Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com

Security continues to be a major concern for both Internet users and technology developers. *Standards Development Organizations* (SDOs) such as the *Internet Engineering Task Force* (IETF) have approached security by developing new—or enhancing old—protocols. Examples include *Resource Public Key Infrastructure* (RPKI) for routing and *Domain Name System Security Extensions* (DNSSEC) for the DNS. But protecting and securing the collection of networks that comprises the Global Internet requires a comprehensive analysis of attack traffic patterns as well as a coordinated approach by network operators. Leslie Daigle of *The Global Cyber Alliance* (GCA) provides some examples of measurements from so-called “honeypot” networks and offers suggestions for ways to improve the response to cyber attacks.

The term “Internet Governance” emerged sometime in the mid-1990s to describe numerous existing and emerging administrative efforts to manage Internet resources such as IP addresses and top-level domain names. According to Wikipedia, Internet Governance is “...the effort by governments, the private sector, civil society, and technical actors to develop and apply shared principles, norms, rules, and decision-making procedures that shape the evolution and use of the Internet.” The term “multistakeholder” is used to refer to the various parties involved in these activities. Like Internet Governance itself, multistakeholderism is subject to some debate. In this issue we bring you two opinion pieces on this topic. First, Geoff Huston provides some history and background and then asks if multistakeholderism has ended. Avri Doria responds with a counter-opinion and provides an overview of current efforts and future directions for multistakeholder approaches.

All 95 previous issues of this journal are available on our website. You will find two ZIP archives; one will expand to a folder with each individual issue, and the other will expand into a single PDF file with more than 3,600 pages. Our website also contains index files for each volume as well as a cumulative index file of all issues to date. Check out protocoljournal.org for more details.

Securing a Borderless Internet:

Observations from Global Attack Data and the Case for Collaborative Defense

by Leslie Daigle, Global Cyber Alliance

The Internet's continued expansion into every sector of society has elevated its importance and correspondingly heightened the impact of its vulnerabilities. As critical services move online, the Internet's loosely coupled, globally distributed architecture faces increasing pressure from malicious activity that exploits both technical weaknesses and operational inconsistencies between networks.

This article outlines several ongoing attack campaigns observed at global scale and the important consequences of this seemingly “innocuous” low-bandwidth traffic, and provides objective evidence in recent data collected from the *Global Cyber Alliance* (GCA)^[6] honey farm. Discussion includes why traditional defensive measures such as geographic blocking are inadequate, and how collaborative approaches, including *Mutually Agreed Norms for Routing Security* (MANRS)^[1,7], can be a model for improving resilience across the Internet's shared infrastructure.

The Internet's Security Challenge: A Structural Overview

The Internet is amazing, powerful, chaotic. And *absolutely impossible to secure alone*. Traditional approaches to security focus on curtailing reach and imposing restrictions. Whether applied at the national level through regulation, or at the organizational level by administrative blocking, those approaches fail to provide real security improvements, and they generally lead to inconsistent (non-interoperable) behavior.

A better target is “Internet integrity”—ensuring both security and accessibility across a resilient infrastructure.

Unlike closed, centrally administered systems, the Internet is an interconnection of independently operated networks. These entities cooperate voluntarily through shared protocols, routing policies, and operational conventions. The strength of this model lies in its openness, but its distributed nature also complicates coordinated security measures. The global mesh that gives us connectivity everywhere also creates a complex attack surface. Resources can be registered in one country, hosted in another, used in a third, and abused in a fourth.

Three characteristics are particularly relevant:

- *Jurisdictional Diversity*: The administrative domains responsible for registering IP resources, hosting infrastructure, and operating networks often reside in different countries. Attackers routinely exploit these jurisdictional discontinuities.
- *Operational Heterogeneity*: Network operators vary widely in maturity, staffing, automation, and security posture. This situation creates uneven defenses, producing opportunities for attackers to move laterally or launch global campaigns by abusing weaker networks.

- *Inherent Reachability*: The Internet’s default is connectivity. With few exceptions, networks are reachable by any other network. This reachability is essential for global interoperability, but it provides attackers with immediate, worldwide access to potential targets.

Together, these factors make it impossible for any single operator to “secure the Internet” in isolation, or even secure their own resources. No network can ensure its own routing security, for example—networks must rely on their neighbor networks. Effective defense depends on consistent practices adopted collectively.

Insights from a Global Honey Farm

To better understand the operational realities of contemporary threats, the GCA maintains a network of roughly 200 honeypot sensors distributed across multiple regions. These systems present no advertised services; their purpose is solely to observe unsolicited traffic^[2].

Despite their passive configuration, the sensors receive a continuous stream of probing attempts—ongoing, simultaneous interactions between networks spanning every continent. The volume and global distribution of this traffic demonstrate that unwanted scanning and exploitation attempts reach essentially all IPv4 addresses, regardless of geography or network size.

In discussing this “unwanted traffic” with network infrastructure operators, it is often dismissed as inconsequential, neither consuming undue bandwidth nor impacting their customers. In fact, analysis of this data reveals not only the scale of background noise on the Internet but also the presence of distinct, well-coordinated attack campaigns that have massive impact on real-life commercial and regional interests.

Here are four examples of campaigns that have had significant global impact, as seen from GCA’s vantage points:

APT36

APT36 (*Transparent Tribe*) provides a clear example of how advanced persistent threat groups increasingly exploit legitimate telecommunications infrastructure to conduct operations in plain sight. Long associated with geopolitical espionage, the group is believed to be aligned with Pakistani state interests, and it typically targets Indian government and military entities through phishing, credential harvesting, and targeted malware delivery. While its activity has been observed for more than a decade, operations surged in 2025—first identified in external reporting and then independently confirmed through data from GCA’s *Automated IoT Defence Ecosystem* (AIDE) platform.

AIDE supports multiple protocols, including *Secure Shell* (SSH), *Telnet*, *File Transfer Protocol* (FTP), *Hypertext Transfer Protocol* (HTTP), *Hypertext Transfer Protocol Secure* (HTTPS), and the *Simple Mail Transfer Protocol* (SMTP). Between April and August 2025, AIDE recorded 116,374 incidents on Indian sensors alone, originating from 75 *Autonomous System Numbers* (ASNs) based in Pakistan.

The breadth of this activity demonstrates that APT36 operations are neither localized nor opportunistic; instead, they rely on widely distributed *Internet Service Provider (ISP)* infrastructure to obfuscate origin, increase resiliency, and sustain long-running campaigns. Traffic attributed to the group appears globally across sensors, reflecting an architecture deliberately built to avoid geographical confinement.

AIDE data shows how APT36 leverages these networks to deploy multi-architecture malware, route attacks through legitimate providers, and take advantage of gaps in routing hygiene. This combination allows the group to operate at Internet scale while blending malicious traffic into ordinary global flows. See Figure 1.

Figure 1: APT36 Attack Origins by ASN Industry (Industry classifications sourced from PeeringDB)

The implications extend well beyond technical routing anomalies: abuses of telecom and backbone infrastructure undermine trust in critical networks, create economic disruption, and contribute to rising geopolitical tension. What happens inside ISP and backbone networks ultimately affects hospitals, schools, businesses, and governments that depend on stable, secure connectivity. Strengthening routing security and addressing systemic weaknesses is therefore more than an operational best practice—it is essential for national security, regional stability, and the reliable functioning of the Internet as a whole. See ^[3] for more details about this campaign.

Red Tail

Cryptocurrency mining malware is often treated as background noise—malicious but largely inconsequential beyond wasted compute cycles. The *RedTail* campaign challenges that assumption. Financially motivated and attributed to infrastructure associated with the Lazarus Group, RedTail represents a sustained, multi-month crypto-mining operation that exhibits the persistence and sophistication more commonly associated with state-aligned activity than routine cybercrime.

Between February and August 2025, GCA's AIDE honeypot network recorded recurring RedTail activity, including pronounced surges in late April and again in July. Much of this traffic originated from legitimate ISPs, cloud-hosting platforms, and other network service providers, illustrating how abused or compromised infrastructure can be repurposed to deliver attacks at scale.

AIDE data shows that RedTail operators exploited known vulnerabilities, deployed custom binaries across multiple architectures, and maintained their infrastructure for months at a time. When attacker nodes are ranked by longevity rather than raw event volume, a consistent operational discipline emerges: some nodes remained active for nearly the entire 26-week observation period, others for 20–24 weeks, and even the shortest-lived persisted for more than 8 weeks. Maintaining infrastructure for this duration requires resource investment, coordination, and an ability to operate across multiple networks without rapid takedown—traits that align with state-sponsored operations.

The campaign also reflects known Lazarus Group tradecraft. Recent operations—including the \$1.46 billion Ethereum theft from *Bybit* and the earlier *AppleJeus* malware distribution campaign—demonstrate the group's capacity for financially motivated attacks executed with speed, scale, and cross-platform capability. RedTail's deployment of multi-architecture malware and its dependence on private mining pools for monetization mirror these patterns, reinforcing the assessment that the campaign sits well above typical crypto-mining activity in sophistication and strategic intent.

Although AIDE captures attacks in controlled environments, the concentration of RedTail activity targeting sensors in India, Australia, and Singapore—nearly 40 percent of its global footprint—suggests that real-world networks in major financial and technology hubs would face similar exposure. The phased lifecycle of the campaign, spanning reconnaissance through escalation and sustained exploitation, underscores the fact that crypto mining at this level is not merely an operational nuisance. It is a strategic risk: long-running, resource-intensive campaigns that leverage legitimate network infrastructure can degrade provider networks, impose economic costs, and contribute to broader geopolitical and financial instability. See ^[4] for more detail.

Kimsuky

Kimsuky represents another example of how state-aligned actors exploit global infrastructure to support persistent, policy-focused espionage. Widely assessed in open-source reporting, including analyses by the *Cybersecurity and Infrastructure Security Agency* (CISA) and The MITRE Corporation, to be associated with North Korean intelligence collection, the group is known for targeting diplomats, researchers, policy institutes, and think tanks in South Korea, Japan, and the United States. These organizations often lack high-assurance security postures, making them attractive targets for actors seeking strategic or policy-relevant information.

Kimsuky's operations commonly involve social engineering, spear phishing, reconnaissance activity, credential theft, and the deployment of custom malware families such as *BabyShark* and *AppleSeed*. Although some threat intelligence providers characterize the group as state-directed, this attribution stems from external assessments rather than any conclusions drawn from our own data. What can be confirmed is the pattern of behavior: a sustained interest in research institutions and policy environments, combined with a resourceful approach to global infrastructure use.

AIDE data illustrates this infrastructure strategy clearly. While some traffic originates from Asia-Pacific economies consistent with the group's primary targets, the highest volumes are associated with offshore hosting, with Panama-based services leading, followed by infrastructure in the United States, United Kingdom, and Germany. This strategy reflects a deliberate preference for leveraging non-APAC providers to obscure operational footprints and complicate attribution. This approach is aligned with external reporting on Kimsuky's 2024 "forceCopy" campaign, which relied heavily on offshore *Virtual Private Server* (VPS) nodes to evade takedowns.

The resulting geographic distribution underscores a broader trend: threat actors increasingly route operations through diverse, globally distributed infrastructure to bypass regional controls and extend campaign longevity. In Kimsuky's case, this approach enables sustained espionage activity against organizations whose missions intersect with national policy and international security, yet whose defensive resources are often limited. For more information, see ^[5].

Dark Pink

The *Dark Pink* campaign illustrates how modern cyber espionage operations rely on globally distributed infrastructure to sustain persistent targeting of governmental and military systems. Public reporting since 2022—beginning with Group-IB's initial analysis—has used the "Dark Pink" label to describe activity aimed at government, defense, and education organizations across Southeast Asia, including Cambodia, Indonesia, Malaysia, the Philippines, and Vietnam.

External researchers have characterized the group's behavior as consistent with long-term strategic access operations. CrowdStrike has further linked Dark Pink to an earlier activity cluster known as *Ocean Buffalo*, which it associates with Vietnam-originated domestic surveillance that later expanded internationally. These associations, however, reflect external assessments rather than conclusions derived from GCA's own data.

AIDE observations align with the narrative of an evolving campaign that continues to broaden its operational footprint. While Dark Pink's historical focus lies in Asia Pacific, AIDE data shows that much of the infrastructure used to stage activity now resides outside the region. Of all sessions attributed to the campaign, 47 percent originated from European networks, followed by 33 percent from Asia Pacific and 19 percent from the United States. This distribution suggests that even if the operators of the campaign began by targeting organizations within Asia Pacific, they have increasingly shifted to European and North American hosting to obscure the origins of their operations, improve reach, and complicate defensive analysis.

Operationally, Dark Pink exhibits a wave-like pattern: periods of low activity punctuated by concentrated bursts of probing and exploitation attempts, particularly against military and governmental systems in Indonesia, the Philippines, and Malaysia. The reliance on staging infrastructure across Europe and North America reinforces the broader trend seen across multiple campaigns: attackers use globally dispersed hosting and service providers to mask activity, evade localized defensive measures, and sustain long-duration operations aimed at high-value targets. For more details, see ^[6].

Why Geographic Blocking Fails

Whether the full scope of the nature of attack campaigns is understood or not, anyone connecting to the Internet today must engage in some level of defensive posture toward attack traffic.

In response to increased malicious activity, some organizations apply coarse filtering, such as blocking entire regions or countries. Honey farm observations suggest that such approaches offer limited security benefits for several reasons:

- *Attack traffic is globally distributed:* Even region-specific campaigns employ infrastructure across multiple continents. Blocking by geography frequently misses the actual sources.
- *Legitimate infrastructure is commonly abused:* A significant proportion of unwanted traffic originates from compromised hosts within well-established ISPs and cloud providers. Blocking these networks would be operationally unacceptable.
- *Blocking introduces negative externalities:* Users accessing services from abroad may be inadvertently denied access, despite legitimate need. Furthermore, over-blocking can encourage brittle application behavior and complicate troubleshooting.

- *Outbound traffic may be the real problem:* Networks can inadvertently source attacks if customer equipment becomes compromised, thereby harming the reputation of the network and, in some cases, the valuation of its IPv4 address space.

Geographic controls do not address the fundamental problem: inconsistent operational practices across networks.

The Hidden Cost: The Reputation of Your Network

Attack traffic doesn't just consume bandwidth or CPU cycles. It degrades the reputation of the networks it comes from. IPv4 space that becomes associated with malicious behavior loses value. Connectivity providers may quietly de-prefer your IP address ranges. Security vendors may red-flag your AS.

Collaborative Security: A Path Forward

Given the structural characteristics of the Internet, meaningful improvements in security require coordinated operational norms. The MANRS initiative provides a useful model^[1,7].

MANRS defines a baseline of routing-security actions, such as filtering incorrect announcements, validating route origins, and coordinating incident reporting. Crucially, these norms were developed in consultation with operators rather than imposed externally. Data from the *MANRS Observatory* shows:

- Steady growth in participating networks,
- Increasing deployment of *Route Origin Authorizations* (ROAs), and
- A decline in observed routing incidents and misconfigurations.

These trends demonstrate that collaboratively defined practices can measurably improve global routing hygiene.

The success of MANRS suggests a broader lesson: operational security challenges are best addressed by communities of practice within the network operator ecosystem. When operators adopt common standards and coordinate responses, they reduce the attack surface not only for themselves but also for the entire Internet.

Conclusion

The Internet is not a monolith. It is a collective artifact shaped by millions of networks, thousands of operators, and countless decisions made every day. Its vulnerabilities are shared. Its strengths are shared. And its future depends entirely on whether collaboration remains its guiding principle.

The Internet's openness and global reach—qualities central to its success—also expose it to sustained, globally distributed malicious activity. Data from GCA's honey farm illustrates the breadth of these threats and the degree to which attackers exploit legitimate infrastructure across many regions.

Traditional defensive strategies such as geographic blocking are insufficient and may introduce new risks. Instead, improving the security of the Internet requires coordinated action among network operators. Initiatives like MANRS demonstrate that voluntary, consensus-driven norms can lead to measurable improvements.

Security cannot be achieved through panic or isolation. It must come from coordinated action, shared norms, and a willingness to confront uncomfortable truths about the role our own networks play.

As the Internet continues to evolve, its security will depend on sustained collaboration among the networks that collectively operate it. No single organization can secure the Internet, but together, operators can significantly reduce the scale and impact of malicious activity across the global ecosystem.

Opinion: The End of Multistakeholderism?

by Geoff Huston, APNIC

When the Internet outgrew its academic and research roots and gained some prominence and momentum in the broader telecommunications environment, its proponents found themselves to be opposed to many of the established practices of the international telecommunications arrangements—and even opposed to the principles that lie behind these arrangements. For many years, governments were being lectured that the Internet was *special*, and to apply the same mechanisms of national telecommunications and trade regulations to the Internet might not wreck the entire Internet, but they would surely isolate the nation that was attempting to apply these measures.

Within this broad category was the notion that conventional means of conducting trade in services were not applicable to the Internet. While an early mantra of “The Internet must be free!” quickly foundered when it encountered pragmatic realities of trying to pay the bills, the next mantra of “Don’t tax the Internet!” gathered significant momentum. What was meant here was an admonition to governments not to attempt to unduly constrain the flow of data with taxes and related imposts, as such actions applied carelessly would likely imperil the future value of the Internet. This situation offered a unique opportunity to take the role of public communications away from the sclerotic and bloated telephone monopolies and apply some of the vibrant innovative energy that was driving the computer industry into the communications realm.

WSIS

But while the Internet might have had some claim to exceptionalism in the 1990s, such a characterisation was unsustainable in the longer term. It was clear by the time of the millennium that the previous regime of national telephone operators and the treaties that governed the international aspects of this global service had been sidelined. The Internet was sweeping all before it, and each time it engaged with another sector it appeared to emerge from the encounter as a clear victor. The Internet might still be exceptional, but by the year 2000 people recognised that it was not always exceptional in a good way. In 2003 and 2005, the *United Nations* (UN) hosted the two-part *World Summit on the Information Society* (WSIS)^[1] to try to help nations accept these changes, and ideally to ensure that all economies would benefit from this revolution in computing and communications.

This WSIS summit was in the context of the emergence of the so-called “Information Society” and a recognition of a widening *Digital Divide*, where richer nations were in an obvious position to exploit the possibilities that became apparent with the combination of abundant computation and communications services—and thereby amass further wealth—while poorer nations yet again found themselves on the other side of the divide.

Far from being a tool to help equalise the inequities in our world by allowing all to access information, education, and open global markets for their services, the Internet appeared to be yet another tool to further entrench this divide between rich and poor.

The United States was a focal point in these discussions. At the time the Internet was still strongly associated with the United States, and the US had spent much of the previous decade both promoting its benefits and profiting from the revenue flowing into US companies that were early adopters of Internet-based services. This promotion of the Internet and the free flow of information was certainly not without elements of self-interest on the part of the US, as it appeared that the interests of the newly emerging corporate behemoths of the Internet and the geo-political and geo-economic aspirations of the US appeared to have much in common.

However, it's often difficult to tackle the larger picture in these large-scale international forums, so it was no surprise to see attention turn to the individual elements that were contained within this picture. One of these elements that became a topic of discussion in its own right was the status of the body that oversaw the protocol parameters of the Internet—including the names and IP addresses that are used as part of the central core of the Internet. This oversight, implemented by the *Internet Assigned Numbers Authority* (IANA)^[2], was originally part of the activities that the US *Defence Advanced Research Project Agency* (DARPA) funded. After a few more changes within the US Government agency landscape, responsibility for this function was shifted to a self-funded model operated by a private sector entity, the *Internet Corporation for Assigned Names and Numbers* (ICANN)^[3], with some level of US engagement remaining in place. This setup was variously portrayed as a control or as a safeguarding measure. Irrespective of the nature of the motivation, the result was that the *National Telecommunications and Information Administration* (NTIA)^[4], part of the US Department of Commerce, oversaw a contract between the US government and ICANN regarding the operation of the IANA function.

Perceptions matter, and the lingering perception here was that the Internet was still essentially under the control of a single sovereign state, the United States.

This unique US role was always going to be a problem for other nations. The international telephone and postal networks were governed by international treaty instruments that had been in place for more than a century. To have a single nation state positioned at the apex of this Internet structure was—to say the least—controversial. Naturally this topic was a major one in 2003 at the first WSIS gathering. The UN Secretary General at the time, Kofi Annan, convened a *Working Group on Internet Governance* (WGIG)^[5], a grand title that either conflated this topic to an even greater level of prominence or appropriately stated its central importance to the entire set of concerns with the structure of the Internet at the time.

Again, opinions vary here. No clear consensus came out of this WGIG activity, and the 2005 WSIS gathering could not reach any form of agreement on this matter either.

Internet Governance Forums

During the WSIS process the US apparently refused to consider any changes to its pivotal role in the management of the protocol parameters of the Internet. The WSIS summit eventually agreed on a compromise approach that deferred any determination on this matter and instead decided to convene a series of meetings to discuss the underlying policy principles relating to Internet Governance. We saw the inauguration of a series of *Internet Governance Forum* (IGF)^[6] meetings. These forums were intended to be non-decisional forums for all stakeholders to debate the issues. Originally intended to be convened for a period of five years, culminating in the fifth IGF meeting in Vilnius, Lithuania, in 2010, it has continued with a further five-year extension of its mandate, and then a ten-year extension, culminating with the recent IGF meeting in Norway at the end of June 2025.

Even within its limited objectives of being a forum for little other than discussions, the IGF found it challenging to claim universal success in achieving its mission. The IGF did not manage to address the underlying tensions relating to the pivotal position of the US in the Internet. In 2011 we saw the *IBSA* proposal (called *IBSA* because it came from a summit convened by India, Brazil, and South Africa) for a UN committee in Internet Related Policy. In 2013, as a reaction to the US surveillance stories being publicly aired on *WikiLeaks*, numerous Internet organisations, including ICANN, the *Regional Internet Registries* (RIRs)^[7], and the *Internet Engineering Task Force* (IETF)^[8], released the “Montevideo Statement,” calling on the US to step back from its central role. The US surveillance disclosures also appeared to be a major factor in Brazil’s sponsorship of the 2014 *NetMundial*^[9] initiatives, which also appeared to have the support of ICANN. Once more the call was for the cessation of US control over the protocol parameter function of the Internet. At much the same time Edward Snowden released a set of materials that documented how US agencies were undertaking widespread surveillance by using the Internet.

These *WikiLeaks* and Snowden disclosures weakened US resolve, and in October 2016 the previously unthinkable happened: The US Government signed away its functional role and passed control of the protocol parameter function to an independent ICANN.

If the IGF was the forum to discuss the public policy issues related to the privileged position of the US Government with respect to the Internet, then the principal rationale for the IGF also finished in October 2016. In theory, at any rate, the US no longer claimed the ability to place its finger on the scale with respect to the carriage of these matters.

On the other hand, this definition of the role and scope of the IGF is perhaps far too narrow. The IGF process has managed to gather a more sophisticated shared understanding of the layers within the Internet and the ways in which these various components both share common objectives and create tensions when competing to achieve similar objectives. The elements of carriage networks, consumer devices, servers and service delivery networks, applications, and application behaviours all operate in a semi-autonomous manner. The previous model of the locus of control of an entire service environment sitting within the telephone company within each nation state was not repeated with the Internet. The Internet has exposed each of the various component service activities as discrete activities, and instead of orchestrating these components within the framework of the procurement processes of the larger service entity, a variety of new markets have been exposed. Technology standards, fibre and mobile services, and computers in all forms from handsets to servers, applications, service providers, and content publishers all operate semi-autonomously, and the orchestration of their actions is through markets and market interactions. The Internet is not operated by a single service delivery company, nor is it a defined destination; it is a series of inter-twined markets. The implication for governance processes was profound, and the IGF has managed to both expose these changes and steer a constructive path of commentary and dialogue on these changes as they have happened.

Internet Governance Today

I'd like to nominate three major themes of national and international interest in today's Internet that have some relevance to the topic of Internet Governance.

The first is the issues that can still be summarised as the *Digital Divide*. The haves and have nots still exist across the full spectrum of our world. The digital divide is as big as it ever was, and there is no visible movement in directions that might ameliorate the societal impacts of these changes. If anything, the scope of this divide has further broadened. In absolute terms it may be that more individuals have some form of Internet access than was thought could possibly be achieved even 10 years ago. But today that's still only half of the world's population, and the other four billion people remain isolated from the mainstream. The divide also operates across other dimensions, including the cost of access; the quality and speed of access; the accessibility of information; and the extent to which goods, services, and information are accessible using a local language. They all form both subtle aspects and not-so-subtle aspects of digital exclusion.

But when we talk of a digital divide, we can broaden our view and look at the position of the world's most valuable digital enterprises, namely Apple, Microsoft, Nvidia, Amazon, Alphabet, and Meta, which have a market capitalisation of some 12 trillion USD (just before the recent Trump-induced stock meltdown).

The aggregate position of these six enterprises is so substantial and so powerful that everybody else—individuals, corporations, and most governments—find themselves on the impotent side of this digital divide.

The second theme is also not new, but it has dramatically increased in importance in the past two decades. Its components have various labels, including Cyber Security, Malware, Abuse, Spam, and Viruses. It can be summarised in the observation that today's Internet is a toxic place that provides haven not only for various criminal and fraudulent activities but also for darker actions encompassing the current set of concerns relating to terrorism and cyber-offensive tactics from state-based actors. The uncomfortable observation is that technology-based countermeasures may be failing us, and the fabric of our society seems to be very vulnerable to concerted hostile cyberattacks. We've adopted strong encryption in many parts of the environment as a means of protecting users against various forms of organised surveillance, but in so doing we've turned off the lighting that would otherwise expose various acts of malfeasance to our law enforcement bodies. We have had to make some tough decisions about balancing personal privacy and open attribution. But this lack of clear attribution and greater ability to embed communications behind strong encryption means that various forms of policing the digital world have become expensive, frustrating, and ultimately very selective in their application. Some also have observed that these digital megaliths have made vast profits from their dominant position, while at the same time they have managed to transfer the costs of large-scale deployment of poor-quality software and tools back on the public sector.

The third theme lies within the changes occurring within the Internet itself. In recent years we've seen the proliferation of *Content Distribution Networks* (CDNs)^[10, 11] that attempt to position all of the data and services that any user might request as close as possible to the user. It used to be the role of the network to bring the user to the content portal, but now we are seeing content shifting itself ever closer to the user. In and of itself that's a relatively significant change to the Internet. The public carriage component of the Internet is shrinking and being replaced by private feeder networks that service these rapidly expanding CDNs. The bigger question concerns the residual need for global names and addresses in this CDN-centric environment. The Internet is no longer a telecommunications network that carries user traffic across a common network. Today's Internet is a content distribution network that is very similar to a television broadcast network where the transmission component is limited to the last-mile access network. The essential difference here is that on the Internet each user can define their own program.

One possible response to these concerns is the perception that these situations are instances of collective failure of the Internet Governance framework. Allowing the private sector unfettered control of the public communications space has produced very mixed results.

Yes, the obsessive concern with catering precisely to what users want has produced a remarkably efficient and capable supply chain that can bring the economies of massive scale to market of a single unit, and it is a modern-day marvel. But at the same time the private sector is largely uninterested in the general health and welfare of the larger environment, and the Internet appears to be the victim of such collective neglect.

The public sector's forbearance with the cavalier attitude that various Internet players show may be reaching a breaking point. The EU initiative with *General Data Protection Regulation* (GDPR)^[12] is a clear signal that the honeymoon with technology is over, and various national regimes clearly want to see a more responsible and responsive attitude to public concerns from these players. Doubtless we will continue to see fines being set at levels intended to be eye-watering for even the largest of players. While this measure has the unintended side effect of eliminating the smaller players from the market and potentially stifling competition, a major public sector goal is to bring some sense of broader social responsibility back to the major players. This regulatory stance will no doubt continue in both the EU and in many other regimes.

But is this increased national engagement a failure of the Internet Governance framework or a failure of a more conventional role of public sector regulation of a market? Private corporate entities have a primary duty to their shareholders, and they do not necessarily have the same over-arching obligation to the public good. If self-interest and public interest coincide, then that is a wonderful coincidence of fortune, but when they differ, corporate self-interest necessarily wins. It is naive to expect the private sector to heed any messages of constraint and prudence unless it has the authority of regulatory impost with some form of punitive enforcement measure.

If governments are feeling emboldened to enact regulatory measures for an industry that until now has enjoyed some level of immunity from conventional social responsibilities, then how do these same governments feel about the actors that look after the elements of Internet infrastructure?

Rebuilding National Barriers

The recent erratic moves by the US President to initiate a trade war on a global scale will have far-reaching implications far beyond stock markets and will inevitably include the digital world and what we refer to as Internet Governance. The US moves on the unilateral imposition of tariffs can be interpreted as a vote of no confidence in global trade and open markets—and a resurgence of a theme of strategic national self-reliance in all areas of economic activity, including the digital realm.

The question, of course, is how will others react?

Recently I saw a notice from a DNS hosting provider that relates to hosting Russian domain names:

“We are contacting you about a recent communication from the Russian Federal Service for Supervision in Communications and Information Technologies and Mass Media (Roskomnadzor).

This message relates to the potential future restrictions on foreign hosting providers and the need for domain administrators who use foreign DNS infrastructure to transition to Russian hosting providers listed in the official register.”

Many national regimes are visibly concerned about the large amounts of their digital infrastructure that foreign enterprises are operating, and by “foreign” it is more often than not simply “US.”

Today’s deregulated digital communications environment is held together by commercial contracts. The extent to which such arrangements can be torn asunder by seemingly erratic US presidential edicts no doubt causes many to lose sleep! In a bad-case scenario, can these US entities be coopted to hold a country’s digital infrastructure hostage as part of the “art” of a national trade deal? In the extreme worst-case scenario, can these entities be forced to operate in an overtly hostile and disruptive manner in terms of services provided to foreign entities? What happens in a modern national digital economy when its infrastructure underpinnings are deliberately sabotaged by such entities acting under duress from some form of executive order?

The order in which we operate the Internet today is held apart from the conventional treaty body for communications, the *International Telecommunication Union* (ITU)^[13]. The reason is that President Clinton in the late 1990s led a coalition of friendly economies, notably Australia, Canada, Japan, and the EU, to support the move to recognise a private institution to perform the allocation and administration functions for Internet infrastructure elements (notably names and addresses) based on what we came to call “multistakeholderism.” The US recognition of this form of industry self-regulatory governance was more like an insubstantial veneer for many years, as the US administration (in the guise of the *National Telecommunications and Information Administration* (NTIA) within the Department of Commerce) performed an oversight role of the root zone of the DNS in the background. However, as we’ve already noted, the US administration withdrew from this oversight role around a decade ago and has largely disengaged, being unwilling to continue to pay the diplomatic price of being the backstop in holding this coalition together in the face of large-scale devaluation of US international diplomatic capital by the WikiLeaks and Snowden incidents.

You could argue that by 2020 the job was done in any case. The “value” of the Internet was tightly held by a small elite of truly massive US enterprises, and any role of the US administration to support these enterprises in the international realm was no longer necessary. Other countries have been willing to go along with these arrangements for a variety of reasons—one is the ill-defined promise of digital prosperity and that other national communities could benefit from this shift to digital infrastructure.

But the distribution of wealth and social power in this “new” world is vastly different from the old industrial world. Having valuable digital enterprises domiciled in a nation does not translate to widespread economic prosperity. The digital enterprise does not rely on large workforces, and the immense concentration of wealth often results in inventive efforts to avoid conventional forms of corporate taxation by the state. The problem is that the distribution of this digital wealth is very uneven, and while a small clique of individuals may live in an extreme level of opulence, large proportions of domestic populations are disenfranchised and marginalised.

Not unsurprisingly, we are now seeing a response to this situation, in the form of a wave of populism gaining social power in many national communities: not just in the US, but in Germany, France, Hungary, the UK, and other western economies. Such populism is based in part on restoring an old-world order that “protects” national economies and eschews many forms of globalism.

At the moment this situation is being expressed in various ways in a visible shift to national compartmentalism, not only in limiting the cross-border flow of physical goods through the imposition of punitive tariffs, but also in the efforts to contain digital assets and infrastructure roles to national entities domiciled within national boundaries.

Obviously, this situation does not look good for the Internet. It is increasingly likely that we will return to an order where international dealings are strictly defined by using a myriad of regulations overseen by treaty-based organisations. It’s extremely challenging to espouse the benefits of an open multistakeholder global communications environment when the dream has been so basely corrupted by the exploitative excesses of the small clique of digital megaliths.

The year 2025 is particularly challenging when WSIS+20 is reopening the basic debate about the merits of multistakeholderism. “National Internet Sovereignty” is a powerful meme these days, and multilateralism, as compared to multistakeholderism, has a seductive appearance of addressing demands for greater levels of national autonomy, particularly in communities where populism is a dominant social force. This debate is taking part in an environment when the change in the stance of the US administration has effectively scrapped all the old order.

It is unclear as to how (or even whether) the US will continue to expend efforts to support multistakeholderism, and the erratic record of the US on the recent topic of tariffs lends further credence to the stance that the US is no longer a widely trusted and stable advocate of the benefits of multistakeholderism in the international realm.

In mid-2024 we saw efforts by other national entities, *.au Domain Administration* (auDA) for **.au**, *Canadian Internet Registration Authority* (CIRA) for **.ca**, *InternetNZ* for **.nz**, and *Nominet* for **.uk** to create a coalition to speak up for multistakeholderism: A *Technical Community Coalition for Multistakeholderism* (TCCM)^[14] is evidence of others attempting to fill this clear gap. Notable is the absence of the US.

I wish this group well, but it is extremely challenging to make the case that today's international climate is in their favour. Given the significant problems in cyber vulnerabilities, the entrenched position of US megalithic digital corporates, and the extremely erratic position of the US administration at present, the case that the ideals of the Internet that were espoused in WSIS some 20 years ago, and the promises of multistakeholderism in the development of digital economies where everyone benefits are still realistic prospects today is extremely hard to make. It's far easier to observe that we gave it a try and Alphabet, Microsoft, Amazon, and Meta should be grateful to us for enabling their rapid rise to global dominance.

To come?

I can't help being very pessimistic about the coming years. The attempt to coopt private enterprises to work in a manner that safeguards the public interest in our common public telecommunications realm has failed, again. It reminds me of Theodore Vail's efforts in the early 20th century to come to an understanding with the US Congress to bestow on AT&T a monopoly in national telephone services in exchange for an undertaking that the company would act with restraint as an enlightened private sector entity that would act in the national public interest^[15]. As it turned out, AT&T could not resist itself from exploiting its monopoly position for any more than a decade!

It looks like national pressures are calling for an end to multistakeholderism in Internet Governance, hastened by a tectonic shift in the position of the US in international circles. The most likely direction we will now pursue in Internet Governance is a shift to multilateralism and an increased role for the United Nations and the World Trade Organisation for the middle-ranked nation states, accompanied by a tumultuous period of US unilateralism.

Is this situation caused only by the outcome of the 2024 US Presidential election? If there had been different candidates and a different election outcome, would the position we find ourselves in today be materially different?

It seems to me that there are much larger social forces at play that transcend individuals and their actions, however erratic they may be! We are embarking on changes in our society that are as dramatic—and even as traumatic—as the industrial revolution of the nineteenth century. Such revolutions leave a trail of social dislocation and uncertainty in their wake, and this information revolution is no exception. It is perhaps unsurprising that nation states tend to be more assertive in such situations as they try to mitigate some of the worst excesses of such social disruptions. One side effect of this increasing nationalistic stance is that various international institutions, both regional and global, tend to be regarded with increasing levels of distrust from these national regimes and from populist national fora. In times of uncertainty and stress, nations naturally try to raise the drawbridge and attempt to insulate themselves from such disruptions by asserting greater levels of control within their own national realm. The root cause of all social dislocation is attributed to the actions of foreign bodies, and they claim that greater levels of national determinism will restore some aspect of a myth of prior national greatness and prosperity.

The industrial revolution was certainly triggered by the refinement of the steam engine, but the social revolution was far larger in scope than the invention of a simple mechanical device. In a similar line of thought, maybe it's not the Internet or its governance that lies at the heart of many of today's problems. Maybe it's the broader challenges of our enthusiastic adoption of computing and communications that have formed a propulsive force for widespread social dislocation in today's world.

GEOFF HUSTON AM, B.Sc., M.Sc., is the Chief Scientist at APNIC, the Regional Internet Registry serving the Asia Pacific region. He has been closely involved with the development of the Internet for many years, particularly within Australia, where he was responsible for building the Internet within the Australian academic and research sector in the early 1990s. He is author of numerous Internet-related books, and was a member of the Internet Architecture Board from 1999 until 2005. He served on the Board of Trustees of the Internet Society from 1992 until 2001. At various times Geoff has worked as an Internet researcher, an ISP systems architect, and a network operator. E-mail: gih@apnic.net

Counter-Opinion: Multistakeholderism Is Not Ending; Rather, It Is Moving to a Next Stage

Avri Doria, Technicalities

Multi-stakeholderism is not ending, but the honeymoon is over. No more handwaving about what multi-stakeholderism, also written as multistakeholderism, is and what it isn't—without a deeper dive and a few definitions. However, as is so often the case in *Internet Governance*^[1], where we cannot even all agree on how to write relevant terms like “multistakeholderism,” we cannot agree on how to define them either. I will try to indicate the definitions I choose to use as I go along. Accounting for the fractal nature of definition, where every word used blossoms into its own definitional frond, I will endeavor to be frugal.

Multistakeholderism, a History

I define the term multistakeholderism as: the study and practice of participatory models in decision making. These participatory models are often referred to as *multistakeholder models*, though other terms are sometimes used. I think that both the understanding and use of participatory models in decision making are the keys to the origin story of the Internet. As I expect that Geoff^[0] is not making any claims about the study of such models, I will concentrate on the use and abuse of multistakeholderism in the Internet^[2]. In some ways I believe he is referring more to a general multistakeholder environment that existed before and that can be seen as no longer existing. While the environment in 2025 is not that of the 1970s, neither the advent of TCP/IP, nor that of 2005—the time at which the *World Summit on the Information Society* (WSIS) agreed on the *Tunis Agenda*—nor even the same as it was in 2014 around the time of *WSIS+10*, I believe the opportunities for multistakeholder models of governance remain in the present and are increasing. Not only is the study of multistakeholder models increasing, but the applications of multistakeholder models and methods are increasing as well. The environment is one in which discussion of multistakeholder methodologies is growing despite the number of people claiming to “no longer believe in multistakeholderism.” This disbelief applies not only to the digital divide, cyber security, and the spread of governance to other layers of Internet technical policy such as content, but it also applies to any and all decisions that need to be made in dealing with the Internet and Internet technologies, whether global, regional, or local.

I think Geoff gives a very good description of one perspective, a political perspective, on the history of Internet Governance and its relation to the term multistakeholderism.

I have no real disagreement with the coherence of that description, and will not offer an alternative political perspective as counter balance, though there are several ways of looking at the history of Internet Governance, possibly enough for a full semester's study on the subject of history and philosophy of Internet Governance; practically everyone I discuss the issue with has a somewhat different view of the history, depending on their perspective. I am more concerned with the interpretation of where the application of multistakeholder models to Internet Governance is at the moment and where it is headed. Beyond the technology itself and activities that the Internet enables, it is the sustainability and evolution of multistakeholderism, with its methods and modalities for finding consensus among nations and the stakeholders of the Internet, that seem most important.

In one sense, I agree with Geoff, that the laissez-faire multistakeholderism that rejects “kings, presidents, and voting”^[3a, 3b], and declares its independence from governments^[4] no longer exists. If it ever existed, it did so before the Tunis Agenda, before governments started to care, though it takes a stretch of imagination to believe that a network being built with government money is ever free of government influence. In a strong sense, the early developers did not think in terms of being multistakeholders; they were engineers and scientists working on a difficult and interesting problem, cooperating with each other to get the job done. The term multistakeholder was not part of common vocabulary until the WSIS process with its notions of an open, inclusive, just, and democratic process, began using the term. In retrospect, the group of engineers and scientists who invented the protocols found a way to cooperate in building the Internet that can easily be defined as having been one of the foundational examples of a multistakeholder model. They gave us, and continue to give us, a model that can hopefully be followed and improved.

Multistakeholderism Today

In the 20 years since WSIS, gradually more and more institutional entities have declared themselves to be supporters of multistakeholderism, if not actually multistakeholder entities themselves. At the same time, we have seen support for multistakeholderism grow and then ebb in popularity with the cognoscenti. Yet, today pretty much for any topic related to internets, data, or AI governance, multistakeholderism is a term of art that many use to describe the governance they want.

As the scope and reach of WSIS grew, more and more processes declared themselves to be multistakeholder. None of them necessarily meant the same thing that the Tunis Agenda meant, nor did they necessarily mean the same thing that anyone else meant. More and more participants began to group themselves into clubs they called “stakeholder groups” in a process that I refer to as “multistakeholder groupism.” In Internet Governance, as defined by the Tunis Agenda, there were originally three Stakeholder groups—*Governments*, *Business*, and *Civil Society*—with at least two cross-cutting groups, the *Academic* and *Technical* communities.

Neither of these cross-cutting groups was defined as a stakeholder group in their own right because the people in those groups were often also members of the primary three defined stakeholder groupings. It was important to the technical community to be recognized as a stakeholder group in itself. They finally were recognized as such at the time of WSIS+10. It is very good to see the *Technical Community Coalition for Multistakeholderism* (TCCM) active, and participating successfully in today's policy tussles^[5]. Since WSIS, many different groups have been defined as stakeholder groups in a variety of fora, without having been included in the Tunis Agenda model.

The Tunis Agenda's notion of a multistakeholder model is a top-down model with fixed roles and responsibilities for all the stakeholder groups defined 20 years ago, in a member states-only decision process. Only a few entities qualify as multistakeholder in the sense defined by the Tunis Agenda, such as the *Internet Governance Forum* (IGF), and to a partial, and hopefully only-incipient extent, the *International Telecommunication Union* (ITU), which led the prototype of a Tunis Agenda-based multistakeholder model in the way it ran the ITU's WSIS. These groups are top-down groups that have been given a definition and view that they must follow and for which they are accountable to the *United Nations* (UN) system. And if they behave, they are given a consultative voice. At the ITU, decisions are still made at councils that exclude all but state actors, whereas the IGF is barred from making decisions because there are no purely state actor councils. Still, a little bit at a time, the UN-dominated bodies allow more and more stakeholders to approach the table and to have a voice. It is a start that should be encouraged.

Many of the other groups that have referred to themselves as following a multistakeholder model have developed their models more organically, usually from a bottom-up perspective. I include groups like the *Internet Engineering Task Force* (IETF), the *Internet Corporation for Assigned Names and Numbers* (ICANN), the *Regional Internet Registries* (RIRs), and others. Though often related to each other, each of these organizations developed its own model. For example, the IETF was always dedicated to the individual stakeholders, no matter what Tunis Agenda-style stakeholder group they belonged to, company they worked for, or nationality. While they may have grouped themselves into siloes based on technology or operational principles that were practical and mutable over the years, these siloes have changed as the technology and structure of the Internet changed. They are very different in nature from the silo-based stakeholder groups defined by the Tunis Agenda and imitated by most every other organization.

Policy Making: Unilateral, Multilateral, or Multistakeholder?

Where are actual policies to be made? In multilateral political caldrons, or in the work done within multistakeholder organizations that design and deploy the networks? If multistakeholderism is dead, does that mean that governance will come only from the multilateral processes of states?

It is a simplification to believe that the state, or a multilateral collection of states like the UN, can develop a set of directives that spell the end of multistakeholder governance. On the contrary, every regulation, every rule comes with its own emergent set of opportunities, for crime and for simply working the rule to get around the rule. These effects are often extra juridical, or perhaps just pre juridical, and are within the purview of the multistakeholder policy makers who are responsible for keeping the networks working and the users happy. More multilateral rulings bring greater need for multistakeholder remediation. Just look at the amount of multistakeholder effort that has gone into dealing with the requirements of the trans-jurisdictional *General Data Protection Regulation* (GDPR). I shudder to think of all the multistakeholder efforts, with corresponding staffing and expenditures, that go into dealing with all of the output of unexpected results arising from the European Commission's NIS2 Directive: *Securing Network and Information Systems*. And though the decisions that come out of the WSIS+20 deliberations will be made by governments after consultations that are giving all stakeholders a chance to comment, making these decisions work will require great amounts of multistakeholder "sweat and tears." The more the states do, the more work is required from the multistakeholder multitudes who make the Internet what it is. Some body has to figure out how to cope with the regulatory fuss so that the Internet can continue to function and grow. Some multistakeholder groups invest time and effort into self-governance they hope will sate the eagerness of regulators. Whether it is work to dissuade the creation of regulations, or work to survive them, regulations help motivate the need for more multistakeholder efforts.

But it then comes back to the question: what does multistakeholder governance mean, and how is it to be done? Is it just a reaction to the dictates of the states? Or does it have an importance and power of its own?

Multistakeholderism Moving Forward

A major development in the lifecycle of global multistakeholder models is the work that was done in the *NETmundial* and the *NETmundial+10* events. "Convened in São Paulo, Brazil, in April 2014, stakeholders from academia, civil society, governments and International Organizations, private sector, and technical community around the world asserted the need for improvements to Internet Governance and digital policy processes. The event spelled out how to bring all stakeholders, people, cultures, countries, and distinct economies together to solve the common challenges we face"^[7]. It was quite a daring move, but one that has given a pointer on a way to move forward with the model. *NETmundial* established principles for multistakeholder processes, giving a good basis for a definition of governance within a multistakeholder environment.

NETmundial+10 reaffirmed the principles from 2014 and went beyond them in two important ways: The event established guidelines and process steps ("Guidelines") for multistakeholder collaboration, consensus-building, and decision-making, and for how multistakeholder and multilateral efforts could coexist and cooperate.

Figure 1: NETmundial 2014 Internet Governance Process Principles^[6].

- Multistakeholder
- Open, participative, consensus driven
- Transparent
- Accountable
- Inclusive and equitable
- Distributed
- Collaborative
- Enabling meaningful participation
- Access and low barriers
- Agility

The “São Paulo Multistakeholder Guidelines,” with its 13 specific guidelines and the dozen process steps, goes beyond the general feeling of the original undefined notions of multistakeholder cooperation in Internet building and maintenance, and the strict top-down regimentation of the Tunis Agenda for Internet Governance. They also recognized that “one size would *not* fit all;” in fact, it turns out that every instantiation of a multistakeholder model or creation of a multistakeholder environment will be unique. See Figure 2 and Figure 3.

As time goes on, there is a good chance that newly formed and existing organizations committed to a multistakeholder model will take heed of these guidelines, and perhaps discover a few more along the way. Now let’s consider a second manner in which the development of the model continues. In a multistakeholder-based organization, especially one with some degree of bottom-up modelling, there is almost always a stakeholder group advocating for improvement. Many have processes to organize continuous improvement, while some lurch from one improvement campaign to another, but all spend some part of the time trying to improve themselves. While some disparage these efforts sometimes as “navel-gazing” or as “wastes of time and bandwidth,” they are nearly ubiquitous and are a necessary ingredient in the improvement and proliferation of multistakeholderism in contributing to both understanding and process development.

Another notion is developing in the evolution of multistakeholder models—that is the idea of “multistakeholder all the way up and multistakeholder all the way down.” That means that a multistakeholder model can be applied at every organizational layer. At every level of organization, separate stakeholder types can be defined with their own set of process-specific roles and responsibilities. Both of these types bring their own concerns and principles to the discussions, and the basic rules of democratic inclusion, fairness, and consensus are applied to decisions, whether it is decisions on technology or policy. When a multistakeholder model can be applied at every layer of an enterprise, the power of the model comes to the fore. As a student of multistakeholderism, I would argue that most decision processes are improved by a multistakeholder modality.

Figure 2: NETmundial Guidelines^[7]

1. Multistakeholder processes should be mindful of power asymmetries between diverse stakeholders, and empower stakeholders by providing them with the necessary information, resources, and skills to participate effectively, meaningfully and sustainably. Transparency measures should aim for making policy processes known, accessible, comprehensible and actionable.
2. Multistakeholder processes should involve informed and deliberative discussion among stakeholders. Meaningful dialogue is a conflict-preventing mechanism throughout all steps of the process.
3. Multistakeholder processes should strive to treat all stakeholders fairly and equitably, considering their respective needs, capacities, realities, and vulnerabilities. Stakeholders should participate on equal footing, treat one another with mutual respect, recognizing the value of diverse viewpoints and contributions and the different nature of their roles and responsibilities in an issue-specific manner.
4. Multistakeholder processes should be governed by the rule of law and respect to international human rights principles, including economic, social, cultural, civic and political rights.
5. Multistakeholder processes should respect and value the linguistic diversity of participants, and be accessible to all stakeholders, regardless of their background, status, or level of expertise.
6. All stakeholders should share responsibility and uphold accountability and transparency in their respective roles for the outcomes of the multistakeholder process, with legal and political accountability for protection of human rights remaining the primary responsibility of governments, also recognizing the private sector's responsibility to respect human rights in line with the *United Nations Guiding Principles on Business and Human Rights*.
7. Internet governance and digital policy processes should be agile and adaptable to changing circumstances, evolving technologies, emerging issues, and changing geopolitical dynamics.
8. Mechanisms for resolving conflicts among stakeholders within collaborative multistakeholder processes should be in place to enable decision-making.
9. A global multistakeholder approach to Internet governance and digital policy processes should recognize the need for collaborative action across national borders and stakeholder groups, while duly considering and leveraging local and regional perspectives.
10. Decisions should consider the long-term implications and sustainability of outcomes for human rights, and inclusive and sustainable development, as per the Tunis agenda.
11. Capacity-development efforts that enhance the understanding and skills of stakeholders, particularly those from developing countries and under-represented communities, should be in place throughout all steps of a multistakeholder process^[11].
12. Cooperation and dialogue should actively be sought with other governance fora and processes, in order to avoid duplication of efforts and to share outcomes, best practices and lessons learned.
13. Collaboration processes should be oriented towards practical, actionable outcomes that lead to tangible results and positive changes for Internet governance and digital policy processes.

Figure 3: NETmundial Process Steps Oriented Guidelines

Recommended process steps for an open and inclusive multistakeholder process:

1. Scope the issue/s: define the issue or set of issues to be considered by the multistakeholder collaboration process, considering, as much as possible, all affected perspectives.
2. Identify stakeholders: Identify all relevant stakeholders as inclusively and flexibly as feasible, including individuals, groups, organizations, and communities affected by the decision or collaboration.
3. Engage stakeholders: Actively engage all interested stakeholders throughout the process consistently and in a sustained fashion, through methods such as public consultations, surveys, workshops, and fora to gather input and feedback.
4. Share information: Provide clear and full information about the process, objectives, and outcomes to ensure transparency and understanding among stakeholders, making full use of accessible digital records including related process documentation.
5. Ensure equitable participation: Ensure equitable participation of all relevant diverse perspectives and interests, including marginalized or under-represented groups.
6. Facilitate dialogue: Facilitate open dialogue, collaboration and deliberation among and between relevant stakeholders, encouraging respectful communication and consensus-building.
7. Prepare draft outcomes: develop draft outcomes for consultation on the basis of dialogues between relevant stakeholders, and consult the wider community of all interested stakeholders over results.
8. Factor in feedback from wider community: adapt the draft outcomes taking into account the inputs stemming from the consultation, transparently reporting on how inputs were considered, and the corresponding reasons.
9. Open decision-making: use collaborative decision-making processes that involve all the relevant stakeholders in identifying solutions, exploring trade-offs, and reaching agreements.
10. Community powers: submit final outcomes to the consideration of the wider community, providing for mechanisms empowering the wider community to react to outcomes that are inconsistent with the wider community interests.
11. Implementation and accountability in decision-making: Establish mechanisms for implementing decisions and holding stakeholders accountable for their commitments.
12. Monitor and adapt: Monitor progress, evaluate outcomes, and be willing to adapt the process based on feedback and changing circumstances.

When I first saw the title of Geoff's essay, I wondered: "what about multilateralism, is it ending too in this age of unilateralism," as hinted in Geoff's writings. While not the topic of this comment, it may be relevant to the discussion. Multistakeholder methods may actually be one element of salvation for the multilateral model. An example can be found in the São Paulo Multistakeholder Guidelines.

While the guidelines focus mostly on maintaining and furthering the use of multistakeholder models in Internet Governance, it also accounts for the necessity of cooperating instead of competing with or ignoring the multilateral processes. Unless replaced by deterioration into competing unilateral models, the multilateral model will persist as long as nation states persist, because it is their intrastakeholder group way of governance, and very few state-based organizations use a multistakeholder-based model for their internal governance. The only possible exception that comes to mind is Switzerland.

The question of whether governments belong inside the multistakeholder models occasionally comes up. Some believe the states are too important to waste their time with stakeholders. Some believe that including states constitutes a category error in that stakeholders are subject to states. Others believe that states rarely have unity of purpose and are themselves made of stakeholders, such as executives, parliamentarians, judicial, and others like regulators and enforcers. Some believe that including states in multistakeholder models is confusing at best and a profanity at worst. But, if only to protect people from other people with law enforcement activities and to be dutiful shepherds of Human Rights as defined in the set of treaties and covenants termed the *International Bill of Human Rights*^[8], nation states are necessary stakeholders. Some other stakeholders who see no reason to include governments as stakeholders sometimes dispute this idea. I cannot think of a stakeholder group whose existence is not disparaged on occasion by those from other stakeholder groups. Among civil society, I know stakeholders who disparage government, and I know many who despair at the participation of industry, not remembering that industry and government have cooperated for as long as capitalism has been society's primary economic religion.

Some, members of the technical community, but certainly not all, have no use for civil society and their references to human rights, believing that is just a form of gaming, and they maintain that old fallacy that engineering and science are value-free. Some users strive to be considered stakeholders, while others refuse to recognize them as relevant, even though each of us is a user when we go home at night. While there are many who are devoted to multistakeholder principles and who respect the growing types of self-defined stakeholder groups, we still have a long way to go in identifying the relevant stakeholder for each issue. We also have a long way to go in understanding the roles and responsibilities of each stakeholder group in the various phases of decision making.

The first phase of laissez-faire, undefined multistakeholderism, may indeed be ending. In its place a new generation of multistakeholder models, built for specific purposes, is just emerging. These models include considerations such as determining the relevant stakeholder mix, and having varied decision-making processes depending on roles and responsibilities that correspond to the types and phases of programs. It is not a dead movement; it is a young movement that is evolving. There is still so much to understand about the nature and power of multistakeholder governance.

Multistakeholderism and Current Affairs

Over time, some people have become disillusioned by the current model because it cannot deliver the nirvana of perfect participatory governance. Over time, people may rename the stakeholder environment and the multistakeholder model, but neither the study of such participatory models nor their deployment is over—it's not even close.

During the last year, much of the governance community, if it can be called that, has been discussing governance of the Internet in all of its multilayer richness, fragmented networks, massive data, and AI everywhere. In the *Pact for the Future*^[9], specifically in the *Global Digital Compact*^[10], a key governmental motivation describing a multilateral future, we find:

“Governments, the private sector, civil society, the technical community, academia and international and regional organizations, in their respective roles and responsibilities, are essential to advance an inclusive, open, safe and secure digital future. Our cooperation will be multi-stakeholder and harness the contributions of all;”^[10]

The next step in the movement of governance of the Internet and all the emerging new issues and technology developments are all being discussed in terms of a multistakeholder future in a multilateral world. Its methods and ways of finding agreement are becoming part of mainstream decision making. There are still many arguments about who makes decisions for a specific issue during a phase of public policy development, but for the most part there is recognition, often grudging, that no stakeholder group is capable of making the best decisions alone. In many deliberations, there is the beginning of the realization that multistakeholder methods are often necessary for finding the best solution, or at least an adequate solution, for a problem in its time.

As I write this, there are ongoing discussions on the WSIS+20 Outcomes that will come out later this year. While this process is controlled by governments to develop a document that is a government outcome and not a multistakeholder one, it has done better stakeholder consultations than the UN usually does. The current *Zero Draft*^[12] contains support for the use of multistakeholder models in the areas of Internet, Data, AI governance, and human rights in the Information society. It remains to be seen how much is retained in the final draft when it is finalized in mid December 2025.

Multistakeholder governance is not ending; it is entering its next stage of development, implementation, and deployment.

- [11] *Capacity Development or Capacity Building* are general terms used throughout Internet Governance and many development programs. The terms can refer to any skill necessary for participation in the technological or policy aspects of the Internet and related areas like Internet Governance or Human Rights on the Internet as well as the skills needed to build a community network in a rural unserved location or maintain a network in an urban region. In most any forward-looking document on Internet Governance, one can expect to find many references to the necessity for enabling capacity development. It can be used in reference to individuals, but is most often used in reference to enabling populations of groups, regions, or nations.

Book Review: Geopolitics at the Internet's Core

Geopolitics at the Internet's Core, by Fiona M. Alexander, Laura DeNardis, Nanette S. Levinson, and Francesca Musiani, ISBN 978-3-031-89477-0, Springer Nature, 2025^[0].

The book *Geopolitics at the Internet's Core* is a most unusual and very helpful effort by four co-authors who have long been involved in shaping technology policy and governance: Fiona M. Alexander and Nanette S. Levinson, who both hold various research positions at American University in Washington, DC; Laura DeNardis, a professor at Georgetown University and author of numerous books on tech governance; and Francesca Musiani, a researcher at the French National Center for Scientific Research.

While I consider myself well-read and steeped in Internet technologies and have some technical understanding of the underlying Internet protocols, this is a unique, useful, and educational book that should have wide appeal.

The book concerns itself with the evolution of Internet protocols as it relates to its governance and technological history. It traces this path from the Internet's beginnings as a U.S. science experiment to the underlying worldwide phenomenon that we know today. That link may seem a well-visited side issue, especially for a network engineer or someone who has written numerous *Requests for Comments* (RFCs), but *Internet Governance* is becoming increasingly important, and having that context should be a critical part of anyone's job today. For example, most readers of *The Internet Protocol Journal* are familiar with *Distributed Denial of Service* (DDoS) attacks, how they are caused, and their consequences in terms of systemic outages or data corruption. But behind that technical layer is a deeper failure of the trust and geopolitics of the compromised IP addresses, and how these attacks can be prevented with particular security and political changes. "As geopolitical strategies are increasingly embedded in technology, IP addresses will certainly continue to be a bone of contention in terms of security," the authors write.

The authors take us behind the scenes to numerous cross-country border conflicts that demonstrate the shifting winds of geopolitics and ways that Internet infrastructure and design have been co-opted for various political and economic purposes. They write, "The Internet Protocol has been born out of conflict since its inception. One remarkable feature of its evolution is that, as each issue becomes resolved, geopolitical tensions seem to only escalate." They show how IP has been at the center of these conflicts and show how it is a lens that can help explain some of these issues, even though, as they point out, "who is doing the governing and what is being governed have often been over-simplified or just grossly incorrect."

Many of the events dissected in this book will be familiar to IPJ readers, some of whom directly participated in them, such as the transition of the *Internet Corporation for Assigned Names and Numbers* (ICANN) from a US-owned entity to an international standards and multi-stakeholder body, the rocky transition to IPv6, or the fight to select TCP/IP over *Open Systems Interconnection* (OSI) protocols. The authors' treatment, however, delves into the central governance issues that might not be as familiar as the technical arguments for these choices, showing the influence of various institutional controls and public policies. "If design is governance, the process matters. And design going forward matters," they write. This is part of the book's unique perspective.

Indeed, the notion of multistakeholderism might be a new term for you. The authors take pains to demonstrate how "government top-down mandates were not the decider" in the development of TCP/IP, which adopted many innovations thanks to consensus and more bottom-up approaches. (See Geoff Huston's and Avri Doria's essays on multistakeholderism in this issue of IPJ^[3,4].) To dive further into this concept, the authors devote a chapter on embracing more inclusive audiences. The authors document several ways to measure this inclusion:

If we look at how IP protocols are distributed across the globe, we'll see that their U.S.-based *Defense Advanced Research Projects Agency* (DARPA) origins are still very much in evidence. There are several ways to measure this distribution. One is by counting *Internet Exchange Points* (IXPs)—the places where large ISPs can connect to each other. These places are still mostly congregated in western countries, and many countries have either no IXPs or a single place^[1]. The absence or paucity of an IXP means that residents of that country will have longer latencies, less local content, and higher cost of Internet access.

There is also measuring the number of available IP address ranges in any given locality. We know that the IPv4 "classic" address ranges have been consumed, but in Africa there are still many available address ranges. And then there are the distributions of *Domain Name System* (DNS) servers, because having one logically "nearby" also affects traffic latency and resiliency of digital networks. It took until 2022 before Africa had its own managed DNS cluster, meaning that prior to then most of the DNS traffic had to transit to another continent.

If we move our lens to a wider angle to examine the actual languages used online, we see that English dominates, and despite there being thousands of different languages spoken and written, 82% of online content is represented by ten languages: English, Chinese, Spanish, Arabic, Portuguese, Japanese, Russian, German, French, and Malaysian^[2]. For much of the Internet's early years, non-*American Standard Code for Information Interchange* (ASCII) characters for domain names were not supported, and today there are still gaps in having local character set domain support.

Let's move our lens to a still wider angle to Internet Governance. This exercise is also instructive in showing the unequal distribution of resources. The various standards bodies that determine Internet policy still have a very western bias, which can cloud any cross-national decisions, because who is on these various governing bodies can be significant. The result of this situation is that the distribution and control over Internet resources have become entangled in various political conflicts, such as the Russia/Ukraine and Israel/Hamas wars and various sanctions against Iran. These events are examined in detail from the geopolitical points of view, and they show how IP addresses can become political proxies and form a basic social resource. The authors ask, "Do [the Internet governing] organizations most people have never heard of hold the power to unplug an entire country from the Internet? In part, yes." Protocols have become a proxy for political purposes, and now outages, whether directed from inside a country by authoritarian purposes or requested from the outside by well-meaning humanitarian actors, are now the new norm. The governance is murky, and cutting off Internet access could support less freedom of expression, because "one country's illegal hate speech is another country's protected speech," as they write. "It is true that the experience of the Internet in one part of the world—whether as a user, government official, or developer—is quite different than in other parts of the world. There is uneven distribution, uneven filtering and censorship, and uneven economic opportunity."

Another chapter concerns how Internet protocols will evolve to adapt to future technologies. I recall when the web was still fresh and text-based, when video streams were still a technical challenge, when blockchain was just a thought experiment, and when a firewall was just connecting two networks and not an essential Internet security appliance. All of these technologies have been influenced greatly by TCP/IP protocols. This is also the case for what is now happening with the influence of Artificial Intelligence. "AI and the Internet are entangled in every way. AI has diffused into the Internet's architecture at all layers. Machine learning techniques are at the heart of many cybersecurity mechanisms detecting DDoS attacks and other irregular patterns that indicate the presence of malware or unauthorized network intrusions."

They distill the Internet's possible future into five broad themes:

- Tension between bordered nations and how a borderless Internet will influence data governance decisions and regulations,
- Governments will seek economic or political objectives by co-opting various pieces of Internet infrastructure,
- There will be attempts to modify TCP/IP design through political means, such as overlaying security features,
- A move towards more privatization efforts on Internet infrastructure, and
- Changes in the multistakeholder governance that will be shaped by a variety of factors.

Other chapters address content moderation issues and security innovations. Each chapter could serve as the touchstone for a college class on the subject, and with excellent footnotes, a useful source document if a professor were so inclined to create one. I don't mean to give these chapters short shrift, because each one contains a series of insights that I found refreshing and thought-provoking—such as an observation that content moderation has moved down the tech stack into more infrastructure controls. Another set of observations is showing where trust fails in compromised certificate authorities and DNS servers or IP address blocks used for DDoS attacks—and why these failures must be front and center of any governance and policy efforts.

The book occupies a useful place for many different audiences:

- Academics who may want to use it as a text for a course in IP history or geopolitics or some combination,
- Engineering staff at digital technology vendors, who may want to understand where their role is in a wider governance context,
- ICANN groupies (both pro and con), which could include the IPJ readership,
- GenZ and other youngsters, who were born after most of the action depicted in this book took place and are tired of reading low-content online articles, and
- Policy wonks in major national capitals who are about to embark on formulating changes to their country's Internet Governance.

The authors point out that while Internet Governance has changed over time, sometimes quite radically, “life did not change for the average Internet user.” That perhaps is testament to the Internet's resilience and design. Many of us know how the Internet routes around outages or breaches. This book is perhaps the first one I have read that shows how it also routes around many policy changes that impact its basic core protocols.

In Memoriam: Fearghas McKay: October 15, 1963 – October 1, 2025

Ed.: Fearghas was an active member of several Internet communities. Included here are reactions to his passing from a few of them.

The North American Network Operators' Group (NANOG)

Fearghas McKay was a remarkable individual known for his ability to forge connections worldwide. His impact was particularly evident within the NANOG community, where he attended over 25 NANOG conferences and dedicated more than 7 years of service on various NANOG Committees. The relationships he built and the community he fostered are reflected in his work on the Program Committee, Hackathon Committee, Elections Committee, and, most recently, the Workshop Committee.

The European Peering Forum (EPF)

We are deeply saddened to hear of the passing of a beloved figure in our industry. Fearghas McKay was more than a pioneer—he was a mentor, a sharer of knowledge, and a source of inspiration to countless colleagues and friends. His passion, generosity, and unwavering commitment to our industry left a mark on all of us. As we mourn this profound loss, we also celebrate the orange legacy he leaves behind—one that will continue to shape and uplift our community for years to come. Our thoughts are with his family, friends and colleagues across the industry. Fearghas, you will be greatly missed.

The European Internet Exchange Association (Euro-IX)

We are deeply saddened to learn of the passing of our friend and colleague, Fearghas McKay. As a founder member of Euro-IX and a Director on its first Board, Fearghas played an important role in shaping the interconnection community in its early days. He was an enthusiastic and long-standing supporter of Euro-IX, *Internet Exchange Providers* (IXPs) and the wider industry, contributing tirelessly to the growth and collaboration that define our community today.

Fearghas also served for many years on the Forum Programme Committee, both within Euro-IX and for other industry events, committed to the highest quality of knowledge sharing and discussion with a deep passion for presentations that really brought more knowledge and insights to the community. His presence was well known across the globe—a very familiar face, a trusted voice and a generous contributor of technical insight.

Beyond his professional contributions, Fearghas was a steadfast supporter of NOGs, IXP events and the broader networking community. He brought people together, encouraged new ideas and championed the work that IXPs do to strengthen the Internet.

Our thoughts are with his many friends and colleagues across the industry especially his colleagues in Flexoptix and with those who stood by him and especially after the loss of his beloved Susan Forney in 2021.

Fearghas will be remembered with deep respect and fondness. In the spirit of his Scottish heart, we will raise a glass to him—a dram of peaty whisky with just the smallest drop of water, exactly as he liked it. He will be greatly missed.

The Global NOG Alliance

It is with heavy hearts that we learned on October 1, 2025, that an important member of our international community has passed away. This has hit all of us at the Global NOG Alliance very hard. Each and every one of us worked closely with Fearghas McKay, and the grief runs deep and the loss is painful.

Fearghas was a builder of communities, a believer in open communication, and one of those people who quietly kept the global NOG world turning. He didn't just show up to meetings—he changed the tone of the room. If things were stuck, he'd unstick them. If people were drifting, he'd bring the conversation back to what mattered.

Sometimes that meant producing a bottle of whisky to get the discussion moving. Other times it meant sitting back and, with a single comment, cutting through the nonsense with more common sense than most committees can muster in a week. He gave his time freely—to programme committees, working groups, IXPs, and anyone who needed a steer—and he did it across regions, time zones, and years.

Fearghas was direct in the way only someone who genuinely cares can be. Say what matters, fix what's broken, move on. He did not waste time, and he did not let others waste it either. He didn't suffer fools, but he gave generously to people who were trying. That mix—sharpness and generosity—made everyone around him a little better, a little clearer, and a little braver.

For those of us who worked with him, he was the honest voice in the room and the steady hand behind the scenes. Thank you, Fearghas, for the clarity, the time, the advocacy, the late-night fixes, the dry humour, and the straight talk. We'll keep the channels open—you'd expect no less.

For anyone who didn't cross paths with him: he gave years to the community through roles like Euro-IX Forum Programme Committee Chair, RIPE working groups, and NOGs around the world. Most recently, at Flexoptix, he kept doing what he always did—connecting people, ideas, and networks.

We extend our sincere condolences to friends, mentees, colleagues, and above all, the family.

On October 25, 2025, we said goodbye to Fearghas in Copenhagen together with family and friends from the community. On behalf of everyone in the international community, we would like to thank Paddy, Magnus, and the family for organizing a memorial service in Copenhagen.

With shocked regards,
The Global NOG Alliance Team

RIPE

We were all very saddened yesterday to learn that Fearghas McKay had passed away. No doubt this will come as a shock to his family and those of us who knew him from his work in the community.

Fearghas has been an active participant in the RIPE community for many years. He served as Chair of the *European Internet Exchange* (EIX) Working Group from 1998–2013, and has been a part of programme committees and steering groups for a number of Network Operator Groups and peering forums, including the *African Peering and Interconnection Forum* (AfPIF), the *Central Asia Peering and Interconnection Forum* (CAPIF) and the *United Kingdom Network Operators' Forum* (UKNOF), often taking the role of co-chair within these groups. He was also a RIPE Atlas Ambassador for several years, helping to introduce Internet measurements to network operators around the world.

His contributions have helped shape the RIPE community and the interconnection world more broadly. We will miss his energy, his humour, and his friendship.

On behalf of the RIPE community we wish to extend our condolences to Fearghas's family and friends.

Kind regards,
Mirjam Kühne, RIPE Chair

Our Privacy Policy

The *General Data Protection Regulation* (GDPR) is a regulation for data protection and privacy for all individual citizens of the *European Union* (EU) and the *European Economic Area* (EEA). Its implementation in May 2018 led many organizations worldwide to post or update privacy statements regarding how they handle information collected in the course of business. Such statements tend to be long and include carefully crafted legal language. We realize that we may need to provide similar language on our website and in the printed edition, but until such a statement has been developed here is an explanation of how we use any information you have supplied relating to your subscription:

- The mailing list for *The Internet Protocol Journal* (IPJ) is entirely “opt in.” We never have and never will use mailing lists from other organizations for any purpose.
- You may unsubscribe at any time using our online subscription system or by contacting us via e-mail. We will honor any request to remove your name and contact information from our database.
- We will use your contact information only to communicate with you about your subscription; for example, to inform you that a new issue is available, that your subscription needs to be renewed, or that your printed copy has been returned to us as undeliverable by the postal authorities.
- We will never use your contact information for any other purpose or provide the subscription list to any third party other than for the purpose of distributing IPJ by post or by electronic means.
- If you make a donation in support of the journal, your name will be listed on our website and in print unless you tell us otherwise.

Read Any Good Books Lately?

Then why not share your thoughts with the readers of IPJ? We accept reviews of new titles, as well as some of the “networking classics.” In some cases, we may be able to get a publisher to send you a book for review if you don’t have access to it. For more information, contact us at ipj@protocoljournal.org

Check your Subscription Details!

Make sure that both your postal and e-mail addresses are up-to-date since these are the only methods by which we can contact you. If you see the words “Invalid E-mail” on your printed copy, this means that we have been unable to contact you through the e-mail address on file. If this is the case, please contact us at ipj@protocoljournal.org with your new information. The subscription portal is located here:

<https://www.ipjsubscription.org/>

Thank You!

Publication of IPJ is made possible by organizations and individuals around the world dedicated to the design, growth, evolution, and operation of the global Internet and private networks built on the Internet Protocol. The following individuals have provided support to IPJ. You can join them by visiting <http://tinyurl.com/IPJ-donate>

Call for Papers

The *Internet Protocol Journal* (IPJ) is a quarterly technical publication containing tutorial articles (“What is...?”) as well as implementation/operation articles (“How to...”). The journal provides articles about all aspects of Internet technology. IPJ is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. In addition to feature-length articles, IPJ contains technical updates, book reviews, announcements, opinion columns, and letters to the Editor. Topics include but are not limited to:

- Access and infrastructure technologies such as: Wi-Fi, Gigabit Ethernet, SONET, xDSL, cable, fiber optics, satellite, and mobile wireless.
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance.
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping.
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, cloud computing, and quality of service.
- Application and end-user issues such as: E-mail, Web authoring, server technologies and systems, electronic commerce, and application management.
- Legal, policy, regulatory and governance topics such as: copyright, content control, content liability, settlement charges, resource allocation, and trademark disputes in the context of internetworking.

IPJ will pay a stipend of US\$1000 for published, feature-length articles. For further information regarding article submissions, please contact Ole J. Jacobsen, Editor and Publisher. Ole can be reached at ole@protocoljournal.org or olejacobsen@me.com
